Predicting clinical response to anticancer drugs remains a major challenge in cancer therapy research. The current treatment of patients with ovarian cancer involves surgery and platinum-based chemotherapy, which still result in recurrence on advanced stages of the disease. During tumor progression, cancerous cells continuously accumulate mutations giving rise to a heterogeneous population of cells. Additionally, spatial distribution of stromal, endothelial and immune cells in the microenvironment affects tumor progression, cell morphology, and ultimately drug response. In order to predict clinical outcome of chemotherapy in *vitro*, tumor heterogeneity and microenvironment constituents must be conserved. Current models of tumor biology and microenvironment consist in xenografts of human tumors implanted in immunodeficient mice. These models allow studying systemic treatment response, but its application is limited to small developmental studies. Here, we present a high throughput in *vitro* 'grafting' platform where we co-culture blood vessels with tumor explants. Each unit in this platform is composed of two parallel microfluidic channels and a central chamber. Two endothelial tubules are generated in the microfluidic channels and cultured in presence of a gradient of angiogenic factors (S1P, VEGF, bFGF and PMA) added to the central chamber of the culture unit. An giogenic tubules form vascular beds within 3-5 days, after which tumor explants are loaded to the central chamber on top of the vascular beds. The model shown in this study consists of ovarian serous papillary adenocarcinoma collected after xenograft growth in immunodeficient mice. This ovarian cancer explant was previously characterized as resistant to Paclitaxel. In this study, we observe how the vascular bed remodels in the presence of the explant and closely interacts with ovarian tumor tissue. Vessel perfusion and stabilization of vascular bed was monitored by real time imaging of 150 kDa FITC-Dextran. Cultures were evaluated by assessment of morphology and presence of endothelial and tumor cell biomarkers. Moreover, co-culture response to Sorafenib (anti-angiogenic), Palbociclib and Paclitaxel was detected by distinctive proliferation rates as compared to control conditions. The established ovary cancer-on-a-chip platform enables the study of fundamental aspects of tumor disease and progression. In addition, these co-cultures serve as a platform for understanding tumor-endothelial cell crosstalk and its consequences for tumor aggressiveness. Moreover, these models constitute a suitable platform for drug screenings of anti-cancer and anti-angiogenic compounds, making them a powerful tool for drug selection in personalized medicine applications.

Quantitation of Interleukin-10 Using a Novel Enzyme-linked Darkening Assay.

T. Yu, J. Hull, D. Jaferian, A. Henderson, S. Shresta, A. S. Basu; Bioelectronica, Reno, NV.

Antibody-based immunoassays are powerful tools used throughout the life sciences including drug discovery, diagnostic tests, and academic research in the STEM fields. This paper introduces the enzyme-linked darkening assay (ELDA), a novel hydrogel particle-based suspension array immunoassay that offers ease of use, adaptability to ELISA antibodies, a large capture area, and does not require expensive instruments for detection. ELDA achieves this by encapsulating the immunoassay complex and the enzymatic product within porous hydrogel beads. The beads are prepared using a proprietary method in which the mesh size and rigidity can be controlled. In an ELDA assay, the capture antibodies are

immobilized in the beads' inner matrix by anchors. As these "capture" beads are incubated with antigen, the antigen molecules bind to the capture antibodies and accumulate within the beads, which are then incubated with AP-conjugated detection antibodies and detection reagent. The reporter enzyme converts the soluble substrate into an insoluble product that is trapped within the matrix of the beads with picoliter volumes, resulting in progressive darkening of the beads based on antigen concentration. Unlike most particle-based immunoassays that measure fluorescence as signal outputs, the optical darkness of ELDA beads is measured as a function of antigen concentration using brightfield microscopy and computer vision detection, and can be imaged using Bioelectronica's proprietary lensless imaging system. The computer vision workflow includes image processing methods to locate each bead and determine the grayscale intensity of the bead centroid region. The rapid imaging of thousands of beads provides grayscale distributions and statistically rigorous confidence intervals. As an initial proof of concept experiment, we demonstrate here that the ELDA assay can detect IL-10, a major inflammation biomarker, using standards prepared at concentrations of 48, 480, and 4800 pg/mL with a total hands on time of <2 hrs. The limits of detection for a variety of biomarkers are still under investigation.

P1796/B34

Improvement of High Throughput Cardiotoxicity Testing System Using Multielectrode Array with Agarose Microchambers.

N. Tadokoro, **T. Kaneko**; Hosei University, Tokyo, JAPAN.

Drugs always have side effects, so that toxicity testing is indispensable for drug discovery research. In particular, cardiotoxicity causes arrhythmia, so that the cardiotoxicity testing is the most important item for drug discovery. Since the toxicity testing takes a huge amount of time and cost, a method that further improves cost, ethics, and technical aspects are required. To overcome these problems, a multi-electrode array (MEA) system has been used for cardiotoxicity testing. In the MEA system, cells are cultured on a dish with 64 electrodes, and extracellular potential can be measured for long term without damaging cells. In the conventional cardiotoxicity testing on MEA, only one data was obtained from one dish. Therefore, we aimed to construct a high throughput cardiotoxicity testing system capable of taking 64 pieces of data in one dish by adhering cells only on each electrode. As a method, we used the agarose microchamber (AMC) technology which can control the cell adhesion site. For automated AMC making on each electrode, we investigated the parameters for irradiation of laser (e.g., focal distance, output, and irradiation time). As a result, when the laser focal length was shifted 115 μm in the Z-axis, and the laser output was 4.8 mW on focus, processing by direct laser irradiation to the electrode part as possible. Besides, two-parameter, the laser irradiation time and the processed portion area are related to positive correlation, hence to control the area of the processed portion by controlling the laser irradiation time is possible. Hence, by using this technique, individual cardiomyocyte clusters adhered to only around every 64 electrodes on the MEA chip. The efficiency of cell adhesion was above 95 % (n=4) and the efficiency of cell beating was above 90 % (DIV 3). The extracellular potential on each electrode was simultaneously measured at multiple points. Now we analyze the wave formation of extracellular potential on each electrode and measure the beating rate and field potential duration like QT interval of real heart. In the future, we will validate the efficacy of this high throughput cardiotoxicity testing by applying the several drugs (e.g., E-4031, verapamil, and astemizole).

P1797/B35

Automated Tracking of *S. Pombe* Spindle Elongation Dynamics.

A. M. Uzsoy, A. F. Kemper, M. W. Elting; North Carolina State University, Raleigh, NC.

The mitotic spindle is a microtubule-based machine that pulls the two identical sets of chromosomes to opposite ends of the cell during cell division. Improper spindle mechanics can lead to the chromosomes failing to segregate correctly, which is associated with cancer, miscarriage, and birth defects. The fission yeast Schizosaccharomyces pombe is a popular model organism for studying mitosis due to the simple, stereotyped spindle structure and genetic tractability. S. pombe spindle length is a useful metric for spindle progression, but manually tracking spindle ends in each frame to measure spindle length over time is laborious and can limit experimental efficiency. We have developed an ImageJ plugin that can automatically track S. pombe spindle length over time and replace manual tracking of spindle elongation dynamics. Using an algorithm that detects the principal axis of the spindle and then finds its ends, we reliably track the length and angle of the spindle as the cell divides. The plugin both integrates with existing ImageJ features and exports its data for further analysis outside of ImageJ, and does not require any programming by the user. In the future, we plan to expand the scope to include other applications, such as tracking the poles of mammalian spindles and tracking filament ends for applications such as in vitro motility assays.

P1798/B36

Combining Live Cell Imaging with Cellular Impedance to Monitor Apoptotic Cell Death in Real Time.

B. J. Lamarche[1], J. Zhang[1], G. Yang[2], J. Zhang[2], P. Ye[2], N. Li[1], Y. Abassi[1]; [1]AGILENT TECHNOLOGIES, INC., San Diego, CA, [2]AGILENT TECHNOLOGIES, INC., Hangzhou, CHINA.

Essential to diverse biological processes such as embryonic development and wound healing, apoptosis (also known as programmed cell death) is an evolutionarily conserved process that enables multicellular organisms to eliminate cells without triggering an inflammatory response. Once triggered by intrinsic or extrinsic stimuli, apoptosis causes a broad array of biochemical and morphological modifications ranging from cytoskeleton degradation and chromatin cleavage to protein cross-linking and phospholipid translocation. The net result of these events is fragmentation of the cell into apoptotic bodies that are rapidly phagocytosed by macrophages. Although apoptosis can be tracked using various biomarker-based assays, these typically require multiple manual handling steps and only yield endpoint measurements. Requiring just a cell seeding step and a drug addition step, we used the Agilent xCELLigence RTCA eSight to continuously monitor drug-mediated apoptosis over the course of multiple days. Providing a direct and objective assessment of cell number, cell size, cell-substrate attachment strength, and cell barrier function, impedance biosensors embedded within the base of eSight microplates are shown to quantitatively track early (cell shrinkage) to late (fragmentation) apoptotic events with high analytical sensitivity. Concurrently, eSight captures live cell images in brightfield and three fluorescence channels (red, green, and blue), providing an orthogonal readout of apoptosis processes such as caspase 3 activation and phosphatidylserine translocation. By combining the strengths of real-time impedance monitoring (simplicity, analytical sensitivity, and objectivity) with that of live cell imaging (specificity of the readout), eSight is shown to increase the information richness of the apoptosis assay without increasing the workload. Importantly, the drug EC50 values determined using these two approaches are nearly identical, suggesting that eSight can simultaneously provide both the primary and secondary (confirmatory) readouts for apoptosis studies.

P1799/B37

Proliferation of Induced Pluripotent Stem Cells Can Be Evaluated by Measuring Exosome Component in Cell Culture Supernatant.

H. Saito, M. Kato, K. Hirai, M. Kiyama, K. Ohyama, H. Hanzawa, S. Takeda; Center for Exploratory Research, HITACHI, Ltd., Kobe, JAPAN.

Quantitative evaluation of cell conditions during cell culture is important for improvement of cell production efficacy. In the field of cell manufacturing, the major cell growth verification method is optical microscope observation so far. An other aproach is metabolites (glucose, lactate and so on) measurement in cell culture supernatant. However, these techniques are not sufficient to grasp cell conditions because microscope images or metabolites do not necessarily accurately reflect cell conditions. In recent years, exosomes, functional vesicles released into blood circulation, have attracted attention as cancer biomarkers. Because exosomes possess wide variety of information of source cells, we expect them as effective index of cell culture conditions. In this study, we demonstrated evaluation of exosomes secreted into cell culture supernatant to verify over time alteration of exosome components (protein expression of CD63 and gene expression of GAPDH) during induced pluripotent stem (iPS) cell proliferation. First, iPS cells (201B7-Ff) were cultured for 7 days and cell culture supernatant was obtained every 24 hours. Cells were harvested and cell number was counted. Then cell culture supernatant was ultracentrifuged, the pellet was observed by transmission electron microscope and particle size distribution was analyzed by resistive pulse sensing. As the results, we found spherical granules and particle size was from 50 nm to 100 nm, the peak of distribution was about 70 nm. Next, we analyzed exosome specific marker expression of CD63 in cell culture supernatant by ELISA. We also quantified GAPDH gene expression ,which is known to be expressed in exosome stably, by quantitative RT-PCR. As the results, expression level of CD63 in cell culture supernatant was increased over time and highly correlated with cell number (R=0.958). Gene expression level of GAPDH was also increased over time and highly correlated with cell number (R=0.955). We showed that iPS cells secrete exosomes into cell culture supernatant by morphological and expression analyses. The expression of CD63, one of exosome markers, and GAPDH expression correlated with cell number, which indicated that these exosome derived signals function as index of cell proliferation. We conclude that exosome can be a novel evaluation index not only for cancer diagnostics, but also for cell conditions during cell culture. This research was partly supported by the Research and Development Grants, Kobe Medical Innovation Cluster.

Fast and Efficient DNA Transfection in Hard-to-transfect Cells.

V. Toussaint-Moreau, M. Denu, T. Benchimol, F. Prémartin, M. Porte, M. Dumont, G. Guerin-Peyrou, M. Hellal, Y. Philipson, F. Stock, P. Erbacher; Polyplus-transfection, ILLKIRCH GRAFFENSTADEN, FRANCE.

DNA transfection remains challenging for scientists working with primary cells, stem cells and particular cell lines. This is mainly due to the fragility and slow-dividing rates of these cells. Considering the limiting steps in these hard-to-transfect cell types and based on our knowledge and expertise in transfection, we screened a proprietary chemical compounds library. Lead molecules were selected based on their superior transfection efficiencies while maintaining excellent cell viability in different hard to transfect cell types, leading to the development of a novel DNA transfection reagent, jetOPTIMUS®. This reagent

improves cellular uptake and endosomal escape of DNA resulting in higher gene expression in cells. jetOPTIMUS® combines higher transfection efficiency and lower toxicity compared to other commercially available delivery solutions.

P1801/B39

New Strategies for Quality Control in Cell-based Assays.

F. Cohen; BERTIN TECHNOLOGIES, Montigny-les-bretonneux, FRANCE.

New strategies for quality control in cell-based assays Despite the increased focus on sophisticated analysis and advanced cell culture platforms, many of the more traditional assays in 2D format remain central to the research that underpins drug discovery. Conventional techniques used to monitor cell cultures samples are often subjective or destructive, which can lead to erroneous results downstream. Cell counting and confluency analysis are especially important quality controls in cell-based assays, for example to prepare cells for transfections or to prepare samples for downstream experiments. Here we optimize cell culture quality control methods by developing a label-free, trypsinization-free automated process to calculate confluency, cell count, and transfection efficiency directly on the bench. By using cell culture apps, coupled with a cell imager (InCellis, Bertin Technologies, France), we can perform accurate measurements to qualify cell culture sample in order to verify optimal handling, determine cell health and integrity, and collect data. We then validated this method in several experimental contexts from cell proliferation studies, drug assays, cell migration studies, to cell viability assays. We showed that automated calculations of confluency, cell count and transfection efficiency reduces human error and improves overall data integrity.

P1802/B40

Development of a Novel Tunable Synthetic 3D Hydrogel Platform for the Study of Tumor and Stromal Cell Interactions.

N. Asbrock; MilliporeSigma, Temecula, CA.

Numerous cancer cell models exist used to investigate disease mechanisms and to screen potential cancer therapeutics. Roughly 90% of promising preclinical drugs fail to result in efficacious human treatments. Traditional two-dimensional (2D) tissue culture models lack realistic complexity, while animal models are expensive, time consuming, and too frequently fail to reflect human tumor biology. Recently, three-dimensional (3D) cell culture models are a new method to generate new drug candidates before moving to expensive and time-consuming animal models. We have developed a biochemically defined hydrogel platform formed by mixing various polymers with chemical crosslinkers with enhanced functionality. The hydrogel system employs one of two types of backbone polymers: a synthetic non-degradable polyvinyl alcohol (PVA) or an enzymatically-degradable dextran. Both polymers are functionalized either with fast or slow thiol-reactive groups. Crosslinkers consist of either PEG non-cell-degradable or a CD cell-degradable crosslinkers containing peptide sequences that create cleavage sites for matrix metalloproteases (MMPs) that allow cell migration. The technology provides mechanical and biochemical cues to investigate both morphological and physiological properties of cells in a 3D environment. The hydrogel allows precise control over hydrogel stiffness, gelation speed, cell migration and allows cell recovery for downstream applications. Here, we demonstrate the utility of this hydrogel platform to grow epithelial, fibroblast and tumor cells in 3D cell cultures with high cell viabilities and functionalities. Furthermore, we have constructed a 3D tumor/stromal cell co-culture

using the hydrogel to model the dynamic tumor cell microenvironment. This technology will allow the creation of more accurate 3D cancer cell models for basic research and drug discovery applications.

A Novel Method for Total Protein Normalization in Western Blotting That Avoids Invalid Results Obtained When Using Housekeeping Proteins.

T. Diller, J. M. Thompson, B. Steer; Thermo Fisher Scientific, Carlsbad, CA.

Protein normalization for westerns has relied upon housekeeping proteins which exhibit signal saturation and cellular expression level variations under studied conditions. Consequently, employing housekeeping proteins for normalization of target proteins produces spurious results that lead to erroneous conclusions. A superior method to protein normalization using housekeeping proteins is Total Protein Normalization, a method now recognized as the gold standard for quantitative westerns. Total Protein Normalization requires that proteins on a membrane be stained or labeled uniformly, imaged, and then analyzed for total protein. It is important that such a normalization process not interfere with typical immunodetection methods, fits within existing western workflows, and shows a linear relationship of signal intensity to protein load under all experimental conditions. We have developed a new reagent enabling Total Protein Normalization, and, with this reagent, we demonstrate superior protein normalization capabilities through our analysis of four target proteins in HeLa, MCF-7, Jurkat, and A431 cell lines. Our data illustrate how three housekeeping proteins show signal saturation, yield erroneous normalization data, and display greater than 50% variation. Conversely, signal intensities obtained using our new method show a linear relationship to protein sample load, thereby providing accurate protein normalizations with less than 8% variation. In conclusion, utilization of housekeeping proteins for protein normalization leads to errors in quantifying westerns and subsequently invalid conclusions from experimental studies, while our new Total Protein Normalization method provides an elegant alternative for achieving accurate quantitative westerns.

Separation of Cells Via Dielectrophoresis on a Novel, Integrated, Benchtop Platform (Cyto R1): Impact of Assay Conditions on Cell Viability.

A. R. Hyler[1], D. Hong[1], R. V. Davalos[2], E. M. Schmelz[2]; [1]CytoRecovery, Inc., Blacksburg, VA, [2]Virginia Tech, Blacksburg, VA.

Tumors are dynamic environments that contain a variety of resident and recruited cells with changing phenotypes. Their phenotype and interactions are increasingly the focus of research since they determine cancer cell survival and progression. We have developed an integrated benchtop platform (Cyto R1^{TM}) to separate and enrich cells from heterogeneous cell mixtures via contactless dielectrophoresis (DEP) that uses the motion of polarizable particles in a spatially non-uniform electric field to electronically interrogate and discriminate between different cells. Using unique electrophysiological properties of cells rather than protein markers, our goal is to generate enriched viable cell subpopulations for further analyses. Thus, we investigated the viability of various cell lines by exposing the cells to the buffers necessary for the Cyto R1^{TM} platform and electronic stimulation over time and determining cell numbers 24h after plating by MTT. The traditional cDEP buffer reduced cell viability after just 1 hour of exposure by 20-45% for all cell lines, and declined further after 3 hours of exposure (<50%). Cancer cells were more resistant to this treatment than benign epithelial and stromal

cells. We then altered the traditional DEP buffer formulation to balance conductivity, osmolality, and pH to physiologically relevant values (Cyto Buffer A™). Exposing the most sensitive, benign cell line to the Cyto Buffer A™ significantly ($p<0.0001$) increased viability to at least 65% for 3 hours. Using this improved reagent, benign and cancer cell lines were exposed to Cyto Buffer A™ for 2h while undergoing electrical field stimulation on the Cyto R1™ platform. Our results indicate that benign cell lines respond at 628 Vpp whereas cancer cell lines do not respond until 640 Vpp for given frequencies ranging from 200-400kHz indicating separation is feasible on the Cyto R1 ™ platform using the new buffer. Cells exposed to both Cyto Buffer A™ and electrical field stimulations were then resuspended in tissue culture media and plated for growth. After 48 hours, all cells had successfully grown at known doubling rates. Together, our results indicate that the Cyto R1™ system using Cyto Buffer A™ can successfully discriminate between benign and cancer cell lines while sustaining significant cell viability and functionality after 2-3 hours of experimental exposure.

P1805/B43

Functional Recombinant Hydroxysteroid 17-beta Dehydrogenases (HSD17Bs) Produced in HEK293 Cells.

R. Lin, 20850, A. Tran, A. Wang, X. Li, X. Liu, Y. Kim; OriGene, Rockville, MD.

Hydroxysteroid 17-beta dehydrogenases (HSD17Bs) catalyze oxidation/ reduction of various metabolites generated in sex steroid hormone biogenesis, neurosteroid hormone, retinoid, or cholesterol and fatty acid metabolisms. Studies on genetic variants have indicated HSD17B3, HSD17B4, HSD17B9, HSD17B10 and HSD17B13 as causative factors of human disorders including chronic liver disease. Pathogenic variants of HSD17B and researches on sex-hormone dependent cancers, osteoporosis, and Alzheimer disease suggest that HSD17Bs are potential therapeutic targets. The purpose of the present study was to produce the functionally proven recombinant protein for a better understanding of the biological functions of HSD17Bs and discovering the potential therapeutic drugs of the associated human diseases. HSD17B recombinant proteins expressed in human HEK293 cells were purified using affinity column chromatography. The purity was confirmed by SDS-PAGE and the functional activity was validated by oxidoreductase luminescent assays. This study demonstrated that HSD17Bs produced in HEK293 cells can catalyze oxidoreductive reaction on steroid substrates, which is monitored by concurrent changes in NAD(P)H quantity. In a HSD17B13 kinetics study, it is evidenced that leukotriene B3 is as good as β-estradiol being a HSD17B13 substrate. In addition, the protein sequencing using purified HSD17B13 also addresses the role of the proposed N-terminus signal peptide in its subcellular localization. OriGene Technologies developed over 10,000 full-length human proteins, including HSD17Bs, that are produced in human HEK293 cells, in which the protein structure and post-translational modifications are well preserved. This study suggests that OriGene recombinant HSD17Bs are biologically active and can meet academic and industrial standards in drug discovery.

P1806/B44

Automated Micro-patterning for the Generation of Large Living Cell Arrays on Soft Hydrogels of Adjustable Stiffness.

L. Guillaume[1], L. Malpartida[2], J. Cau[1], C. Vieu[2], E. Trevisiol[2]; [1]Innopsys, Carbonne, FRANCE, [2]LAAS-CNRS, Université de Toulouse, CNRS, INSA, Toulouse, FRANCE.

The different cellular mechanisms that underlie cell-to-cell and cell-ECM interactions can be studied in *vitro* by controlling cellular microenvironment based on ECM structuration and substrate stiffness. However, current tools for generating cell adhesion microstructures on different biocompatible materials of adjustable stiffness are limited to small surfaces and not really automated. Here, we present an innovative technological tool for the automated generation of large cell arrays applicable to supporting layers of different stiffness. This technological process is based on microcontact printing techniques allowing to automatically produce large arrays (1cm²) of living cells (40 000 cells) immobilized on printed biomolecular micropatterns on microscope glass slides and Polyacylamide (PAA) hydrogels with adjustable mechanical stiffness (Young's modulus from 0.5 to 40 kPa). Different cell lines (PC3, HEK, HeLa) were cultured on this kind of micro-patterned surfaces. The pattern homogeneity and cell spreading inside/outside the defined patterns were statistically analyzed with unprecedented precision thanks to the large population of cells immobilized. Results show excellent conformation of the living cells to the adhesive patterns of different shapes (square, circle and triangle). The square patterns exhibited the highest quality in terms of homogeneity and dimensional control, having a percentage of size variation of only 5.7%. When using these substrates with human cell lines (HeLa), the rate of occupancy of the micropatterns of 20µm size by living cells was found to vary from sample to sample between 38% and 76% with 90% of them accommodating a single cell. This study also highlights the possibility to obtain living cell arrays on PAA films with a bio relevant mechanical stiffness between 0.5 to 40kPa and to conserve the pattern homogeneity on these substrates of choice for the investigation of mechanobiology. This new approach shows for the first time the easy and automated fabrication of large cell arrays of individual living cells on a soft hydrogel material. This innovative bioengineering tool can be applied for the investigation of complex cellular mechanisms at the single cell level but compatible with a large number of observations for statistical consistency.

P1807/B45

Electroporation as a Post-embryonic Delivery Tool for Uncovering Mechanisms of an nelid Regeneration.

E. Kelley, **D. Ozpolat**; Marine Biological Laboratory, Woods Hole, MA.

Post-embryonic tools are necessary for testing gene function in juvenile to adult-stage processes such as regeneration yet they are not well-developed for most animal models that regenerate. The development of post-embryonic tools would allow studying regeneration in *i)* organisms when traditional early embryonic manipulation of a gene is lethal due to requirement in embryogenesis, *ii)* in species with long generation times, and/or *iii)* inaccessible embryonic stages (e.g. In animals that reproduce primarily asexually). Electroporation is a widely-used method for delivering large molecules into cells via temporary pores in the cell membrane created by electrical pulses. The technique has already been successfully used as a post-embryonic delivery tool in some regenerative organisms such as the axolotl and zebrafish. This ongoing study aims to develop electroporation as a viable tool for post-embryonic reagent delivery into cells to test gene function during regeneration in annelids; a highly

regenerative group of organisms. To date, we have found that regeneration blastema injection followed by electroporation in *Platynereis dumerilii* (a marine annelid) and *Lumbriculus variegatus* (a freshwater annelid) yielded high uptake of fluorescent-dextran complexes into tissues and individual cells in the blastema, with little to no uptake in injection-only controls. Our future objective is to test delivery of other reagents (ie. morpholinos, siRNAs and CRISPR/Cas9) in these annelid species to provide insight into molecular and cellular mechanisms of regeneration. Funding: Hibbitt Fellowship Startup Funds.

P1808/B46

Novel Basal Cell Culture Media Formulations Enable Long-term Storage at Room Temperature.

J. Richter; Thermofisher Scientific, Frederick, MD.

Due to its heavy use in many cell biology laboratories, basal cell culture media is often stocked at high levels in cold storage spaces. Not only do these spaces account for approximately 25% of the energy consumption in typical labs, they are also generally shared across multiple users and can easily become overcrowded. To address this problem, we have developed a set of novel cell culture media that can be stored at room temperature without compromising cell growth, health, or function. An alytical shelf life studies have shown these BenchStable™ media retain critical components during room temperature storage for a period of up to 13 months. To confirm these results aligned with the biology of cell culture, 8 commonly-used cell lines were selected to be maintained over multiple passages in both BenchStable and typical catalog formulations. These studies showed that culture in BenchStable media resulted in populations that exhibited equivalent rates of population doubling and viability relative to culture with conventional media. Because BenchStable media is intended to be stored outside of a refrigerator, it is much more likely to be exposed to light than other formulations. To demonstrate the necessity of additional light-protective packaging, cultures of HEK293 were grown in BenchStable media that had been exposed to common laboratory fluorescent lights for ~21 days. This was compared to age-controlled BenchStable media stored in dark conditions. Cells grown in media that had been exposed to light showed a drastic reduction in growth rate, indicating that breakdown of media components had a negative impact on culture performance. Properly protected from light, room-temperature stored BenchStable media perform equivalently to traditional formulations in all applications tested. Transfection, cryopreservation, differentiation and simple apoptosis assays all show uniform results across both media types. To examine potential differences at the gene expression level, mRNA from MCF7 breast cancer cells grown in traditional and BenchStable media was isolated and converted to cDNA. A customized TaqMan PCR assay focusing on the expression of key signal transduction genes showed that there was no significant up- or down-regulation of genes across more than 15 signal transduction pathways. Taken together, our results show that BenchStable media can be substituted for conventional, refrigerated basal media with very little risk to cell culture performance.

P1809/B47

Monitoring the Interactions and Activation of the Her Family of Receptor Tyrosine Kinases Using Multiplex Duolink and Pan Anti-phosphorylation Antibodies.

C. Melm, C. Herring, J. Day, K. Keys, J. Marler, T. Adair-Kirk, J. Turner; MilliporeSigma (formerly EMD Millipore and Sigma-Aldrich), St. Louis, MO.

Monitoring the interactions and activation of the HER family of receptor tyrosine kinases using multiplex Duolink and pan anti-phosphorylation antibodies Christopher Melm, Cassandra Herring, Jacqueline Day,

Kelly Keys, Jacob Marler, Tracy Adair-Kirk, and Jeffrey Turner MilliporeSigma, 2909 Laclede Ave., St. Louis, MO 63103 USA the human epidermal growth factor receptor (HER) family of receptor tyrosine kinases consists of four members: epidermal growth factor receptor (EGFR or HER1), HER2, HER3, and HER4. Upon stimulation by different ligands that contain an epidermal growth factor (EGF)-like domain (e.g., EGF or neuregulin), these cell surface receptors can form homodimers or heterodimers, become phosphorylated, and signal through AKT, MAPK, and many other pathways that regulate cell differentiation, migration, proliferation, and apoptosis. Many HER family members are over-expressed in various forms of cancer, making them important drug targets. Here we show that Duolink in *situ* proximity ligation assay (PLA) in combination with high-content screening analysis or flow cytometry can provide a sensitive, quantitative method for screening various inhibitors or biologics. EGF-induced EGFR activation and dimerization with HER2 in SKOV3 human ovarian cancer cells in a multiplex PLA were monitored. PLA allowed precise detection and quantification of this protein-protein interaction, translocation, and protein modifications (e.g., phosphorylation of EGFR and HER2), whereas fluorescent imaging alone could not. We also examined the effects of various EGFR-specific inhibitors on EGFR phosphorylation using a site-specific anti-phosphotyrosine antibody paired with an anti-EGFR antibody. In addition, when site-specific modification antibodies are not available, pan anti-modification antibodies could also be used with target-specific antibodies in a PLA, eliminating the need for directed anti-modification antibodies. Furthermore, we monitored the induced activation and interactions between other HER family members (e.g., HER2-HER2, HER2-HER3, and HER2-HER4 dimerization) in multiplex PLA and determined the effects of therapeutic biological antibodies cetuximab (anti-EGFR) and trastuzumab (anti-HER2) on the HER dimerization pattern. In conclusion, multiplex Duolink PLA allows simultaneous detection of up to four protein events within the same sample and creates an ideal method for screening potential therapeutic agents that affect protein expression, protein-protein interactions, and/or protein modifications.

P1810/B48

Utilizing Fluorescent-based Technology Detecting Protein-protein Interaction (Fluoppi) System to Characterize Targeted Protein Degraders in Cells.

T. Kaji, H. Koga, M. Kuroha, T. Akimoto, K. Hayata; Daiichi Sankyo RD Novare Co., Ltd., Tokyo, JAPAN.

Inducing the removal of proteins including undruggable targets through targeted protein degradation (TPD) has become a promising approach for novel anti-cancer therapeutics. TPD molecules are bifunctional small molecules that recruit E3 ligases to their target proteins, followed by the initiation of ubiquitination and the degradation of target proteins through the ubiquitin-proteasome pathway. Therefore, TPD molecule-induced intracellular ternary complex, composed of target proteins, E3 ligases, and degraders themselves, is indispensable for the degradation abilities of TPD molecules. However, the intracellular dynamics of ternary complex formation remains unclear. To overcome this problem, we utilized the Fluorescent-based technology detecting Protein-Protein Interaction (Fluoppi) system, which can visualize the protein-protein complex as detectable fluorescent foci in live and fixed cells. Via confocal microscopy or live-cell imaging, we here demonstrate that bromodomain and extra-terminal (BET) protein degraders induced specific foci in dose- and time-dependent manners in cells coexpressing Fluoppi-tagged BRD4 and E3 ligase, but their moieties did not. Intriguingly, these specific foci were seen in the region of the cell nucleus where BRD4 was localized, suggesting that the Fluoppi system can be used to clarify where the TPD molecules-induced ternary complex occurs. We further demonstrate that the kinetics of the formation of foci induced by BET protein degraders correlated with that of the levels

of target protein degradation. Taking these findings together, we propose that the Fluoppi system could be a useful research tool for validating TPD molecules by visualizing the spatiotemporal formation of the ternary complex in cells.

Active Patch for Transdermal Drug Delivery and Beauty Treatment Using Photoreactionbased Microcurrent.

J. Kim, Male; Inha Univresity, Incheon, KOREA, REPUBLIC OF.

This presentation reports a photoreactive micro-current generation patch that can be used for a beauty treatment system and transdermal drug delivery (TDD), and more specifically to an element including a drug composition and the application of the element to therapeutic and beauty treatment applications. A normal transdermal electrical potential is present in the skin of a human body. The fact that current is important to the maintenance of the healthy skin can be seen from the successful results of electrotherapy in the treatment of the damaged skins. Electrophoretic treatment designed to apply a low-intensity direct current (DC) flow to ulcer sites reduced the pain and discomfort of ulcers and improved cure rate. A DC electric field is effective in the processes of ligament fibroblast migration and wound healing, and cutaneous lesions are stimulated by external current in the treatment thereof. Accordingly, the maintenance of current in the skin is important for the sustained maintenance of the intact skin. Micro-current patches for transdermal drug delivery and beauty treatment, which are each characterized by a considerably thin power supply and electrodes printed or stacked on a flexible plastic substrate have emerged in recent years, and have been used for active beauty treatment or transdermal drug delivery. This presentation explains the active patch that generates micro-current through the photoreaction of the zinc oxide part obtained by combining zinc oxide and cellulose as long as light is radiated and allows the micro-current to continuously flow to the skin through the drug carrier, thereby achieving transdermal drug delivery and skin care effects. This patch is flexible, self-powered and convenient to attach on skin. The concept and test results of the patch will be explained.

Dual Antigen Capture and Detect. Evix Tools for Sorting and Phenotyping Ev Populations.

M. Wolf, J. Orf, P. Everson; InCepix, St. Paul, MN.

Determining the physiological role of extra-cellular vesicles (EVs) requires identification and characterization of proteins associated with each type of vesicle. Using EVix tools to capture antigen specific EVs (Capture) followed by detecting these structures in a subsequent antigen specific assay (Detect) we report on the variety of specific EVs isolated from human urine. EVix tools allow for simple and sensitive immune-phenotyping of human EV populations and reveal unique surface antigen population profiles. Normal human urine EVs present CD10 and other cell surface enzymes and specific markers (CD13, CD24, CD 133, CD147 and CD26) in unique combinations. EVix tools reveal unique distribution patterns of human EV specific antigens when samples are characterized on size exclusion chromatography columns Capture with cholera B toxin generates unique detection antigen profiles. Examination of specifically captured EVs demonstrates the presence of unique populations of EVs within the sample. We show that EpCAM (CD326) is present on normal urine EVs and EVs containing CD326 can be specifically captured and characterized for the presence of other antigens. We show that capture of specific antigen is critical in uncovering certain rare or less prevalent subpopulations within the overall

EV population. Capture strategies relying on tetraspan specific antigens (CD9, CD63, CD81) were not successful in revealing EpCAM (CD326) positive EVs. This is most likely because tetraspan positive but EpCAM negative EVs obscure the low level signal from the less prevalent EpCAM positive EVs. Our data also suggests that EpCAM (CD326) is present as a single or very low copy number on the EVs captured, unlike Neprilysin (CD10) and other surface markers.

Actin and Actin-Associated Proteins 3

Rapid Production of Acetylated, Methylated, and Arginylated Actin Isoforms in *Pichia Pastoris*.

T. Hatano, L. Sivashanmugam, A. Suchenko, H. Hussain, M. K. Balasubramanian; the University of Warwick, Coventry, UNITED KINGDOM.

Actins are major eukaryotic cytoskeletal proteins, which perform many important cell functions, including cell division, cell polarity, wound healing, and muscle contraction. Despite obvious drawbacks, muscle actin, which is easily purified, is used extensively presently for biochemical studies of actin cytoskeleton from other organisms / cell types. Previously, we reported a rapid and cost-effective method to purify heterologous actins expressed in the yeast *Pichia pastoris*. Actin was expressed as a fusion with the actin-binding protein thymosin β4 and purified using an affinity tag introduced in the fusion. Following cleavage of thymosin β4 and the affinity tag, highly purified functional full-length actin is liberated. We purify actins from *S. cerevisiae*, *S. pombe*, and the β- and γ- isoforms of human actin. Recent work has highlighted the importance of post-translational modifications in the regulation of actin function. Three modifications have been characterized in detail. 1. N-terminal acetylation 2. N-terminal arginylation and 3. His73 methylation. Recently, we have further developed methods to express in Pichia and allowing us to purify a single actin in the apo-form and bearing five different post-translationally modified forms. To achieve this, we have created Pichia strains expressing human NAA80 acetyl transferase and / or SETD3 methyl transferase. We demonstrate the utility of this synthetic system in the expression of human non-muscle and Arabidopsis actin. Finally, we demonstrate the utility of our method in the purification of actin bearing point mutations, including those that cause human disease. The methods should greatly facilitate biochemical and cell biological studies of the actin cytoskeleton and the effects of post-translational modifications therein.

P1814/B53

Quantification of Intracellular N-terminal Beta Actin Arginylation.

L. Chen, A. Kashina; University of Pennsylvania, Philadelphia, PA.

Actin is a ubiquitous, essential, and highly abundant protein in all eukaryotic cells that underlies muscle contraction, as well as cell adhesion, migration, and leading edge dynamics. The two non-muscle actins, beta and gamma, are ubiquitously present in every cell type and are nearly identical to each other at the amino acid level, but play distinct intracellular roles. The mechanisms regulating this distinction have been the focus of recent interest in the field. Work from our lab has previously shown that beta, but not gamma, actin undergoes N-terminal arginylation on Asp3. While functional evidence suggest that this arginylation may be important to actin's function, progress in these studies so far has been hindered by difficulties in arginylated actin detection, precluding estimations of the abundance of arginylated actin in cells, and its occurrence in different tissues and cell types. The

present study represents the first antibody-based quantification of the percentage of arginylated actin in migratory non-muscle cells under different physiological conditions, as well as in different cells and tissues. We find that while the steady-state level of arginylated actin is relatively low, it is consistently present in vivo, and is somewhat more prominent in migratory cells. Inhibition of N-terminal actin acetylation dramatically increases the intracellular actin arginylation level, suggesting that these two modifications may directly compete in vivo. These findings constitute an essential step in our understanding of actin regulation by arginylation, and in uncovering the dynamic interplay of actin's N-terminal modifications in vivo.

P1815/B54

Essential Roles of Beta-Actin Protein in Maintaining Primary Cillia.

P. Vedula, S. S. Nikonov, A. Kashina, **D. W. Dong**; University of Pennsylvania, Phipladelphia, PA.

Lack of cytoplasmic beta-actin gene (Actb) leads to early embryonic lethality in mice, however targeted editing of Actb coding sequence by introducing five point mutations to encode cytoplasmic gamma actin protein does not affect mouse viability. Mice with beta to gamma actin replacement (Actbc-g mice) develop normally and show no detectable phenotypes at young age, despite complete lack of beta actin protein. Here we investigated the effect of the replacement of beta actin with gamma cytoplasmic actin in the retina --- the tissue where these two cytoplasmic actin isoforms predominate. Actbc-g mice developed progressive loss of vision and disorganization of photoreceptor outer segments, a phenotype reminiscent of retinitis pigmentosa, which arises in a variety of ciliopathies. Our data strongly suggest that beta-actin protein is essential for maintaining photoreceptor cilia and normal vision.

P1816/B55

Novel, Rapidly Evolving Actin-Related Proteins Have Acquired Specialized Functions at Critical Actin Structures in the Male Germline.

C. M. Schroeder[1], J. R. Valenzuela[1], G. M. Hocky[2], H. S. Malik[1]; [1]Fred Hutchinson Cancer Research Center, Seattle, WA, [2]New York University, New York, NY.

Cytoskeletal proteins perform many fundamental biological processes in all eukaryotes, and given their essentially, they are conventionally thought to be highly conserved among most phyla. Actin-related proteins (Arps) are among the cytoskeletal proteins that originated more than a billion years ago in eukaryotes and are thought to be well conserved. However, some Arps in both mammals and flies display evidence of genetic innovation via rapid expansion of gene families and accelerated amino-acid substitutions (positive selection). Rapid genetic innovation is often indicative of an adaptive advantage for sequence diversification. While the canonical Arps are ubiquitously expressed in all tissues, divergent Arps in mammals and *Drosophila* are surprisingly expressed exclusively in the male germline, suggesting they have evolved specialized roles in male reproduction. Given the paucity of information regarding the function of gametic Arps in any species, we sought to understand the role of *D. melanogaster* Arp53D in the testis. We find that Arp53D, which is most closely related to cytoplasmic actin, localizes to two critical germline-specific cytoskeletal structures. First, during male meiosis, Arp53D localizes to the fusome, an actin-enriched membranous organelle that connects all germ cells in a cyst. Second, following spermatid elongation, Arp53D colocalizes with the molecular motor myosin VI at the leading edge of actin cones, unique structures that separate syncytial spermatids into individual cells and push excess cytoplasm to the end of the sperm flagellar tail. We also find that an unusual N-terminal tail, but

not its canonical actin fold domain, is required for Arp53D's novel localization. Furthermore, loss of Arp53D results in reduced organismal fitness, most likely as a result of male subfertility. Taking a broader phylogenomic approach to identify additional cases of genetic innovation among Arps, we discovered a 15-million-year-old expansion of functional Arp paralogs in one clade of *Drosophila.* Intriguingly, similar to Arp53D, the clade-specific Arps are also expressed exclusively in the testis and localize to unique germline cytoskeletal actin structures, including actin cones. Our findings reveal an unexpected, recurrent specialization of divergent Arps for roles at male germline actin structures.

P1817/B56

Tissue Specific Pleiotropy of β- and γ-cytoplasmic Actin Depends Differentially on Nucleotide Or Amino Acid Sequence.

L. J. Sundby[1], X. Patrinostro[2], J. M. Ervasti[2]; [1]Department of Molecular, Cellular, Developmental Biology, and Genetics, University of Minnesota - Twin Cities, Minneapolis, MN, [2]Department of Biochemistry, Molecular Biology, and Biophysics, University of Minnesota - Twin Cities, Minneapolis, MN.

Many studies over the years have revealed conflicting data regarding the tissue specific roles of highly similar β- and γ- cytoplasmic actins, showing unique and redundant functions which appear to rely on either the nucleotide sequence, amino acid sequence, or both. The two proteins differ by only 4 biochemically similar amino acids but show more variability in the nucleotide sequences. At the organismal level, the β-actin nucleotide sequence, but not protein, is essential for viability. Mice expressing the γ-actin protein sequence from the β-actin locus are almost entirely phenotypically normal, in contrast to β-actin knock-out (KO) mice that are early embryonic lethal. In tissue specific conditional KO models, the two cytoplasmic actins have similar functions. In the stereocilia of the inner ear, β- and γ-actin are redundant in development but have unique functions in stereocilia maintenance with KO causing unique types of progressive hearing loss. Muscle specific KO of either isoform causes a mild, but progressive myopathy. A primary mouse embryonic fibroblast (MEF) model shows that β-actin KO causes loss of proliferation and severely impaired motility while γ-actin KO MEFs present with a smaller, but significant decrease in proliferation and normal motility. Here, we attempted to understand why the primary MEFs were so severely affected by β-actin KO. Using qRT-PCR we assayed for expression of truncated *Actb* or *Actg1* transcripts, deleted for exons 2 and 3 but encoding exons 4-6, to mirror the mouse KO models. β-actin expression was 86 fold higher than γ-actin in control cells, and increased to 314 fold for truncated β-actin transcript in the KO cells. Because the β-actin KO cells have such severe phenotypes and γ-actin KOs do not, the greatly increased expression of the truncated β-actin transcript may be toxic. Our analysis also revealed a significant, 3.5 fold increase in expression of the truncated transcript from the β-actin locus in primary MEFs and an insignificant increase in immortalized MEFs. These results are of interest because only the primary β-actin KO MEFs have failed proliferation and impaired motility, further suggesting that overexpression of the truncated transcript is toxic. We conducted the same analysis on γ-actin KO MEFs and β- and γ-actin KO muscle, but measured a slight, but non-significant increase in expression of the truncated transcripts. Further evaluation of the impact of overexpression of exogenous β-actin transcript deleted for exons 2-3 will help uncover the cause of the variable mechanisms of pathogenesis resulting from dysregulated cytoplasmic actin expression.

P1818/B57

The Role of Clp36 in Pancreatic Cancer Cells during Migration and Cell Shape Change.

E. Parajon, D. G. Thomas, D. Robinson; Johns Hopkins School of Medicine, Baltimore, MD.

Cancer is a disease characterized by uncontrolled cell proliferation, migration, invasion, and morphology. Actin and alpha-actinins (ACTNs) are key players that underpin these cellular processes. Due to the overexpression of ACTN4 and its adaptor protein CLP36 in other cancers, we hypothesized that these proteins might contribute to migration, cell morphology, and mechanoresponsiveness of pancreatic cancer cells. We assessed CLP36 expression and found that CLP36 is highly expressed in stage IV ascites-metastasis-derived AsPC-1 cells, but less so in immortalized human pancreatic ductal epithelial HPDE, stage II pancreatic adenocarcinoma-derived Panc10.05, colorectal carcinoma-derived HCT116, and HeLa cells. We then knocked down CLP36 using shRNA in AsPC-1 cells and used scratch wound assays to test whether CLP36 is necessary for cell migration. In two knockdown cell-lines, removal of CLP36 resulted into significantly decreased cell motility. Immunofluorescence was then performed on AsPC-1 cells, and we found that CLP36 and actin filaments co-localized at the cell cortex. In contrast, in HPDE cells, CLP36 was distributed perinuclearly, while actin remained cortical, while in Panc10.05 cells, CLP36 was largely cytoplasmic. We are now exploring how CLP36 contributes to alpha-actinin-4's role in cell mechanics and mechanoresponsiveness. Overall, our results already suggest CLP36 is an important component of pancreatic cancer cell migration and may contribute to cancer progression.

P1819/B58

Tropomyosin Isoforms Expression in Healthy and Injured Kidney Podocytes.

A. Keller, D. Hammad, J. H. Miner, **H. Suleiman**; Washington University, Saint Louis, MO.

The podocytopathies are a group of glomerular diseases that affect the kidney's ability to filter the blood, and often lead to kidney failure. To help establish and maintain the filtration barrier, healthy podocytes cover the glomerular capillaries with thousands of extensions called foot processes that interdigitate with one another and are joined by a special cell-cell junction, the slit diaphragm. Podocytes maintain their elaborate cell shape by tightly regulating their actin cytoskeleton, which is linked to the slit diaphragms. Interestingly, podocytes respond to insults in a stereotypical fashion by undergoing foot process effacement (FPE), a dramatic shift in podocyte morphology and disappearance of the intricate foot processes. Tropomyosins (Tpms) are coiled-coil dimers that form co-polymers along actin filaments and change the filaments' biophysical properties. Over 40 different Tpm isoforms have been identified as the gene products of 4 *Tpm* genes: *Tpm1*, *2*, *3* and *4*. Various Tpm isoforms target to different locations inside cells and change the type of actin cables assembled in those locations. We hypothesize that podocyte shape is controlled by a specific set of Tpm isoforms that regulate actin cytoskeletal dynamics. Changing the tropomyosin isoforms after injury might be linked to changing podocyte shape and the FPE phenomenon. To test that, we used RT-PCR and immunoblotting and identified various Tpm isoforms as enriched in podocyte cell lines and in isolated healthy glomeruli. Using different mouse models for podocyte injury (i.e., *Cd2ap* KO, *Lamb2* KO, *Col4a3* KO and Adriamycin-nephropathy (AdrN)), we identified a change in Tpm isoforms in the glomeruli isolated from these mice. To reveal the entire array of Tpm isoforms in podocytes, we utilized RNAseq using isolated glomeruli to obtain both short reads as well as long-reads using an Illumina and PacBio instruments, respectively. RNAseq results from WT glomeruli show a different pattern of Tpm expression than the counterparts in injured glomeruli, with the most significant changes occurring in Tpm 1.7 and Tpm 3.4.

We next isolated RNA from WT and AdrN glomeruli taken from podocyte-specific translating-ribosome-affinity-purification ("TRAP") mice. By pulling down GFP-tagged ribosomes and purifying the attached mRNA for RNAseq, we were able to purify podocyte mRNA away from that in other glomerular cells types (mesangial and endothelial cells). Comparing the isolated RNA from WT-TRAP and TRAP mice subjected to AdrN, we are able to identify the podocyte-specific Tpm isoforms that are associated with injury. Collectively, this study suggest roles for tropomyosin isoform changes in regulating podocyte shape in health and injury conditions.

P1820/B59

Tropomyosin and Myosin 18a Play Important Roles in the Organization, Dynamics and Function of the Actomyosin Arcs That Form at the T Cell Immunological Synapse.

D. Schrock; NIH-NHLBI, Bethesda, MD.

T cells are a critical arm of the adaptive immune system because they kill virally-infected or transformed cells and facilitate the function of other immune cells. T cell dysfunction can lead to an array of severe pathologies including susceptibility to infection and autoimmunity. T cell activation requires recognition by the T cell's unique T cell receptor (TCR) of specific peptide antigen bound to major histocompatibility complex (MHC) on the surface of an antigen-presenting cell (APC). This recognition can lead to long-term stable engagement with the APC and the formation of a highly-organized structure at the T cell: APC interface termed the immunological synapse (IS). The IS itself is a multidomain structure divided into distal, peripheral, and central supramolecular activation complexes (dSMAC, pSMAC, cSMAC). TCR microclusters contact antigen-bearing MHC at the periphery of the IS and are then transported across the dSMAC and pSMAC to the cSMAC. This centripetal movement of microclusters is driven by the retrograde flow of an Arp2/3-generated, branched actin network in the dSMAC and the contraction of formin-generated, myosin 2-rich, concentric actin arcs in the pSMAC. Perturbation of either of these actin structures dampens TCR signaling and impairs T cell activation. The goal of this study is to characterize the roles of tropomyosin and myosin 18A in the organization, dynamics and function of the pSMAC actomyosin arcs. Tropomyosins are actin-binding proteins that form head-to-tail polymers along the actin filament. Several tropomyosin isoforms have been shown to associate preferentially with linear, formin-generated filaments, where they promote the recruitment and activation of myosin 2 and thwart cofilin-mediated filament disassembly. In preliminary experiments, we find that the low-molecular weight tropomyosin isoforms 3.1 and 4.2 associate with the pSMAC arcs, and that the tropomyosin inhibitor TR100 disrupts their organization. Myosin 18A is a myosin 2-like protein that lacks motor activity and contains unique N- and C-terminal extensions harboring both recognizable and uncharacterized protein: protein interaction domains. Importantly, myosin 18A co-assembles with myosin 2 to make mixed filaments, suggesting that myosin 18A serves to recruit proteins to these mixed filaments or attach them to cellular structures. Preliminary experiments show that the myosin 18A isoform myosin 18Aβ is highly expressed in T cells and that it co-assembles with myosin 2 in the pSMAC arcs. Moreover, knockdown or knockout of myosin 18A alters arc organization and attenuates proximal signaling. Current efforts are directed at further clarifying the roles played by tropomyosin and myosin 18Aβ in arc organization and function, as well as in T cell effector functions.

P1821/B60

Expression and Characterization of Non-muscle Tropomyosin Isoforms.

P. Carman, R. Dominguez; University of Pennsylvania, Philadelphia, PA.

Tropomyosin is a coiled-coil dimer that polymerizes along the length of actin filaments and regulates the binding of other proteins to actin. In muscles, tropomyosin regulates myosin binding and contraction, while in non-muscle cells tropomyosin plays roles in diverse functions such as cell motility, adhesion, cytokinesis, and neuronal development. While there is high sequence similarity among these proteins, in cells they do not compensate for each other upon knockout or overexpression. A major gap in knowledge remains, which is the mechanism that allows specific sets of tropomyosin isoforms to perform specific roles in cells. Previous work in the field has attempted to characterize these isoforms biochemically, but has been inconclusive because of major difficulties obtaining physiologically relevant protein for in *vitro* study. In this work, we have developed a new mammalian-cell expression system that allows specific tropomyosin isoforms to be purified with native post-translational modification and binding partners. We report that all N-termini are acetylated in cells, and that the major isoforms of non-muscle tropomyosin exist in cells as heterodimers. We provide evidence that these heterodimer pairs of tropomyosin exhibit different actin binding affinity and capping activity across isoforms.

P1822/B61

The Actin Crosslinking Protein Filamin, Promotes Cortical Stiffness to Mediate Leader Bleb Based Migration of Melanoma A375 Cells Under Non-adhesive Confinement.

G. Adams Jr[1], A. Jha[1], M. Preciado-Lopez[1], M. Baird[1], R. Fischer[1], J. Logue[2], C. Waterman[1]; [1]National Institutes of Health, Bethesda, MD, [2]Albany Medical College, Albany, NY.

Within the confines of tissues, cancer cells can use blebs to migrate throughout the interstitium. In confined 3D microenvironments mimicking the tissue microenvironment, cancer cells exhibit plasticity of migration modes depending on the degree of confinement, level of contractility and the availability of ligand adhesion. Under high confinement and contractility and low adhesion, intracellular pressure drives the formation of a large bleb that mediates rapid persistent migration in a process termed ‘leader bleb-based migration’ (LBBM). LBBM is characterized by an unusual, highly polarized cell morphology with a long (~20 um) sausage-shaped bleb that points in the direction of movement, separated from a smaller (~10-15 um) spherical cell body by a contractile neck. LBBM is driven by actomyosin assembly and retrograde flow along the bleb coupled to non-specific friction with the microenvironment. However, neither the fundamental organization of organelles nor the role of actin regulatory proteins mediating this unusual mode of motility is known. We performed a survey of the localization of organelle markers and actin-associated proteins including nucleators, bundlers and crosslinkers in metastatic human A375 melanoma cells undergoing LBBM in non-adhesive confinement. We expressed fluorescent fusion proteins in cells confined to a 3um space under polydimethylsiloxane (PDMS) imaged by time-lapse spinning-disk confocal microscopy to analyze the spatial distribution within the cell body and leader bleb, as well as the frequency of morphology switch and cell motility parameters. Our results indicate that most cytoskeleton and membranous organelles examined are localized in the cell body; however, microtubules and intermediate filaments as well as the Golgi and ER also extend into the leader bleb, peroxisome markers localize near the neck at the base of the bleb, and the nucleus and centrosome translocate between body and bleb. We found that actin nucleators Arp2/3 and mDia2 localizes towards the leader bleb tip, while a/β-spectrin are confined to the cell body and fascin and

filamin are found exclusively in the bleb. An alysis of morphology and motility parameters in cells overexpressing actin regulatory fusion proteins revealed that overexpression of filamin increased bleb size and LBBM speed, while siRNA knockdown of filamin decreased LBBM directionality. AFM analysis showed that filamin overexpression promotes cortical tension. Our study provides the first description of the cellular "anatomy" during LBBM and suggests an important role of actin crosslinkers in regulating leader bleb formation, speed and directionality.

P1823/B62

Cell Protrusion Across Matrix Gaps Requires T-Plastin Actin Bundling Activity.

D. Garbett[1], A. Bisaria[1], A. Hayer[2], T. Meyer[1]; [1]Stanford University, Stanford, CA, [2]McGill University, Montreal, QC, CANADA.

To migrate in *vivo*, cells move across diverse assemblies of extracellular matrix (ECM) that can be separated by micron-scale gaps. For membranes to protrude and reattach across a gap, actin filaments, which are relatively weak as single filaments, must polymerize outward from adhesion sites to push membranes towards distant sites of new adhesion. Here, using micropatterned ECMs, we identified T-Plastin, one of the most ancient actin bundling proteins, as an actin stabilizer that promotes membrane protrusions and enables bridging of ECM gaps. We found that T-Plastin is specifically enriched in active protrusions where F-actin is devoid of non-muscle myosin II activity. Additionally, loss of T-Plastin caused defects in lamellipodial architecture without perturbing actin treadmilling rates. Together, our study uncovers critical structural roles of the actin bundler T-Plastin to promote protrusions and migration when adhesion is weak or spatially-gapped and under conditions of high membrane tension.

P1824/B63

Osteoporosis Mutations Lead to Impaired Calcium Regulation of Actin Bundling by Plastin-3.

E. Kudryashova[1], C. Schwebach[1], W. Zheng[2], M. Orchard[1], L. Runyan[1], H. Smith[1], E. Egelman[2], **D. Kudryashov**[1]; [1]Ohio State University, Columbus, OH, [2]University of Virginia, Charlottesville, VA.

Mutations in actin-bundling protein plastin 3 (PLS3) emerged as a cause of osteoporosis, but the underlying mechanisms are unknown. Of the five tested in this study osteoporosis PLS3 mutations not associated with gene deletions/truncations, one distorts an actin-binding loop and abolishes F-actin bundling as revealed by cryo-EM and protein interaction assays. The remaining four mutants retained the bundling ability but showed either decreased or increased sensitivity to Ca^{2+} in reconstituted in vitro assays. Not being located in the regulatory calcium-binding domain, the loops harboring the mutations are protected by the regulatory domain, revealing for the first time its position at the interface of the actin-binding domains and suggesting the mechanism of plastin activity inhibition. In cells, wild-type PLS3 was distributed between lamellipodia and focal adhesions. In contrast, the Ca^{2+}-hypersensitive PLS3 mutants were restricted to lamellipodia, albeit their localization at focal adhesions could be partially rescued upon chelation of extracellular Ca^{2+} by EGTA. Accordingly, the Ca^{2+}-hyposensitive mutants were not found at the leading edge but localized exclusively at focal adhesions/stress fibers, which displayed reinforced morphology. These findings suggest that a mutational disruption of actin bundling or the Ca^{2+}-controlled PLS3's cycling between adhesion complexes and the leading edge leads to severe osteoporosis similar to that caused by the PLS3 deletions. To our knowledge, this study is the first direct evidence that the Ca^{2+}-dependent regulation of plastins is essential for their physiological functions.

P1825/B64

Plastin Promotes Fast Actin Filament Bundling Along with Formin-mediated Polymerization to Generate Rapid Filament Alignment during Contractile Ring Assembly.

R. S. Kadzik[1], Y. Li[2,3], D. Kovar[4,3], S. Wignall[1], E. Munro[3,2]; [1]Department of Molecular Biosciences, Northwestern University, Evanston, IL, [2]Committee on Development, Regeneration, and Stem Cell Biology, University of Chicago, Chicago, IL, [3]Department of Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL, [4]Department of Biochemistry and Molecular Biology, University of Chicago, Evanston, IL.

Cytokinesis is the process of physically dividing one cell into two, by means of a contractile ring made up of filamentous actin and non-muscle myosin. A key step in the assembly of the contractile ring is the rapid alignment of actin filaments into an organized array at the equator of the dividing cell. One proposed mechanism for local reorientation of actin filaments is compressive flow in the dividing cell, but whether this flow is sufficient to rapidly and robustly align filaments while the filaments are undergoing constant turnover is unclear. To evaluate what is required for timely assembly of the contractile ring, we used single molecule imaging and particle tracking analysis to measure local filament turnover and cortex contraction rates during the first cell division in the *C. Elegans* embryo. With these measurements and simple mathematical models, we found that compressive flow alone cannot account for the amount of filament alignment we observe during assembly of the contractile ring. Expanding on this model, we found that anisotropic assembly of actin filaments, along with slow realignment of filaments via myosin motor activity, could account for the rapid emergence and maintenance of a circumferentially aligned filament array. To evaluate if this mechanism of alignment operates in *C. elegans*, we imaged embryos expressing CYK-1/formin::GFP and LifeAct::mCherry and found that filament elongation is highly anisotropic at the equator of the cell, but not at the poles. Furthermore, a significant portion of CYK-1-polymerized filaments entering the equatorial region change direction to align with the arrayed filaments in the contractile ring. These results are consistent with templated assembly of actin filaments at the equator. We identified the *C. Elegans* homolog of the actin binding protein plastin (PLST-1) as a likely candidate to promote rapid bundling and alignment of fast-growing CYK-1 filaments in the embryo. Consistent with a role in assembly of the contractile ring, loss of PLST-1 results in slowed or abortive cytokinesis. Using multi-color TIRF microscopy to visualize actin polymerization by fluorescently labeled CYK-1 and crosslinking by fluorescently labeled PLST-1, we found that PLST-1 can rapidly bundle and cause realignment of CYK-1/formin polymerized actin filaments in-line with pre-existing actin filaments, consistent with our findings in *vivo*. Our results demonstrate a role for an actin bundling protein in promoting the templated elongation and alignment of actin filaments in the contractile ring and provide new insights into how the ring is rapidly and robustly assembled during cell division in animal cells.

P1826/B65

The Mechanism of Actin Remodeling by the BAR Domain of ArfGAP ASAP1.

A. Gasilina[1,2], T. Vitali[1,3], R. Luo[1], X. Jian[1], P. A. Randazzo[1]; [1]National Cancer Institute/ NIH, Bethesda, MD, [2]Georgetown University, Washington, DC, [3]University of Michigan, an n Arbor, MI.

The actin cytoskeleton plays an important role in cellular processes. Normal processes, such as differentiation, use the actin cytoskeleton as a signaling and transport platform, while aberrant

processes, such as cancer, repurpose actin for invasion. Actin remodeling involves assembly of globular actin into actin filaments and further assembly of filaments into bundles, which form structures such as stress fibers, lamellipodia and filopodia. While actin remodeling activity of actinin and fascin protein families and their importance in higher order actin assemblies are well established, novel families of actin regulators have emerged. Recently, it was shown that a subset of proteins, most extensively studied for inducing or sensing membrane curvature, the BAR domain proteins, can facilitate formation of higher order actin structures. However, not all BAR domain proteins can remodel actin and their exact mechanism in the regulation of the actin cytoskeleton remains unclear. ASAP1 and ACAP1 are BAR-domain containing ArfGAPs of the human ArfGAP family. ASAP1 is an Arf1/5-specific ArfGAP that regulates migration and focal adhesion dynamics. Its effects on actin and focal adhesions are well documented but can only be partially assigned to its role as the regulator of Arf signaling. ACAP1 is an Arf6-specific ArfGAP that regulates integrin recycling and membrane deformation. Here we show that the BAR domain of ASAP1, but not ACAP1, organizes F-actin into bundles to regulate stress fiber maintenance. Overexpression of the BARPH region of ASAP1 led to increase in actin content and appearance of actin spikes at cell edges across three different cell types, indicating that the BAR domain remodels actin. In vitro cosedimentation- and fluorescence-based binding assays showed that the BARPH of ASAP1 and not ACAP1 binds and bundles actin filaments. Further dissection of the mechanism of actin bundling via structural comparison, followed by site-directed mutagenesis of basic clusters, localizes the actin binding site to the 1st and 2nd helix of the BAR domain of ASAP1. Together these data provide evidence for multimodal mechanism of actin remodeling by ASAP1 and highlights selectivity of BAR domains in actin binding.

P1827/B66

ASAP1 Directly Binds to Actin Filaments Via Its N-BAR Domain.

P. Chen[1], N. Billington[2], K. Chinthalapudi[3], B. Y. Maron[1], J. A. Sload[1], S. M. Heissler[3]; [1]Williams College, Williamstown, MA, [2]National Heart, Lung, and Blood Institute, Bethesda, MD, [3]The Ohio State University Wexner Medical Center, Columbus, OH.

The Arf GTPase-activating protein ASAP1 localizes to and regulates several actin-based mechanosensitive structures such as focal adhesions, invadopodia, and podosomes. The dynamics and organization of actin filaments are crucial for the assembly, maintenance, and turnover of these structures and the related cellular functions including cell adhesion, migration and invasion. The Arf GAP activity of ASAP1 accounts for some but not all cellular functions of ASAP1. In this study we find that the amino-terminal N-BAR domain of ASAP1 directly binds to F-actin and cross-links actin filaments into thick bundles. The actin bundles induced by the BAR-PH tandem of ASAP1 are predominantly unipolar. Further, the BAR-PH tandem reduces depolymerization of the actin bundles and the spontaneous polymerization of G-actin, indicating a role of ASAP1 in stabilizing F-actin bundles. We also find that overexpression of the BAR-PH tandem of ASAP1 in fibroblasts induces formation of cellular projections more effectively than full length ASAP1 whereas ASAP1 lacking the BAR-PH domain fails to induce these structures. Together our data support a model in which ASAP1 regulates the dynamics and higher order structures of actin cytoskeleton, at least in part, by direct binding to F-actin and the effect on actin dynamics is controlled by domains outside of the N-BAR domain. To our knowledge, this is the first report of an Arf GTPase-activating protein that directly interacts with F-actin.

Role of the Size of Actin Crosslinkers in Actomyosin Cortex Tension Regulation.

N. Vadnjal[1], M. Serres[1], G. Lavoie[2], F. Parmeggiani[3], P. Roux[2], R. Henriques[1,4], E. Paluch[1,5]; [1]University College London, London, UNITED KINGDOM, [2]University of Montreal, Montreal, QC, CANADA, [3]University of Bristol, Bristol, UNITED KINGDOM, [4]The Francis Crick Institute, London, UNITED KINGDOM, [5]University of Cambridge, Cambridge, UNITED KINGDOM.

Controlled cell shape changes are key during fundamental processes such as division, migration, and epithelial morphogenesis. In animal cells, many shape changes are driven by the actin cortex, a thin, highly crosslinked actomyosin network that acts as a scaffold for the plasma membrane. The actin cortex is under contractile tension and tension gradients lead to local contractions that result in cell shape changes. It is thus crucial to understand how cortical tension is regulated. Cortex tension is primarily generated by myosin motors pulling on actin filaments. To date, most studies of cortical tension regulation have focused on the role of myosin activity. However, recent studies have highlighted that the organization of the actin network itself is central to cortical tension control. In particular, several studies indicate that changing the levels of various actin crosslinkers, proteins that can bind two actin filaments to each other, can change cortical tension. There are over 20 different actin crosslinkers in the cortex. Interestingly, these crosslinkers greatly vary in size, ranging from ~5 to >100 nm. This project aims to investigate the role of the size of the actin crosslinkers in actomyosin cortex mechanics. To identify the crosslinkers most important in cortex tension regulation we optimised a protocol to isolate cortex-enriched blebs. This allowed us to isolate the actin cortex from cells in different phases of the cell cycle, where cells display different levels of cortical tension. Mass spectrometry of these cortical fractions allowed us to select a subset of potential key crosslinkers involved in cortical tension regulation in an unbiased manner. We then investigated the localisation within the cortex of these different crosslinkers. The actin cortex is only ~200 nm thick in mitotic cells. Thus, super-resolution microscopy is required to investigate the relationship between the size and localization of the actin crosslinkers within the cortex. We use dual colour dSTORM for multi-colour super-resolution visualization of actin cortex and actin binding proteins. Furthermore, to investigate the role of size independently of other features, we developed artificial crosslinkers. The artificial crosslinkers only vary in size while maintaining other structural properties the same. Together, this study will unveil to what extent size affects crosslinker localisation within the cortex, allowing us to explore how cortex structural arrangement affects cortical tension.

P1829/B68

Traction Force Microscopy Reveals Unique Stress Profiles for Cells in the Absence of Arp2/3 and Fascin.

M. Hockenberry[1], R. Superfine[1], J. E. Bear[1,2], M. Falvo[1], S. Asokan[1,2]; [1]UNC Chapel Hill, Chapel Hill, NC, [2]Lineberger Comprehensive Cancer Center, Chapel Hill, NC.

The cytoskeleton and its associated proteins are responsible for force generation and a number of crucial cellular functions including homeostasis, development, and motility. In particular, the cytoskeletal players Arp2/3 and Fascin, have been demonstrated to be crucial for sensing gradients of fibronectin, also known as haptotaxis migration. In order to better understand the role these proteins play in cellular motility and force generation, we require a method of probing cell behavior in the absence of these proteins. Using a system of PAA (Poly-Acrylamide) soft substrate gels embedded with

fluorescent reporter beads localized to the surface, we are able to observe cells exerting stresses and collect traction force data inferred from the displacement of beads. We have used this technique to measure the traction forces and total strain energy exerted by a mouse embryonic fibroblast cell line. We have optimized a MATLAB code to account for increased throughput and data processing by automatic calculations of cellular area and data statistics following traction field generation. Using these methods, we observed that cells plated on PAA substrates of differing stiffness exert traction forces that display a characteristic trend; while bead displacements decrease as stiffness of the gel increases, the average traction force of the cell increases. Furthermore, we have compared the traction forces exerted by Arp2/3 null and Fascin depleted cells to that of wild type fibroblasts. ARP2/3 null cells display a decreased average traction force while maintaining a strain energy density not significantly different to wild type cells. Fascin null cells display a similar trend. Additionally, the traction force profile for the depleted cells show remarkable differences from their wild type counterparts. These characteristic traction force maps were correlated to the underlying mechanisms of cell motility using a GFP Paxilin cell line. An examination of the traction forces resulting from a change in these key cytoskeletal proteins may provide a better understanding of how these molecular players contribute to directed migration.

P1830/B69

Differential Contribution of Actin Filament Bundling Proteins to Filopodia Formation and Maintenance.

G. Dimchev[1], M. Klanschnig[1], J. Liedtke[2], D. Porley[1], F. Faessler[1], K. Rottner[2], F. Schur[1]; [1]Institute of Science and Technology Austria (IST Austria). Am Campus 1, 3400, Klosterneuburg, AUSTRIA, [2]Technical University Braunschweig, Zoological Institute, Division of Molecular Cell Biology, Spiellmanstr.7, 38106, Braunschweig, GERMANY.

Filopodia are dynamic protrusions extending from the cell periphery acting as sensory organelles in migration, adhesion, neuronal guidance and wound healing. They are linked to pathological conditions, such as cancer and viral infections. Filopodia consist of actin filaments spatially organized into bundles by actin bundling proteins, various combinations of which are expressed in different cell types. The reasons for the presence of multiple filament bundling proteins in filopodia and of varying combinations of them in different cell types and physiological contexts, however, are unknown. We therefore decided to define their relative contributions to filopodia formation in a systematic fashion. We employed CRISPR/Cas9-mediated gene disruption in B16-F1 mouse melanoma cells to eliminate expression of Fascin, T-Plastin or Daam1 proteins, all previously reported to participate in actin filament bundling in this cell type. We quantified density, length as well as morphological features such as straightness of filopodia and microspikes (actin bundles sharing filopodia-like characteristics, which are not protruding beyond the cell periphery). (Cryo)-electron tomography was employed to examine the ultrastructure of actin filament arrays within filopodia and microspikes. Our results indicate that no single actin filament bundling protein is essential for filopodial initiation. Whereas removal of Daam1 did not lead to major defects in filopodia numbers or morphology, depletion of T-plastin modestly reduced the number of longer filopodia. Elimination of Fascin resulted in reduced straightness of microspikes and a strong reduction of average filopodia formation frequency, although few filopodia were still observed. Interestingly, both Fascin and T-plastin KO clones displayed faster rates of random cell migration, suggesting an inverse correlation between migration speed and frequency of filopodia formation. Moreover, T-plastin/Fascin double KO cells displayed additive defects in filopodia density and morphology, indicating that both proteins have distinct or partially redundant functions in filopodia

formation. Importantly, ultrastructural characterization revealed double KOs to display major defects in the arrangement of actin filaments within microspikes and filopodia. Despite the significantly reduced numbers of filopodia and clear structural defects upon simultaneous depletion of Fascin and T-plastin, inhibition of the lamellipodial regulator Arp2/3 complex in these double KO cells partially rescued filopodia formation. This suggests that competition between distinct actin machineries driving various types of protrusion (lamellipodia *vs* filopodia) may impact on the requirement of actin bundling proteins for filopodia formation.

P1831/B70

Differential Properties of Calponin-like Repeats Regulate Actin-bundling Activities of Calponin-related Proteins.

S. Ono, K. Ono; Emory University, Atlanta, GA.

Calponins and calponin-related proteins regulate actin filament bundling, actin filament stability, and actomyosin contractility in a wide variety of cell types. Many of these proteins contain multiple calponin-like (CLIK) repeats as actin-binding sites. Previous studies have shown that the presence of multiple CLIK repeats in these proteins confers strong actin-bundling activities. However, whether the CLIK repeats play similar redundant roles or have distinct functions remains unknown. Here, we investigated actin-bundling properties of UNC-87, a *Caenorhabditis elegans* calponin-related protein with seven CLIK repeats, and found evidence that differential properties of CLIK repeats are important for the actin-bundling activity of UNC-87. We found that binding of UNC-87 to actin filaments was resistant to high-salt (0.5 M potassium chloride) but actin-bundling by UNC-87 was significantly reduced under high-salt conditions. Under physiological conditions, UNC-87 bound to actin filaments in the presence of tropomyosin, but actin-bundling by UNC-87 was partially inhibited by tropomyosin. These results suggest that an actin-binding site of UNC-87, which is required for actin-bundling, is sensitive to high-salt and tropomyosin. CLIK-1 is another *C. elegans* calponin-related protein with seven CLIK repeats. CLIK-1 and UNC-87 share 42 % identity (56 % similarity) in their amino acid sequences. Interestingly, CLIK-1 bound to actin filaments without bundling filaments. CLIK-1 and UNC-87 competed for binding to actin filaments, and CLIK-1 partially inhibited actin-filament bundling. By comparing the CLIK repeats in CLIK-1 and UNC-87, the greatest difference was found in the most C-terminal CLIK repeats in the two proteins, suggesting that these are the determinants for the actin-bundling activity. In *C. elegans*, CLIK-1 was expressed in body wall muscle, gonadal myoepithelial sheath, and vulval muscle, where UNC-87 was also expressed. These results suggest that differential properties of CLIK repeats confer distinct actin-regulatory functions of the two calponin-related proteins in *C. elegans*.

P1832/B71

The Mechanical Properties of a Utrophin Construct Encoding the Tandem CH Actin Binding Domain through Spectrin Repeat 3 Is Altered by the Cell Expression System through Post-translational Modification.

M. Ramirez Lopez[1], S. Rajaganapathy[2], W. R. Gordon[1], M. V. Salapaka[2], J. M. Ervasti[1]; [1]Department of Biochemistry, Molecular Biology and Biophysics, University of Minnesota-Twin Cities, Minneapolis, MN, [2]Department of Electrical and Computer Engineering, University of Minnesota- Twin Cities, Minneapolis, MN.

Duchenne muscular dystrophy (DMD) is a lethal muscle wasting disease caused by the absence of dystrophin protein. Utrophin is a dystrophin homologue currently under investigation as a replacement therapy for DMD. Dystrophin and utrophin are hypothesized to function as molecular shock absorbers to mechanically stabilize the muscle cell membrane. Recently, we published atomic force microscopy data showing that utrophin is much stiffer than data previously reported for dystrophin. Here we show that the cell expression system employed impacts both the post-translational modification and mechanical behavior of a utrophin construct encoding the N-terminal actin binding domain through spectrin repeat 3 (UtrN-R3). UtrN-R3 expressed in insect cells showed significantly higher unfolding forces than when expressed in bacteria. Other analyses showed phosphorylation of UtrN-R3 from insect cells but not bacterial UtrN-R3. Our results demonstrate that the mechanical properties of utrophin are affected by the cell expression system employed and phosphorylation status. Our experiments also suggest a potential mechanism by which the mechanical stiffness of utrophin (and possibly dystrophin) can be regulated in *vivo*.

P1833/B72

β_H-spectrin Recruits PP2A to Crumbs to Regulate Crosstalk with the Hippo/Warts Pathway in *Drosophila*.

K. Browder[1], S. Lee[2], E. Klipfell[3], **C. Thomas**[3]; [1]Genentech, South San Francisco, CA, [2]National Institute of Aging (NIH/NIA/IRP), Baltimore, MD, [3]Pennsylvania State University, University Park, PA.

Spectrin is a large F-actin crosslinking protein that most famously forms 2D networks in association with the plasma membrane of red blood cells. There it confers cell shape and strength during the rigors of circulation. In NON-erythroid tissues, spectrin has additional roles in the endomembrane system. We have previously shown that the apically-polarized β_H-spectrin, encoded by the *karst* locus in *Drosophila*, is required for the stability of several apical proteins, through the promotion of endosomal recycling to the plasma membrane - so called, 'dynamic protein stabilization'. The apical protein determinant Crumbs recruits β_H to the apical membrane and is itself trafficked in a β_H-dependent manner. β_H binds to the Hippo/Warts pathway (HWP) regulator Expanded, which mediates Crumbs crosstalk to the HWP. Here we report that a yeast 2-hybrid (Y2H) screen identified the PP2A substrate-specificity subunit Waldorf (a PP2A-PR72/B'' isoform) as a binding partner of β_H-spectrin. Waldorf binds to β_H *via* a short conserved sequence in the globular segment 33 of β_H. Genetic interaction and molecular epistasis experiments strongly suggest that PP2A with the Waldorf specificity-subunit bound to it ($PP2A^{Waldorf}$) acts as a negative regulator of Crumbs by acting to displace aPKC from Crumbs. Consistent with this notion, mutant versions of Crumbs lacking target residues for aPKC in the FERM-domain binding site do not respond to changes in Waldorf levels. The 'output' of Crumbs that appears to be most sensitive to the levels of Waldorf is crosstalk with the HWP and not apical polarity *per se*. Thus

knockdown/overexpression of Waldorf results in the under/overgrowth of wing tissue, and Waldorf has a genetic interaction with Yorkie, but apicobasal polarity is not lost. Waldorf also modulates protein trafficking in a similar way to β_H and its previously reported partner an nexin B9: Knockdown of Waldorf leads to an increase in Rab7-positive and acidic compartments, suggesting that $PP2A^{Waldorf}$ also normally acts by suppressing lysosomal trafficking, most likely in favour of recycling pathways. Our results support a model in which Crumbs recruits β_H in a complex with the HWP activator Expanded, and $PP2A^{Waldorf}$ bound to β_H acts in a homeostatic fashion to limit Crumbs activation of the HWP by displacing aPKC complex. This in turn limits the amount of growth suppression caused by Crumbs-dependent HWP activation.

Actin Bundle Assembly by Formins and Mechanics.

A. Jegou, E. Suzuki, J. Chikireddy, G. Romet-Lemonne; Institut Jacques Monod - CNRS, PARIS, FRANCE.

Formins are central players in the assembly of most actin networks in cells, but how their activity is affected by the geometrical constraints imposed by the network architectures, such as filament crosslinking and formin spatial confinement, is still unclear. We have combined microfluidics and micropatterning techniques to investigate in vitro the dynamics of actin filament bundles induced by fascin and elongated by mDia1 formins. We have measured the impact of geometrical constraints on formin elongation rates and processivity. We show that filament bundling by fascin reduces formin activity. Strikingly, when formins are surface-anchored and elongate cross-linked filaments, formin elongation rate immediately decreases and processivity is greatly reduced, depending on the cumulative impact of formin rotational and translational freedoms, revealing an unexpected crosstalk between the constraints at the filament and the formin levels. Those results highlights the importance of molecular details of the formin anchoring to the plasma membrane in cells to efficiently modulate formin activity.

P1835/B74

The Formin Inhibitor, Smifh2, Inhibits Members of the Myosin Superfamily.

J. R. Sellers[1], S. Shi[2], Y. Nishimura[2], F. Zhang[1], R. Liu[1], Y. Takagi[1], V. Viasnoff[2], A. Bershadsky[2]; [1]National Heart, Lung, and Blood Institute, NIH, Bethesda, MD, [2]Mechanobiology Institute, Singapore, SINGAPORE.

The formin inhibitor, SMIFH2, is widely used in cell biological studies. It inhibits formin-driven actin polymerization in *vitro* with half maximal inhibition (IC50) values ranging from 5 to 15 µM for different formins. In search of formin function in F-actin retrograde flow, we examined the effect of SMIFH2 on the centripetal movement of actomyosin transverse arcs in detergent-permeabilized cells induced by ATP addition. In this system, neither polymerization nor depolymerization of actin can occur, because of the absence of G-actin and the presence of F-actin stabilizer, phalloidin. Nevertheless, SMIFH2 strongly inhibited or completely abolished the centripetal movement of transverse arcs in this system, as well as ATP-dependent contraction of linear stress-fibers. This caused us to question whether SMIFH2 might also be inhibiting non-muscle myosin 2A. Surprisingly we found that SMIFH2 inhibited both the actin activated MgATPase activity (IC50 50 µM) and the rate of actin filament sliding in the in *vitro* motility assay of this myosin (no movement detected at 150 µM SMIFH2). Interestingly, the effect of SMIFH2 on

motility could not be reversed by washout of the flow cell. We next tested the effect of SMIFH2 on other myosin family members. The ATPase activity of skeletal muscle myosin 2 was inhibited with an IC50 of 40 µM. Similarly, the ATPase activity of myosin 10, which is involved in the formation of filopodia in mammalian cells, was inhibited by SMIFH2 with an IC50 of 15 µM. Moreover, ATPase activity of *Drosophila* myosin 5 was inhibited much more potently with an IC50 of 2µM, that is even more potently than SMIFH2 inhibits most formins. Based on this information, we recommend that this inhibitor not be used in cell-based assays where myosins are always present.

P1836/B75

Mechanical Force Promotes the Dissociation of Arp2/3 Complex Branches.

N. G. Pandit, W. Cao, J. Bibeau, E. Johnson-Chavarria, T. D. Pollard, E. M. De La Cruz; Yale University, New Haven, CT.

The branched actin network, primarily comprised of actin and the Arp2/3 complex, generates and sustains force to power cellular functions like motility, endocytosis, and vesicle trafficking. During assembly of the branched actin network, it experiences variable resistance from the cell membrane and responds by adapting it's growth speed, power, and architecture both in vitro and in cells. The network also experiences mechanical force during disassembly but much less is known about how forces affect the disassembly of actin filament networks. Here, we examine how mechanical forces affect disassembly of branched actin networks and focus on the dissociation rate of Arp2/3 complex branches. We used microfluidics to apply force to branches formed from purified actin and Arp2/3 complex and observed debranching events in real time with TIRF microscopy. We found that low pN forces on branches dramatically accelerated the dissociation of branches from the mother filament. We find that the Arp2/3 complex exists in distinct mechanical states and each mechanical state has different sensitivity to force. The mechanical states and sensitivity to force is regulated by the ATPase cycle of the Arp2/3 complex. Interestingly, we also show that the ATPase cycle of the Arp2/3 complex also regulates it's interactions with debranching proteins such as Glia maturation factor (GMF). These observations suggest that the ATPase cycle of the Arp2/3 complex tunes sensitivity to debranching by force and regulatory proteins. These findings have broad implications for cell biology because they reveal a mechanism were older portions of the branched actin network could be specifically targeted for disassembly by force and other debranching proteins.

P1837/B76

Twinfilin Uncaps Actin Filament Barbed Ends to Promote Turnover of Lamellipodial Actin Networks.

M. Hakala[1], H. Wioland[2], M. Tolonen[1], A. Jegou[2], G. Romet-Lemonne[2], P. Lappalainen[1]; [1]Institute of Biotechnology, University of Helsinki, Helsinki, FINLAND, [2]Institute Jacques Monod, CNRS, Université Paris-Diderot, Paris, FRANCE.

Coordinated polymerization of actin filaments at their barbed ends towards membrane generates pushing force, which is essential for leading edge protrusions during cell migration and membrane invagination in endocytosis. Among the most central regulators of actin filament polymerization is the heterodimeric capping protein (CP). It binds to filament barbed ends with high affinity and slow dissociation kinetics to prevent their polymerization and depolymerization. In cells, however, CP displays very dynamic association with actin filaments, but the underlying mechanism has remained elusive. Here we reveal that another ubiquitous cytoskeletal regulator, twinfilin, which interacts with CP, actin

monomers and filament barbed ends, is a critical regulator of CP dynamics in vitro and in cells. By generating twinfilin-1/twinfilin-2 knockout B16-F1 cells, we learned that the lamellipodial actin filaments are less dynamic in the absence of twinfilins, and that this leads to diminished protrusion velocity. With in *vitro* single filament imaging coupled with microfluidics, we revealed that twinfilin does not accelerate actin filament barbed end depolymerization. Instead, these experiments demonstrated that twinfilin drastically accelerates CP dissociation from filament barbed ends through a mechanism that is dependent on twinfilin's actin-binding ADF-H domains. Consistently, loss of twinfilins in B16-F1 cells resulted in ~10-fold slower dynamics of CP, and this could be rescued with expression of wild-type twinfilin-1 but not by a twinfilin-1 mutant in which the ADF-H domains were inactivated. Moreover, whereas in wild-type cells CP was enriched at the distal edge of lamellipodial actin filament networks, it localized throughout the entire lamellipodium in twinfilin-deficient cells. Together, these results uncover the cellular function of twinfilin, and demonstrate that rapid dynamics of CP in cells, as well as its specific accumulation to the very leading edge of lamellipodium, are dependent on filament uncapping by twinfilin.

P1838/B77

Mechanical and Biochemical Factors Regulating the Disassembly of Actin Filaments.

H. Wioland, A. Jegou, **G. Romet-Lemonne**; CNRS - Institut Jacques Monod, Paris, FRANCE.

The disassembly of actin filaments is essential and must be tightly regulated in cells. The central player in actin filament disassembly is the ADF/cofilin protein family. Understanding their action on actin filaments is challenging because it comprises different reactions, including: binding to filaments, severing filaments, and affecting the monomer off-rate at both ends. In addition, actin turnover rates can vary greatly, as the action of ADF/cofilin is modulated by other proteins, by post-translational modifications, by ionic strength and pH, and by mechanical factors. Using microfluidics to study single actin filaments, we quantify the key reactions of ADF/cofilin, independently and in different contexts. In particular, we show that, quite unexpectedly, ADF/cofilin can drive the depolymerization of filaments from the barbed end in physiological conditions. Moreover, we show that the mechanical context of the filaments, and in particular, torsional constraints, can greatly enhance cofilin-induced severing. Our results illustrate the emerging notion that a variety of factors, very different in nature, co-regulate cytoskeletal dynamics.

P1839/B78

Arp3B Containing Arp2/3 Complexes Promote Disassembly of Branched Actin Networks.

D. Carra[1], C. Galloni[1], J. Abella[1], P. Singaravelu[2], D. Barry[1], S. Kjær[1], L. Blanchoin[2], M. Way[1]; [1]The Francis Crick Institute, London, UNITED KINGDOM, [2]Biosciences & Biotechnology Institute of Grenoble, Grenoble, FRANCE.

Branched actin networks generated by the Arp2/3 complex are essential for many different cellular processes, including cell motility, endocytosis and phagocytosis. In addition, a number of intracellular pathogens such as Listeria, Shigella and Vaccinia virus recruit and use the power of Arp2/3 driven actin polymerization to enhance their cell-to-cell spread. The Arp2/3 complex is composed of seven subunits (Arp2, Arp3, ARPC1-5). Interestingly, in humans, Arp3, ARPC1 and ARPC5 exist as two different isoforms (Arp3/Arp3B, ARPC1A/ARPC1B and ARPC5/ARPC5L) that are 91, 67 and 67% identical respectively. This raises the possibility that Arp2/3 is actually a family of 8 complexes with different interactions and

properties. Using Arp2/3 driven motility of Vaccinia as a model system, we have previously demonstrated that ARPC1 and ARPC5 isoforms confer different actin nucleating properties to the Arp2/3 complex (Abella et al., 2016). Our unpublished data now demonstrates that Arp3 and Arp3B also impart different properties to the Arp2/3 complex, despite the proteins being 91% identical. Depletion of Arp3B in HeLa cells results in increased stability of Arp2/3 branched actin networks and faster actin-based motility of Vaccinia. In contrast, over-expression of Arp3B suppresses Arp2/3-driven actin polymerization. In *vitro* assays with recombinant proteins, however, demonstrate that Arp3 and Arp3B containing complexes are equally efficient at assembling actin filaments. Therefore, we examined whether Arp3 and Arp3B impact instead on the stability of the branched actin networks that they generate. Using photoactivatable Arp3 and Arp3B constructs, we find that Arp3B containing-complexes have a significantly faster turnover in branched actin networks. Our collective observations are consistent with a model in which Arp3B containing Arp2/3 complexes promote disassembly of branched actin networks. By analysing a series of Arp3:Arp3B hybrids, we have identified the residues which likely contribute to these differences. Taking into account the ARPC1 and ARPC5 isoforms, our study now clearly demonstrates that in humans the Arp2/3 complex is indeed a family of 8 different complexes, each with unique properties.

P1840/B79

Single-molecule Imaging Reveals Dual Actin Regulatory Roles for IQGAP1.

G. Hoeprich[1], S. Shekhar[1], C. Fees[1], O. Sokolova[2], B. Goode[1]; [1]Brandeis University, Waltham, MA, [2]Moscow M.V. Lomonosov University, Moscow, RUSSIAN FEDERATION.

IQGAP1 is a key effector of Rac1 and Cdc42 that binds to F-actin and links cell signaling events to cytoskeletal rearrangements. Although IQGAP1 is conserved from yeast to humans, and is critical for many actin-based processes including cell motility and cytokinesis, the nature of its interactions with actin filaments and its effects on actin dynamics and spatial organization have remained somewhat elusive. Here, we show that full-length human IQGAP1 forms dimers, which by electron microscopy have a large globular domain (formed by its C-terminal halves) with two long extensions (formed by its N-terminal halves). Using in *vitro* single-molecule imaging, we show that IQGAP1 molecules interact tightly with the sides of filaments (dwell time > 15 min) and organizes them into thin bundles. These activities depend on the N-terminal half of IQGAP1. In contrast, the C-terminal half of IQGAP1 binds transiently to the barbed end of the filament (dwell time ~ 30 sec) and pauses filament growth while it is bound. Decoration of filaments with IQGAP1 also dramatically slows filament disassembly. Thus, IQGAP1 has dual functions as a transient barbed end capper and a filament bundling and stabilizing protein, likely to underlie many of its previously described in *vivo* roles.

P1841/B80

Investigating the Spatiotemporal Regulation of Arp2/3 and Branched Actin Networks during Cell Migration.

M. T. Butler, J. E. Bear; University of North Carolina at Chapel Hill, Chapel HIll, NC.

Cell migration is essential for many important physiological processes, including embryonic development, wound healing, and the immune response. In addition, the signaling pathways and mechanisms governing cell motility are often aberrantly utilized to facilitate cancer metastases. Cell migration can be directionally biased by extracellular guidance cues. The sensing of gradients of

substrate-bound cues through integrin receptors, known as haptotaxis, requires the highly conserved Arp2/3 complex and its critical role in the polymerization of branched actin networks and the generation of lamellipodial cellular protrusions. Using highly tractable embryonic fibroblast cell lines derived from an *Arpc2* conditional knockout mouse, we seek to explore novel aspects of how Arp2/3 and branched actin are regulated by diverse extracellular substrates. CRISPR-mediated labeling of the essential Arpc2 subunit of the Arp2/3 complex allows us to observe branched actin dynamics and affords optogenetic control of the endogenous Arp2/3 complex. High-resolution time-lapse imaging reveals cells plated on fibronectin-coated, integrin engaging substrates have striking differences in the organization and behavior of Arp2/3 and actin-based structures when compared to cells plated on Poly-L-Lysine, which lack substrate-bound integin signaling ligands. In the absence of integrin engagement, optogenetically sequestering Arp2/3 to the mitochondria reveals protrusions in this context are being primarily supported by linear actin bundles, with a minor contribution of Arp2/3 and branched actin, but the release of Arp2/3 from sequestration shows that simply transiently increasing the local concentration of Arp2/3 in protrusions is sufficient to push the balance more towards branched actin polymerization. Micropatterning experiments reveal that Arp2/3 is enriched in protrusions as they push across fibronectin islands and that mere close promixity to fibronectin engagement is not sufficient for this enrichment. Genetic or pharmacological perturbation of several components required for haptotaxis can alter Arp2/3 and protrusion dynamics in cells plated on fibronectin, but none as of yet have been found to mimic the effects of cells plated sans integrin ligand. Additional steps are being taken to further characterize this intimate relationship between integrin-based adhesion signaling and Arp2/3 regulation. Ultimately, these efforts are geared towards developing a deeper and more comprehensive understanding of fundamental cell behaviors by examining how the motility machinery is assembled and organized within cells in response to extracellular cues.

P1842/B81

Assembly of Divergent Actin Rings in *Chlamydomonas*Is Both Formin and Arp2/3 Dependent but Myosin Independent.

D. B. Turkowitch, B. M. Bigge, P. Avasthi; the University of Kansas Medical Center, Kansas City, KS.

Chlamydomonas reinhardtii, a biflagellate green alga, serves as an important model for understanding cilia, photosynthesis, and increasingly actin regulation due to the co-expression of two actins with ~63% sequence identity. *Chlamydomonas* has a conventional actin gene, IDA5, as well as an unconventional actin gene, NAP1. Our previous studies have demonstrated how treatment of wild type cells with latrunculin B (Lat B), an actin depolymerizing agent, results in the formation of a perinuclear ring. We previously showed that NAP1, which is strongly upregulated upon Lat B treatment and insensitive to Lat B, is both necessary and sufficient for formation of these phalloidin-labeled structures. Optimizing the conditions for high incidence of rings demonstrates the importance of strain background, LatB treatment time, light conditions during growth and treatment, and cell culture density. To determine which proteins are important for NAP1 ring formation and maintenance, we looked first at myosin. Treating wild type cells with both LatB and blebbistatin, a myosin inhibitor we previously showed could recapitulate specific actin-dependent phenotypes in *Chlamydomonas*, resulted in no significant difference in the percentage of cells with rings. Conversely, inducing rings in the presence of a formin inhibitor, SMIFH2 completely blocked initial ring formation but didn't affect integrity of already-formed rings. Insertional mutant for the formin FOR1 also produced no rings, confirming the requirement for this actin nucleators in ring assembly. Additional data from the lab shows similar results for Arp2/3, a

branched actin nucleator. Due to the requirement for both nucleators for producing a filamentous actin structure comprised of NAP1 suggests FOR1 and Arp2/3 may be able to nucleate filaments comprised of this divergent actin.

P1843/B82

Investigating the Regulatory Role of the Extracellular Matrix in Cortical Brain Development.

E. S. Wilson, W. Knudson, K. A. Litwa; Brody School of Medicine at East Carolina University, Greenville, NC.

Changes in the ratio of excitatory to inhibitory (E/I) synapses is a common underlying mechanism of many neurological diseases. Increased hyperexcitability of cortical neurons is characteristic of neurodevelopmental disorders, such as epilepsy and autism spectrum disorders. Currently, we know little about how this E/I ratio is established. However, changes in the extracellular matrix (ECM) during neurodevelopment may alter synapse formation. Hyaluronan (HA), the major component of the brain ECM, is a macromolecule that controls cellular spacing. Through interaction with its receptor, CD44, HA regulates RhoGTPase signaling pathways. RhoGTPases are master regulators of actin organization. Since the actin cytoskeleton is enriched in excitatory synapses, we hypothesize that HA restricts excitatory synapse formation through regulation of RhoGTPase signaling. Using human-derived cortical brain spheroids, we manipulated HA levels and observed the resulting effects on synapse formation and neurotransmission. Consistent with our hypothesis, enzymatic digestion of hyaluronan leads to increased excitatory synapses and decreased inhibitory synapses. The elevated excitatory synapse formation resulted in increased spontaneous neural activity. In contrast, the addition of high molecular weight hyaluronan into the environment has opposite effects, decreasing excitability and resulting in decreased spontaneous neural activity. Protein analysis of RhoGTPase activity confirms these results. These data support a regulatory role for the ECM in cytoskeleton remodeling at the synapse and establish a new model of ECM regulation of E/I imbalances associated with human neurodevelopmental disorders.

Characterization of CARMIL-GAP, a *Dictyostelium* CARMIL Isoform Harboring a GTPase Activating Domain for Rac.

G. Jung[1], M. Pan[2], T. Jin[2], J. A. Hammer, III[1]; [1]National Heart, Lung, and Blood Institute, NIH, Bethesda, MD, [2]National Institute of Allergy and Infectious Diseases, NIH, Bethesda, MD.

CARMILs (Capping protein Arp2/3 Myosin I Linker) are ~1000 residue, multi-domain scaffold proteins expressed from protozoa to man that have been studied extensively with regard to their ability to bind Capping Protein (CP) and reduce its affinity for the actin filament barbed end. CARMIL proteins also appear to play important roles in signal transduction, as they exhibit genetic and physical interactions with the Rac GEF Trio (Liang et al MBoC 2009; Vanderzalm et al. Dev. 2009), and T cells lacking CARMIL-2 exhibit a profound block in signaling downstream of CD28, the major co-receptor for T cell signaling (Liang et al Nat. Immunol. 2013). In previous work (Jung et al JCB 2001), we showed that Dictyostelium CARMIL binds CP, the Arp2/3 complex and myosin I (through its SH3 domain), and it is required for actin-dependent processes such as chemotaxis and micropinocytosis to be robust. Here we describe initial studies of CARMIL-GAP, a second Dictyostelium CARMIL that contains, in addition to all the normal CARMIL domains (including the CP-binding CPI domain), a ~130 residue insertion that, by homology, is a

GTPase activating (GAP) domain for Rho-GTPases. This domain is probably functional given that full length CARMIL-GAP can only be over-expressed if its GAP domain contains a point mutation (R737A) that blocks GAP activity in all characterized GAP proteins. Moreover, MS analyses of GAP domain pull-downs indicate that CARMIL-GAP binds the Rac isoform Rac1A. Like CARMIL, CARMIL-GAP localizes to actin-rich structures and is expressed in both vegetative and starved, developing cells. Consistently, CARMIL-GAP null cell lines created by homologous recombination exhibit pronounced defects in several actin-based processes occurring in vegetative and starved cells, including phagocytosis, motility and chemotactic aggregation. Importantly, these defects are specific, as expression of GFP-FL CARMIL-GAP in CARMIL-GAP null cells rescues them. Finally, rescue of CARMIL-GAP null cells with versions of CARMIL-GAP that lack either GAP activity or the ability to bind CP show that while both domains contribute significantly to CARMIL-GAP function, the GAP domain plays the bigger role.

Spire1C and the Arp2/3 Complex Drive a Wave of Filamentous Actin That Promotes Mitochondrial Fission and Motility.

S. M. Coscia[1], A. S. Moore[2], C. L. Simpson[1], E. L. Holzbaur[1]; [1]University of Pennsylvania, Philadelphia, PA, [2]Janelia Research Campus, Ashburn, VA.

Mitochondria are dynamic organelles that undergo fission and fusion and move throughout the cell. The main driver of organelle dynamics is the cytoskeleton. While it is well established that mitochondria are trafficked along microtubules, interactions between mitochondria and actin are less well understood. Novel results from our lab expand on the role of actin in mitochondrial dynamics. Using spinning disk and lattice light-sheet microscopy our lab identified in both immortalized and primary cell types a wave of filamentous (F-) actin that propagates through the mitochondrial network cyclically assembling and disassembling on adjacent subpopulations of mitochondria. In interphase the F-actin wave promotes mitochondrial fission; once actin disassembles daughter organelles often fuse with distinct neighbors leading to mitochondrial mixing. During metaphase the F-actin wave promotes mitochondrial motility via the formation of actin comet tails. To investigate the mechanism underlying the F-actin wave we used both pharmacological inhibitors and RNAi and determined that the wave depends on a diverse set of proteins that facilitate F-actin assembly and disassembly. Specifically, the F-actin wave is regulated by CDC42 and requires the Arp2/3 complex, VASP, and Spire1C. Actin filaments within the wave recruit the stabilizing factor, Filamin A. Active depolymerization of F-actin is also required to maintain the integrity of the wave as siRNA-mediated depletion of ADF, Gelsolin, or Cofilin resulted in significant enlargement of wave size. We propose that the function of the F-actin wave is to allow spatial mixing of mitochondrial contents, including mitochondrial DNA.

Identification of a Novel Regulatory Circuit That Modulates the Actin Cytoskeleton during Sea Star Meiosis.

M. Visconti[1], C. Ross[1], D. Pal[1], J. Henson[2], C. B. Shuster[1]; [1]New Mexico State University, Las Cruces, NM, [2]Dickinson College, Carlisle, PA.

Meiosis in oocytes represents a highly atypical cell division that results in a single viable gamete. In the sea star, oocytes are arrested in G2 of meiosis I, and upon stimulation with the 1-methyladenine (1-MeAde), a signal transduction pathway involving heterotrimeric G proteins and phosphatidylinositol-3

kinase (PI3K) stimulates M phase entry within 30 minutes. To better understand the regulation of the actin cytoskeleton during meiotic maturation, we performed a combination of live cell imaging and micromanipulation on *Patiria miniata* oocytes prior to- and following hormone activation. 4D imaging of oocytes expressing GFP-Lifeact or a biosensor for RhoA activity revealed a transient elaboration of actin-based projections and a general cortical enrichment approximately 2 minutes post-stimulation that decreased to below pre-hormone levels by Germinal Vesicle Breakdown (GVBD). Measurements of cortical tension mirrored these dynamics, with initial tension levels being high prior to hormone activation and dropping dramatically by GVBD. Inhibition of RhoA, either with dominant-negative Rho or a ROCK inhibitor depressed the cortical actin response as well as overall cortical tension levels, suggesting that Rho-ROCK signaling was a key regulator of cortical actin during this period. Inhibition of CDK activity had no effect on the decrease in cortical tension, suggesting that the drop in Rho activity and cortical tension was not a function of M phase entry. In contrast, inhibition of PI3K activity blocked GVBD and entry into M phase, but Rho activity and cortical tension remained elevated, suggesting that PI3K may play a feedback role in downregulating Rho. Together, these data suggest that hormone activation not only triggers meiotic re-entry, but also modulates Rho family GTPases to effect changes in the cortical actin cytoskeleton to promote cortical maturation in preparation for fertilization and development.

Balanced Rho Activation and Inhibition Regulates Exocytosis by Large Secretory Vesicles.

E. Schejter, R. Massarwa, D. Segal, B. Shilo; Dept. Mol. Genetics, Weizmann Institute of Science, Rehovot, ISRAEL.

The small GTPase Rho governs actomyosin-based contractility in a variety of cellular settings, by the parallel induction of actin polymerization and of myosin II recruitment and activation. Regulation of Rho function is mediated by guanine exchange factors (GEFs) and GTPase activating proteins (GAPs), which stimulate and inhibit Rho activity, respectively. We have been exploring the dynamics and molecular design of this fundamental circuitry in the context of exocytosis. Specifically, we study secretion of adhesive “glue” proteins (mucins) from the epithelium of the *Drosophila* salivary gland as a model system. Glue protein exocytosis is achieved via uncommonly large secretory vesicles (>5 um in diameter). Rho-mediated assembly and contraction of an actomyosin coat that forms around these vesicles upon their fusion with the apical cell membrane, is critical for release of the glue material into the gland lumen. We have identified RhoGEF2 as the activator of Rho in this setting. RhoGEF2 is recruited to the fused vesicles, and its function is essential for activation of Rho (as monitored with an active Rho sensor) on the vesicle surface, and for vesicle contraction. Interestingly, an actomyosin coat still forms around the vesicles following knockdown of *RhoGEF2*, likely generated by basal levels of Rho-GTP, which diffuse from the apical membrane following fusion. RhoGEF2 recruitment is actin dependent, implying an amplification mechanism for establishing a coat sufficiently robust to enable contraction. This process is counteracted by a dedicated RhoGAP, RhoGAP71E, which is also recruited by actin, and whose inhibitory function is essential for vesicle contraction. Content release from the giant secretory vesicles thus appears to require a finely timed balance between Rho activation and inhibition. A major challenge is to determine how temporal order is maintained within this circuitry, particularly since actin appears to serve as a shared recruiting element of both activating and inhibiting factors. A corresponding effort aims to elucidate the mechanisms underlying the recruitment and contractile

activity of myosin II, which is distributed in a non-homogeneous, “stripe”-like pattern on the vesicle surface.

P1848/B87

Centrocortin Regulates Axial Nuclear Migration in a Rho1-dependent Manner in the Early *Drosophila* Embryo.

C. Blake-Hedges, L. Kao, C. Zheng, T. L. Megraw; Florida State University, Tallahassee, FL.

In the early *Drosophila* embryo, the first 14 nuclear divisions occur rapidly and synchronously in a syncytium absent of cellular membranes. After the fourth nuclear division, the nuclei spread out along the anterior-posterior (A-P) axis of the embryo to prepare for future patterning steps during a process termed axial nuclear migration. This nuclear spreading relies on actomyosin contractions localized at the cortical plasma membrane that regulate cytoplasmic streaming, which subsequently distributes the nuclei along the A-P axis. Axial nuclear migration is critical for positioning the nuclei at the posterior pole in the proper time window for gametic cell differentiation, as well as regulating the subsequent symmetric nuclear divisions. Axial nuclear migration is necessary for successful development, yet the molecular mechanisms and pathway components that regulate it remain unclear. Our investigations reveal two important components that cooperate to regulate axial nuclear migration: the conserved centrosomal actin regulatory protein Centrocortin (Cen), and one of the major GTPases involved in actin regulation, Rho1. Combining hemizygous *cen* mutants with heterozygous *rho1* mutants (*cen* -/-; *rho1* +/-) results in severe axial nuclear migration failure that is not present in the single mutants, indicative of a cooperative role. The defects in axial nuclear migration result in reduced embryo survival and sterile offspring that are devoid of a germline due to defective pole cell formation. Overexpression of Cen results in asynchronous nuclear divisions, however, axial nuclear migration remains intact. We also found that Cen interacts physically with multiple actin regulators such as Filamin, Formin, and other actin-associated proteins through mass spectrometry analysis. A genetic screen using RNAi lines of actin and myosin regulators in the early embryo in combination with *cen* RNAi identified interactions of *cen* with other components in the Rho1 pathway. Altogether, these data show that Cen is a novel actin regulator that cooperates with Rho1 to regulate the actomyosin dynamics necessary for axial nuclear migration in the early *Drosophila* embryo. In this study, we aim to elucidate the role of Cen in the early embryo as an actin regulatory protein and establish its position in the Rho1-mediated pathway that regulates axial nuclear migration.

Lipid Droplets Contribute to Actin Cytoskeletal Maintenance during *Drosophila* Oogenesis.

J. M. Thomalla[1], M. S. Giedt[2], T. L. Tootle[2], M. A. Welte[1]; [1]University of Rochester, Rochester, NY, [2]University of Iowa Carver College of Medicine, Iowa City, IA.

Lipid droplets (LDs) are ubiquitous cellular fat storage organelles with critical roles in energy homeostasis and metabolism. In addition, LDs also function in protein storage and defense against pathogens. Here, we uncover a novel role for LDs in maintaining the actin cytoskeleton during *Drosophila* oogenesis. During oogenesis, the oocyte and its 15 sisters, the nurse cells, frequently remodel their actin cytoskeleton, leading to dramatic morphological changes. Exquisite temporal and spatial control of actin is in part mediated by prostaglandins (PGs), short-lived lipid signaling molecules synthesized by the COX-like enzyme Pxt. During mid-oogenesis, the cortical actin cytoskeleton in *pxt*

mutants breaks down, resulting in abnormal oocyte development and female sterility. We find that mutants in two LD proteins, the triglyceride lipase ATGL and the perilipin PLIN2, show similar cortical actin breakdown, even though Pxt protein abundance is normal. *ATGL* mutants genetically interact with *pxt* mutants, suggesting that ATGL and Pxt work in the same genetic pathway. We detect no enrichment of Pxt on LDs: biochemically purified LDs show no enrichment of Pxt, and Pxt localizes with either Golgi or ER markers, but not LDs, in *vivo*. These data suggest that Pxt does not act directly at the surface of LDs. Our working model is that the fatty acids used by Pxt to synthesize PGs originate from LDs and are released from the stored triglycerides in LDs by ATGL; PLIN2 may control ATGL activity. Both ATGL and PLIN2 are expressed during oogenesis and germline RNAi reveals that PLIN2, just like Pxt, is required in the germline for actin maintenance; similar experiments for ATGL are in progress. We also employed *DGAT1* mutants, in which nurse cells fail to make LDs. Mutant nurse cells eventually die, but display actin breakdown even before death, consistent with a role for LDs in actin maintenance. Using *in-vitro* culturing, it was previously shown that exogenous PGs can rescue the actin defects in *pxt* nurse cells. We are currently testing whether similar rescue is observed in *ATGL* or *PLIN2* mutants supplied with PGs or fatty acids. Our findings highlight unexpected, non-metabolic roles for LDs and LD proteins and link LDs to actin cytoskeletal regulation.

P1850/B89

Determining the Role for the Arp2/3 Complex and the Formin, Diaphanous, in the Germline of the Developing *Drosophila* Egg Chamber.

J. Thestrup, K. Stark, L. Lewellyn, A. Kindred, M. Tipold; Butler University, Indianapolis, IN.

Proper gamete formation is necessary for fertility in sexually reproducing organisms, and intercellular bridges are an essential structure found in the developing sperm and eggs from insects to mammals. The largest and most studied intercellular bridges are found in the developing fruit fly egg chamber. These intercellular bridges, or ring canals, connect the developing oocyte to supporting nurse cells. The ring canals allow neighboring cells to exchange material such as RNA, protein, and organelles, and defects in their stability or expansion lead to infertility. The ring canals are enriched in actin and actin binding proteins, and ring canal expansion depends on the activity of the Arp2/3 complex, which nucleates the formation of branched actin filaments. Mutations in members of the Arp2/3 complex lead to smaller and collapsed ring canals in mid-oogenesis, but it is not known whether the Arp2/3 complex plays an earlier role in oogenesis, or whether another actin nucleator, the formin, Diaphanous, is also required for ring canal formation or expansion. In this study, we use the GAL4/UAS system to study the effect of depletion of either the Arp2/3 complex member, ArpC2, or the formin, Diaphanous (Dia), from the developing germline. Our results suggest that Dia is essential for incomplete cytokinesis during germ cell divisions, and that both Dia and the Arp2/3 complex are required to regulate ring canal size throughout oogenesis. Additional studies are required to determine how the activity of these two actin nucleators is regulated as well as whether they may function antagonistically or cooperatively to regulate ring canal size.

Coupling of Muscle Stress Fibers to the Extracellular Matrix Drives Their Maturation into Myofibrils in Cardiomyocytes.

N. Taneja, A. Neininger, D. T. Burnette; Vanderbilt University, Nashville, TN.

Forces generated by heart muscle contraction must be balanced by adhesion to the extracellular matrix (ECM) and to other cells for proper heart function. Loss of this force balance is thought to underly the progression of heart diseases such as dilated cardiomyopathies. Despite its clinical significance, how cell adhesion regulates the proper formation and maintenance of sarcomeres is poorly understood. A recent study proposed a new model of "centripetal assembly" in which sarcomeres arise *de novo* from sites of ECM attachment, i.e., focal adhesions. This group made this claim while imaging iPSC derived cardiomyocytes 24-48 hours after they were plated, a time window when sarcomeres are already assembled on the dorsal surface of the cell as we have recently shown. Since this group only imaged the ventral surface of the cells, their data seemingly shows sarcomeres appearing next to focal adhesions. However, close examination of this data revealed this group documented pre-formed sarcomeres at the dorsal surface coming into focus, which we experimentally verified. Instead of appearing out of adhesions, we found that *de novo* sarcomere assembly occurs by a completely different mechanism. Specifically, a population of stress fibers, termed muscle stress fibers (MSFs), undergo translocation away from the edge and transition into sarcomere containing myofibrils on the dorsal surface. We therefore tested the role of focal adhesions in regulating this transition. Live imaging of MSFs and focal adhesions showed that MSFs were connected to focal adhesions sporadically along their length through dorsal stress fiber-like connections during their transition to myofibrils. Furthermore, focal adhesions underwent maturation in parallel with sarcomere formation, suggesting that ECM adhesion may serve as a "clutch" to allow MSFs to generate more force, thus facilitating their maturation. In agreement with this hypothesis, ECM adhesion negatively correlated with the rate of translocation of MSFs away from the edge. Reducing cell ECM adhesion by reducing integrin ligand concentration, knockdown of focal adhesion kinase or over-expression of the head domain of talin led to attenuation of myofibril maturation and faster translocation of MSFs away from the edge. Conversely, increasing ECM adhesion by inhibition of the auto-phosphorylation of FAK or increasing integrin ligand concentration led to faster maturation of myofibrils and slower translocation of MSFs. These findings have led us to propose a counter-model for the role of cell-ECM during sarcomere formation to the one recently proposed; our model is similar in design principles to actin networks of crawling mesenchymal cells.

Tropomodulins Stabilize Actin-tropomyosin Filaments in Migrating Cells to Control the Balance between Protrusive and Contractile Structures.

R. Kumari[1], Y. Jiu[1], P. Carman[2], S. Tojkander[1], K. Kogan[1], M. Varjosalo[1], P. Gunning[3], R. Dominguez[2], P. Lappalainen[1]; [1]University of Helsinki, Helsinki, FINLAND, [2]University of Pennsylvania, Philadelphia, PA, [3]UNSW, Sydney, AUSTRALIA.

Tropomodulins stabilize actin-tropomyosin filaments in migrating cells to control the balance between protrusive and contractile structures the actin cytoskeleton is important for a wide array of cellular and developmental processes, as well as for tissue homeostasis. To contribute to these diverse functions,

cells harbour different protrusive and contractile actin filament structures, which compete with one another for a limited pool of actin monomers. In order to regulate the dynamics of actin filaments, various actin-binding proteins have evolved. These include Tropomodulins (Tmods), which are actin filament pointed-end capping proteins. In muscle myofibrils, Tmods prevent the overgrowth of actin filaments, whereas their functions in non-muscle cells are less well understood. We show that, in U2OS osteosarcoma cells, Tmod1 and Tmod3 are integral components of actin stress fibers, and that they compensate for one another when depleted individually. However, simultaneous depletion of both the isoforms led to the disassembly of tropomyosin-actin filaments, lack of force-generating contractile stress fibres, and an increase in the cortical actin filament networks. Knockout-rescue experiments revealed that Tmod's ability to directly bind tropomyosin is important for stabilization of actin-tropomyosin filaments in cells. Moreover, by combining depletion of Tmods with an inhibition of the Arp2/3 complex, we provide evidence that loss of Tmods shifts the balance from formin-assembled actin filament structures to Arp2/3 complex-nucleated branched networks. This shift in balance between actin filament networks upon Tmod's depletion can be partially rescued by inhibiting the Arp2/3 complex or by depleting Arp2/3 by siRNA. Collectively, this study demonstrates that in non-muscle cells, Tmods are critical for the stability of tropomyosin-actin filaments, and thus for the maintenance of actin cytoskeleton homeostasis.

P1853/B92

Non-muscle Myosins 2 in Cell Polarization and Contact Guidance.

A. Zhovmer[1], E. Tabdanov[2], H. Miao[1], H. Wen[1], J. Chen[3], X. Luo[3], X. Ma[1], P. Provenzano[2], R. Adelstein[1]; [1]National Heart, Lung, and Blood Institute, NIH, Bethesda, MD, [2]University of Minnesota, Minnesota, MN, [3]National Cancer Institute, Bethesda, MD.

Contact guidance refers to the ability of cells to sense the geometrical features of the microenvironment and respond by changing their shape and adapting the appropriate orientation. We have discovered that contact guidance is preserved following loss of nonmuscle myosin (NM) 2B and that expression of NM2A alone is sufficient to establish an appropriate orientation of the cells. Loss of NM2B, and overexpression of NM2A, results in prominent cell polarization that is found to be linked to the increased alignment of microtubules with the actomyosin scaffold. Lack of mechanosensitive NM2B in stable stress fibers affects maturation of the focal adhesions as well as maturation of the actomyosin cytoskeleton. Thus for spreading cells, the loss of NM2B results in numerous thin and dynamic stress fibers which form tightly packed arrays at the cell-surface interface due to the formation of large numbers of small immature focal adhesions at the leading edge. Consequently, the spreading history of cells, encoded by stress fiber network organization, affects organization of microtubules that induce and maintain cell polarity by their structural adaptation to the geometry of the actomyosin at the cell-surface interface.

P1854/B93

The Transition of Podosomes into the Zipper-like Structures in Macrophage-derived Multinucleated Giant Cells.

A. Balabiyev, A. Mursalimov, N. P. Podolnikova, D. Lowry, J. Newbern, R. Roberson, T. P. Ugarova; Arizona State University, Tempe, AZ.

Macrophage fusion resulting in the formation of multinucleated giant cells (MGCs) is a multistage process that requires many adhesion-dependent steps and involves the rearrangement of the actin

cytoskeleton. The diversity of actin-based structures and their role in fusing macrophages is poorly understood. In this study, we revealed the hitherto unrecognized actin-based zipper-like structures that form between MGCs generated on the surface of implanted biomaterials. We established an in *vitro* model for the induction of these structures in mouse macrophages undergoing IL-4-mediated fusion. Using this model, we show that the zipper-like structures develop mainly at cell-cell contacts between large MGCs and rarely between MGCs and mononucleated macrophages. Live cell imaging using macrophages isolated from mRFP- and GFP-Lifeact mice demonstrated that zipper-like structures are dynamic formations undergoing continuous assembly and disassembly and that podosomes are precursors of these structures. Immunostaining experiments showed that vinculin, talin, integrin $\alpha_M\beta_2$ and other typical components of podosomes are present in the zipper-like structures. Macrophages deficient in WASp and Cdc42, key molecules involved in actin core organization in podosomes, as well as cells treated with inhibitors of the Arp2/3 complex failed to form the zipper-like structures. Furthermore, E-cadherin and nectin-2 were found between adjoining membranes, suggesting that the transition of podosomes into the zipper-like structures is induced by bridging plasma membranes by junctional proteins.

P1855/B94

Mechanically Distinct Uptake Mechanisms of Antibody-mediated and Phosphatidylserine-mediated Phagocytosis Revealed by Microparticle Force Microscopy.

D. Vorselen[1], Y. Wang[2], M. J. Footer[1], W. Cai[2], J. A. Theriot[1]; [1]University of Washington, Seattle, WA, [2]Stanford University, Stanford, CA.

Macrophages are able to phagocytose targets of vastly different rigidities, ranging from bacteria during immune response, to apoptotic cell fragments in tissue homeostasis. Phagocytosis can be strongly affected by minor differences in target rigidity and is generally less efficient for softer targets. How target rigidity is sensed by phagocytes, and how phagocytes adapt phagocytic mechanisms for efficient uptake of soft targets is currently poorly understood. Notably, soft targets like apoptotic cells are typically engaged through different ligands, such as phosphatidylserine (PtdS), than stiff targets such as bacteria, which are engaged through *e.g.* IgG. To reveal if uptake mechanics are ligand-dependent, we use microparticle traction force microscopy (MP-TFM), a methodology we recently developed to quantify the mechanical forces in immune-cell target interactions. First, monodisperse (CV < 0.1) deformable polyacrylamide microparticles with cell-like rigidities (Young's modulus 0.1 - 10 kPa) are synthesized using a membrane emulsification approach. These particles can readily be conjugated with a variety of ligands and fluorescent dyes. Using confocal microscopy, we can resolve the three-dimensional shape of individual particles during engulfment with 50 nm precision, after which we use a reference-free strategy to infer both shear and normal traction forces (>10 Pa) directly from the deformed particle shape. During IgG-mediated phagocytosis soft particles (0.3 kPa) are deformed strongly, implying highly localized cellular forces (~nN), and revealing 4 mechanically distinct steps in the phagocytic process. Initially, we observe outward directed pushing forces from the phagocytic cup base. During subsequent pseudopod extension the majority of the deformation is localized in a ring that is initially irregular, but becomes uniform during cup closure. Surprisingly, strong localized punches at the cup base still occur in these stages. After cup closure, we observe some of the strongest forces, seemingly pushing the engulfed target into the cell. These deformations correlate with local accumulation of actin and are likely intimately linked to cytoskeletal dynamics. In PtdS-mediated phagocytosis we observe a clearly distinct mechanical signature, with a striking overall elongation of the

particles and lower actin accumulation. Our novel approach gives us unprecedented detail on the mechanical interaction between phagocyte and target in phagocytosis and reveals critical differences between IgG- and PtdS-mediated phagocytosis.

P1856/B95

Phosphoinositides Regulate Force-independent Interactions between Talin, Vinculin, and Actin in Vitro.

C. Kelley, T. Litschel, D. Dedden, S. Schumacher, P. Schwille, N. Mizuno; Max Planck Institute of Biochemistry, Martinsried, GERMANY.

The focal adhesion (FA) proteins talin and vinculin connect integrin receptors in the membrane to contractile actomyosin networks, acting as the mechanosensitive core of FA complexes. Both proteins have been shown to directly bind F-actin, the phosphoinositide $PI(4,5)P_2$, and each other. Though these interactions are critical to FA formation, stability, and dynamics, the underlying mechanisms of regulation for talin and vinculin within FA complexes remain unclear. Here, talin-vinculin-actin assemblies have been reconstituted in vitro using various synthetic membrane systems, including liposomes, supported lipid bilayers, and encapsulation within giant unilamellar vesicles. Using biochemistry, light microscopy, and cryo-EM, we show that interactions between full-length talin and full-length vinculin are mediated by membrane binding. Previously, it has been suggested that force application is required for release of talin autoinhibition, leading to vinculin binding. Here, we show that the addition of phosphoinositide-rich membranes alone is sufficient to trigger talin-vinculin interactions, even in the absence of force. Additionally, membrane-bound talin and vinculin coordinate the recruitment and reorganization of F-actin at membrane surfaces, suggesting that local regulation of membrane composition could directly control the recruitment, activation, and engagement of proteins, such as talin and vinculin, within FAs.

P1857/B96

Generation of Stress Fibers from the Cortical Actomyosin Meshwork.

J. Lehtimäki, K. Rajakylä, S. Tojkander, P. Lappalainen; University of Helsinki, Helsinki, FINLAND.

Contractile actomyosin bundles are important for motile and morphogenetic processes in animal cells and tissues. Ventral stress fibers are the most prominent actomyosin structures in many non-muscle cell-types. These thick, contractile bundles are typically connected to focal adhesions at their both ends and contribute to cell migration, morphogenesis and mechanosensing. Ventral stress fibers can be generated either from the pre-existing network of two other types of actin bundles; transverse arcs and dorsal (radial) stress fibers (Hotulainen & Lappalainen, *J. Cell Biol.,* 2006; Tojkander et al., *Curr. Biol.,* 2011, Burnette et al., *Nat. Cell Biol.,* 2011; Tojkander et al., *eLife*, 2015; Fenix et al., *Mol. Biol. Cell.,* 2016; Hu et al., *Nat. Cell Biol.,* 2017), or via splitting of pre-existing ventral stress fibers (Young & Higgs, *Curr. Biol.,* 2018). In addition to thick ventral stress fibers, which are typically enriched at the lamellum of motile cells, many cell-types also exhibit thinner stress fibers at their posterior region (e.g. Burnette et al., *J. Cell Biol.,* 2014). Also these thin (basal) stress fibers are connected to focal adhesions at their both ends, but whether they are generated from the pre-existing network of transverse arcs and dorsal stress fibers, or through another mechanism, has remained elusive. Here, by utilizing 3D-SIM and live-cell TIRF microscopy on U2OS osteosarcoma cells and mouse embryonic fibroblasts (MEFs), we revealed that basal stress fibers assemble through NMII-dependent reorganization of the cortical actin meshwork at

the bottom of the cell. This leads to the formation of an actomyosin bundle, and subsequent enrichment of focal adhesion components at the ends of the bundle. The assembly of basal stress fibers is typically preceded by a NMIIA pulse at the ventral surface of cell, and appears to be dependent on formins but not the Arp2/3 complex. Basal stress fibers display periodic NMII pattern and are contractile, although based on traction-force microscopy they exert weaker forces to the substratum compared to thick ventral stress fibers. Live-cell imaging revealed that basal stress fibers undergo dynamic re-organization and are able to 'exchange neighbors': an event where the *de novo* forming actomyosin bundle interacts with another one and subsequently displaces its attachment from a focal adhesion to another in the near vicinity. Collectively, our work provides evidence that basal stress fibers are dynamic, contractile actomyosin bundles, which are generated through reorganization of the cortical actomyosin meshwork by a novel, NMII-dependent mechanism.

P1858/B97

Myofibril Assembly and the Role of the Ubiquitin Proteasome System.

J. Wang, Y. Fan, S. Dube, D. K. Dube, J. M. Sanger, J. W. Sanger; SUNY Upstate Med University, Syracuse, NY.

De novo assembly of myofibrils in vertebrate cross-striated muscles occurs in a step-wise formation that begins with **premyofibrils** built of thin actin filaments linked to muscle specific alpha-actinin. Small bands of nonmuscle myosin II filaments interact with actin filaments forming minisarcomeres. In a second step, incorporation of titin and muscle myosin II filaments onto premyofibrils leads to formation of **nascent myofibrils** with thin filaments of actin and two different isoforms of myosin II: nonmuscle myosin II in short filaments, and overlapping thick filaments of muscle myosin II. In the transition to **mature myofibrils,** late-assembling proteins (telethonin, myomesin, and muscle myosin II binding protein C) are inserted, nonmuscle myosin II is absent, and muscle myosin II filaments align into A-Bands with titin stretching from Z-Bands to the middle of the A-Bands. FRAP analyses of control myofibrillogenesis indicate that the dynamics of the assembling proteins decrease as premyofibrils transform to nascent myofibrils and then to mature myofibrils. In a search for controls of the process of myofibril assembly, we discovered that the transition from nascent to mature myofibril could be halted by inhibitors of the Ubiquitin Proteasome System (UPS). In particular, inhibition of E3 Cullin ligases halted the formation of mature myofibrils from nascent myofibrils. Inhibition of p97 extraction of ubiquitinated sarcomeric proteins also led to an inhibition of myofibrillogenesis at the nascent myofibril stage**.** We were able also to arrest myofibrillogenesis at the transition zone from nascent myofibrils to mature myofibrils by the use of five different proteasomal inhibitors. In contrast to the effects of various inhibitors of UPS, inhibitors of autophagy or lysosomes did not affect myofibrillogenesis. The similarity of the effects caused by three different classes of the UPS inhibitors indicates that removing and proteolyzing sarcomeric proteins from the nascent myofibrils is required to permit their transition to mature myofibrils. An alyses of the dynamics of three selected sarcomeric proteins (actin, muscle myosin II heavy chains and muscle myosin II light chains) by FRAP led to the discovery that the proteasome and the p97 inhibitors decreased the dynamics of each of these proteins in the first two stages of the three-step process of myofibril assembly, i.e. premyofibrils and nascent myofibrils, but not in the mature myofibrils. These results indicate that the exchanges of the sarcomeric proteins are important as premyofibrils and nascent myofibrils are transformed into mature myofibrils.

Role of Amino Acid Sequence Differences in the Global Intracellular Functions of Beta- and Gamma-actin.

P. Vedula, D. Dong, H. Leger, F. Luca, A. Kashina; University of Pennsylvania, Philadelphia, PA.

Actin is one of the most essential and abundant eukaryotic proteins, highly conserved across the tree of life. Among the six mammalian actins, beta- and gamma-cytoplasmic actins are the only two that are ubiquitously expressed in every cell type and share the highest identity at the amino acid level, with only four homologous substitutions within their N-terminus. The underlying mechanisms maintaining their functional differences in vivo are unknown, and constitute one of the major unresolved questions in the field. Here we addressed this by using the mouse model recently developed in our lab, where beta-actin gene (Actb) is altered to encode gamma-actin protein from the endogenous Actb locus (Actbc-g mice). In these mice, beta-actin protein is absent, while the beta-actin gene is nearly intact, enabling us to address the direct effect of amino acid sequence on actin isoform function. While, consistent with previous reports, these mice are viable and appear phenotypically normal at the gross level, lack of beta-actin protein leads to specific defects in tissues that critically depend on the microvilli for their function, including the retina, and the brush border of the small intestine. Both tissues show major morphological changes in Actbc-g mice, including damaged microvilli of the retinal pigment epithelium that are responsible for photoreceptor homeostasis, as well as disorganization of the terminal web and altered microvillus length in the small intestine. In the retina, these defects are accompanied by progressive loss of light sensitivity. Biochemical studies link these defects to the altered binding of specific actin-associated proteins that exhibit a strong bias between beta- and gamma-actin. Our results suggest that beta-actin protein is essential for the microvilli maintenance in multiple cell types, and constitute the first demonstration of the key contribution of specific actin isoform's amino acid sequence to actin's in *vivo* functions. Overall, this study sheds major light on the functional differences between the two closely related cytoplasmic actins, which universally affect a specific subset of actin functions in multiple cell types.

P1860/B99

Barbed End-dependent Clustering of Vasp and Lamellipodin Initiates Filopodia within Lamellipodial Networks.

K. Cheng, D. Mullins; University of California, San Francisco, San Francisco, CA.

The shape of many eukaryotic cells depends on interactions between the actin cytoskeleton and the plasma membrane. Changes in cell shape often result from protrusion of actin-filled pseudopods, including linear structures called filopodia. These filopodia can be created by a variety of mechanisms, including the dynamic reorganization of growing filaments within a two-dimensional lamellipod. A key protein required for the emergence of filopodia from lamellipodial networks is the actin polymerase VASP, whose clustering promotes the formation of linear actin bundles. By imaging the earliest events of this process in migrating B16F1 mouse melanoma cells, we discovered that nascent VASP clusters do not associate with the I-BAR-containing protein IRSp53, but arise from small, pre-existing clusters of the VASP-binding protein, Lamellipodin (Lpd). The small, Lpd-only clusters do not 'skate' across the leading edge the same way as VASP/Lpd clusters. Growth of VASP/lamellipodin clusters requires multivalent interaction between the two proteins as well as the presence of growing actin filaments. VASP/Lpd

clusters grow by accumulating monomers and by fusing with each other, but their size is limited by a previously undescribed, size-dependent instability.

Chiral Bending of Filopodia.

W. Li, 7610001, B. Geiger, A. Bershadsky; Department of Molecular Cell Biology, Weizmann Institute of Science, Rehovot, ISRAEL.

The mechanism underlying the left-right asymmetry in multicellular organisms is still poorly understood. Some evidence suggests that such asymmetry depends on the motile behaviour of individual cells. Indeed, different cell types, growing under isotropic conditions, demonstrate left-right chiral swirling of their actin cytoskeleton. This swirling depends on myosin-II driven actomyosin contractility and formin-mediated actin polymerization, and can be regulated by a number of actin-associated proteins [Tee et al, 2015]. The molecular events responsible for the swirling asymmetry, however, remain to be elucidated. Here, we show that filopodia growth in HeLaJW cells plated on the substrate covered by animal lectin (galectin-8) demonstrate local left-right asymmetry in their growth pattern. Specifically, those filopodia which bend during elongation do it in an asymmetric manner so that a fraction of “left-turning” filopodia was significantly higher than that of “right-turning”. Overexpression of myosin-X, a protein known to be involved in filopodia growth, significantly enhanced the fraction of bending filopodia (up to forty percent) on galectin-8-coated substrate. Over 80% of the ‘bending filopodia’ turned left. The asymmetry of filopodia turning was observed also in cells with inhibited myosin-II function and therefore depended mainly on actin polymerization and function of non-conventional myosins. Interference reflection microscopy (IRM) and TIRF microscopy showed that filopodia turning occurs only in filopodia with tips attached to the galectin-8-coated substrate. Moreover, the bending of filopodia was preceded by significant decrease in filopodia protrusion speed, suggesting that friction between filopodia tip and the substrate triggered the filopodia turning. Since filopodia growth is known to be driven by formin-dependent actin polymerization, we overexpressed the major formins, mDia1, mDia2, FMNL2, and DAAM1 in the cells, and found that the formin overexpressing cells produce less, yet longer and thicker filopodia as compared to controls. These filopodia, however, did not turn. An other method of stimulating filopodia formation and elongation is the knock-down of Arp2 or Arp3. We have found that filopodia induced by Arp2/3 depletion demonstrated myosin-X-dependent bending. This bending was also asymmetric with the preferential left turning, similarly to the filopodia induced by overexpression of myosin-X. Thus, integrin-independent filopodia adhesion to galectin-8 coated substrate revealed intrinsic asymmetry in actin-polymerization dependent and myosin-X -enhanced filopodia turning. Asymmetry of filopodia turning could be one of the factors determining left-right asymmetry in more complex multicellular systems.

Reach Out and Touch Fate: Cytonemes in Sonic Hedgehog Signal Propagation.

E. T. Hall, D. P. Stewart, S. K. Ogden; St. Jude Children's Research Hospital, Memphis, TN.

The formation and maintenance of morphogen gradients is essential during development, but the mechanisms by which morphogens are transported to form gradients are not yet clear. Evidence is mounting in support of their transport by long specialized filopodia known as cytonemes. Despite experimental evidence demonstrating cytoneme based transport of morphogens in vivo, insight into the

mechanisms of cytoneme initiation, regulation, and signal propagation is lacking. This is due to technical difficulties visualizing these fragile structures. We recently overcame this obstacle by developing a fixation technique termed MEM-fix that preserves the cytonemes of cells in culture, allowing investigation of fundamental questions about cytoneme biology, and the role they play in morphogen signal propagation. We find that cytonemes are ubiquitous across cultured cell lines and demonstrate dynamic motile and sensing properties. The expression of the morphogen Sonic Hedgehog (Shh) can affect the occurrence of cytonemes in ligand-producing cells. We show that Shh travels along cytonemes in vesicles with the Shh deployment protein Dispatched. Live cell imaging identified that cytoneme-based Shh deposits can activate the pathway in receiving cells within seconds of release. The use of MEM-fix along with live cell imaging assays, is now providing insight into the functionality and the extent cells use cytonemes for morphogen transport.

P1863/B102

Model for Dendritic Actin Network Formation, Distributed Turnover, and Structural Remodeling.

D. Holz, A. Hall, D. Vavylonis; Lehigh University, Bethlehem, PA.

The dendritic network of actin filaments provides the force for lamellipodial protrusions, driven by actin filament polymerization and branch generation by the Arp2/3 complex. Electron microscopy of keratocyte lamellipodia has revealed a network structure that varies with distance to the leading edge: a dense brushwork composed of short filaments near the leading edge is followed by longer and more linear filaments near the center and rear. Single molecule imaging experiments have shown that actin assembles throughout the lamellipodium and that actin disassembles within a few seconds after incorporation into the filament network, suggestive of frequent severing near the barbed ends. Prior modeling of FRAP and single molecule imaging experiments suggested that diffusing actin oligomers anneal to the network throughout the lamellipodium. To further investigate the precise mechanisms behind network remodeling and the role of the oligomer pool, we created a three-dimensional stochastic model at the filament level that includes mechanisms for polymerization, depolymerization, branching, capping, uncapping, severing, oligomer diffusion, annealing, and debranching. The model reproduces the +/- 35^{o} orientation pattern when branching occurs within 10^{o} of the lamellipodial plane as well as the density of branches, ends and length distribution near the leading edge for both fibroblast and keratocyte lamellipodia (that differ in the magnitude of retrograde flow and polymerization rates). We find that incorporating frequent severing near the barbed ends (occurring at a lower rate near the leading edge) and annealing, provides a mechanism for structural remodeling at the level observed in electron micrographs. This mechanism also leads to short actin lifetimes and distributed turnover, which we compare quantitatively to prior experiments.

P1864/B103

Discrete Mechanical Model of Lamellipodial Actin Networks.

D. M. Rutkowski, D. Holz, D. Vavylonis; Lehigh, Bethlehem, PA.

Determining how mechanical forces and actin filament turnover coordinate within the lamellipodium is important for understanding cell migration. Several computational and mathematical models have been used to investigate the overall stress profile of lamellipodial actin networks, including around focal adhesions, often using a continuum approximation. However, the forces and deformations of individual actin filaments important in lamellipodial mechanics have largely not been considered. We develop a

filament-level computational model of an actin network undergoing retrograde flow simulated via 3d Brownian dynamics. Retrograde flow is maintained in our simulations due to both pushing forces from the leading edge (due to actin polymerization) and pulling forces (due to molecular motors) on the actin network. We develop computational methods allowing us to simulate networks with densities similar to that in prior electron micrographs. Connectivity between individual actin segments is maintained by both permanent and temporary bonds meant to represent the Arp 2/3 complex and actin crosslinkers respectively. Remodeling of the network occurs via the addition of single actin filaments near the leading edge and via filament and bond severing of bonds under high stress. With our model we are able to investigate how several parameters affect the stress distribution, network deformation and retrograde flow speed of the actin network. We focus on varying the network connectivity, the strength of the pushing and pulling forces and the presence and location of nascent focal adhesions. Our model is able to quantitatively capture the experimentally observed reduction in retrograde flow speed when the network is exposed to cytochalasin D, which halts actin polymerization. We also find that increased levels of network connectivity lead to higher levels of stored stress within the network which leads to longer ranged network distortions when focal adhesions are encountered.

P1865/B104

Synaptic Control of Lysosome Trafficking in Dendrites.

A. Konietzny, B. van Bommel, N. Hertrich, J. Baer, **M. Mikhaylova**; University Medical Center Hamburg-Eppendorf, Hamburg, GERMANY.

Organelle positioning within neurites is required for proper neuronal function. In dendrites with their complex cytoskeletal organization, transport of organelles is guided by local specializations of the microtubule and actin cytoskeleton, and by coordinated activity of different motor proteins. Here, we focus on the actin cytoskeleton in the dendritic shaft and describe dense structures consisting of longitudinal and branched actin filaments. As evident from the super-resolution imgaing data, these actin patches are devoid of microtubules and are frequently located at the base of spines, or form an actin mesh around excitatory shaft synapses. Using lysosomes as an example, we demonstrate that the presence of actin patches has a strong impact on dendritic organelle transport, as lysosomes frequently shortly pause or stall at these locations. We provide mechanistic insights on this pausing behavior, demonstrating that actin patches form a physical barrier for kinesin-2 driven cargo. In addition, we identify myosin Va as an active tether which mediates long-term stalling. Does synaptic activity control the switch between kinesin-2 and myosin Va driven transport? We are currently exploring the role calcium binding protein calmodulin and caldendrin in the regulation of myosin Va activity by employing various in vitro reconstitution and cellular assays. Taken together, we propose that the correlation between the presence of actin meshes and halting of organelles could be a general principle by which synapses control organelle trafficking.

P1866/B105

Rapid Treadmilling and Myosin Motors Synergistically Induce Formation of Cortex-like and Ring-like Actomyosin Structures.

Q. Ni, K. Wagh, A. Upadhyaya, G. A. Papoian; University of Maryland, College Park, MD.

Semiflexible actin filaments crosslinked by myosin motors control cell motility and morphology via a dynamic remodeling process - treadmilling. Filaments in living cells are often found to be abundant at

the cell periphery, frequently forming ring-like structures or thin, contractile sub-plasma-membrane cortices. However, in less chemically dynamic reconstituted actomyosin networks, motor proteins induce global geometric contraction, creating cluster-like structures. The fundamental mechanisms underlying the emergence of cortex-like or ring-like actin networks in cells are not well understood. Here we used an advanced computational modeling platform, MEDYAN, which couples stochastic reaction-diffusion treatment with polymer physics and mechanics, to explore the interplay between filament treadmilling and the activity of non-muscle myosin II motors in confined systems. Our results indicate that the actomyosin network geometry is tightly regulated by filament treadmilling. In our simulations, slowly treadmilling actomyosin networks undergo geometric collapse and form clusters. On the other hand, enhancement of filament treadmilling generates cortex-like structures in 3D spherical networks and ring-like structures in quasi-2D disk-like networks, without the necessity to tether filaments to the boundary or preferentially nucleate filaments. We validated the effect of filament treadmilling on the ring-like structures of spreading T cells by using Latrunculin a (LatA) to inhibit actin filament assembly and monitoring filament dynamics via Total Internal Reflection Fluorescence microscopy. With high doses of LatA, actin rings in T cells experience centripetal collapse accompanied by the formation of clusters or bundles, which is consistent with our simulations mimicking the effects of LatA. We hypothesize that rapid treadmilling allows filaments to escape from global clustering and finally reach the network boundary, where myosin motors cause the collapse of these filaments into cortices and rings.

P1867/B106

Leading Edge Maintenance in Migrating Neutrophil-like HL-60 Cells Is an Emergent Property of Branched Actin Growth.

R. M. Garner[1], E. F. Koslover[2], A. J. Spakowitz[1], J. A. Theriot[3]; [1]Stanford University, Stanford, CA, [2]University of California San Diego, San Diego, CA, [3]Howard Hughes Medical Institute, University of Washington, Seattle, WA.

Actin-driven, directional cell motility is one of the most fundamental behaviors in animal cell biology. To maintain polarized migration, cells must coordinate the stochastic growth of tens of thousands of nanometer-sized actin filaments over micron-scale distances along their leading edge. We employed high speed, high resolution microscopy of migrating neutrophil-like HL-60 cells to directly observe leading edge maintenance evolving over time. To our surprise, we discovered that cells' leading edge shape continuously undergoes dynamic sub-micron, sub-second undulations, all while maintaining nearly constant overall cell shape. Under the assumption that these shape fluctuations reflect the underlying actin dynamics driving migration, we set out to quantitatively characterize and then perturb shape dynamics in order to develop a deeper understanding of the mechanisms cells use to maintain leading edge shape, and thus polarized migration. Given that the overall leading edge shape is quite stable, we reasoned that any perturbation from the average shape would have a characteristic amplitude and relaxation timescale, and that this relaxation might have some wavelength dependence. Adapting well-established methods from polymer physics, we used Fourier mode time-autocorrelation analysis to investigate the relaxation of shape fluctuations over time. Surprisingly, we found that shape fluctuations at all wavelengths undergo oscillations as they decay, implying some memory exists in the system that causes fluctuations to "overshoot" as they relax, much like a Hookean spring. Furthermore, live-cell fluorescence imaging of HL-60 cells endogenously expressing GFP-β-actin revealed that actin density fluctuations also undergo oscillatory decay that is perfectly anticorrelated with leading edge

shape fluctuations. The rich behavior and quantitative nature of this dataset made it primed for physical modeling. We thus employed a swath of simple "toy" models to explore potential molecular mechanisms that could explain leading edge oscillations and their relationship to actin density. Remarkably, we found that a simple evolutionary filament orientation model (Maly and Borisy 2001) is sufficient to explain the oscillations. In this model, the network oscillates between a fast-growing, low density state in which filaments grow perpendicular to the leading edge, and a slow-growing, high density state in which filaments grow towards the membrane at approximately one half of the branching angle. Excitingly, these results suggest that branched actin growth against a membrane is inherently self-correcting and thus sufficient for maintaining leading edge shape without requiring higher-level regulation.

P1868/B107

Macromolecular Crowding Modulates the Organization of Actin Bundles Induced by Actin Crosslinking Proteins.

J. Park[1,2], M. Lee[1], B. Lee[1], N. Castaneda[1,3], L. Tetard[1,4], E. H. Kang[1,2,4]; [1]NanoScience Technology Center, Orlando, FL, [2]Department of Materials Science and Engineering, Orlando, FL, [3]Burnett School of Biomedical Sciences, Orlando, FL, [4]Department of Physics, Orlando, FL.

Actin crosslinking proteins such as fascin and α-actinin form higher-ordered actin bundles that play critical roles in various cellular structures including filopodia and lamellipodia. Macromolecular crowding agents are widely used to understand the functional properties of proteins in intracellular environment. While the roles of actin crosslinking proteins in bundling have been well studied in dilute buffer conditions, how they affect bundle organization in crowded environments is not well established. We hypothesize that crosslinked actin bundles by fascin and α-actinin may be modulated under macromolecular crowded environment due to changes in interaction between crosslinking proteins and filaments. Here, we investigate how macromolecular crowding affects the organization of fascin- or α-actinin-induced bundles in *vitro and* in *silico.* Total internal reflection fluorescence (TIRF) microscopy and atomic force microscopy (AFM) imaging revealed that macromolecular crowding agents densely packed fascin-induced bundle and promoted different morphology of α-actinin-induced bundle depending on the type of crowders. Using co-sedimentation assay, we found that binding activity of fascin and α-actinin was affected in the presence of crowders. All-atom molecular dynamics simulation results supported that crowding agents modulate the binding interactions between actin and fascin or the CH1 domain of α-actinin. This work suggests macromolecular crowding affects the organization of actin crosslinking protein-induced bundles by modulating the interaction between actin crosslinking proteins and actin filaments.

P1869/B108

Spatiotemporal Dynamics of Actin and Microtubules in Drosophila Egg Chambers.

G. Logan, B. McCartney; Carnegie Mellon University, Pittsburgh, PA.

Within a single cell, simple actin monomers assemble into structures with a remarkable range of geometries, dynamic properties and subcellular distributions, yet how this is achieved is poorly understood. We are using assembly of actin cables during oogenesis as a model to dissect these mechanisms. One of the last events in oogenesis is cytoplasmic dumping where a syncytial network of nurse cells contracts to expel their contents into the developing oocyte. At stage 10B just prior to

dumping, an array of actin cables initiates at the cell cortex and elongates toward the nucleus in each nurse cell. The cables continue to elongate after nuclear contact, pushing the nuclei away from the ring canals to prevent obstruction during dumping. We assessed the spatial distribution and dynamics of the growing cables and found that during stage 10B actin cables at nurse cell-nurse cell (N-N) and nurse cell-oocyte (N-O) junctions elongate at a rate of 0.11µm/minute. After nuclear contact, cable growth continues at a similar rate. While the majority of cables initiate within the first 45 minutes, new actin cables emerge through the first two hours of stage 10B. We further identified a population of actin cables at nurse cell-follicle cell (N-F) borders that can only be observed live. N-F cables grow significantly slower (0.06µm/minute) and contact the nucleus later than N-N or N-O cables, suggesting that different regulatory factors control their growth. Work from our lab and others has shown that Enabled (Ena), the formin Diaphanous (Dia), and its interactors Adenomatous polyposis coli-1 (APC1) and APC2 are required for proper assembly of actin cable arrays. Interestingly, while APC2 and Dia localize to the cortex at N-N, N-O, and N-F borders, Ena only associates with N-N and N-O borders. This suggests that Ena may be elongating the faster-growing N-N and N-O cables, and that N-F cables are Ena-independent. Consistent with that model, Ena reduction resulted in a reduced growth rate for N-N cables. We are currently assessing cable initiation and dynamics in other actin assembly mutants. In addition to a role for actin assembly factors, we found that acetylated microtubules (MTs) co-align with actin cables during their elongation, and that nocodozole inhibition of MTs blocks cable elongation. Stabilizing MTs with taxol causes actin cables to detach from the cortex. These results suggest that a dynamic MT network is required for actin cable elongation. We are currently investigating the role of MT +-TIP proteins in actin cable assembly (see poster by A. Leslie et al.). Taken together, our results suggest that many factors are orchestrated to control the spatiotemporal and dynamic properties of actin cable initiation and elongation.

P1870/B109

Kinesin-driven Microtubule Networks Control Dynamical Structure of Interpenetrating Actin Networks.

J. Berezney, 02453; Brandeis University, Waltham, MA.

Many of the fundamental physiological operations of the cell are accompanied by the fluid flow: locomotion, chromosome dynamics, cytoplasmic organization and, on an organismal level, embryogenesis. This dynamic reorganization is often generated by the microscale activity of molecular motors coupled to cytoskeletal proteins. The dense and diverse nature of the cytoplasm impedes our ability to interpret and predict this internally-driven motion. Although many of the major components in the cytoplasm are known, the dynamics of fluid flow and its coupling to physiological tasks is not. To capture the rich behavior of such living materials, we built a simple composite system of interpenetrating networks of bundled microtubules and entangled filamentous actin. The bundled microtubules are driven by the kinesin motors which generate flow. We show the activity of the microtubule bundles can fluidize and structurally remodel the interdigitated actin network. By controlling the mechanical properties of the actin network or the magnitude of fluid flow, we can transition the actin from a state of highly heterogeneous structures, characterized by large fluctuations in local density, to a state in which the actin is homogeneously distributed.

P1871/B110

Microtubules and the Microtubule +tips Eb1, Clip-170, and the Gas2 Protein Pigs Regulate Actin Cable Assembly and Organization during *Drosophila* Oogenesis.

A. Leslie, G. Logan-Graf, **B. McCartney**; Carnegie Mellon University, Pittsburgh, PA.

Crosstalk between the actin and microtubule (MT) networks plays essential roles in many cellular processes, but the mechanisms governing these interactions are not well understood. We are using actin cable assembly in *Drosophila* nurse cells as a model for dissecting actin-MT interactions. The nurse cells are a 15-cell syncytium connected to each other and to the developing oocyte through actin-based ring canals. Throughout oogenesis, the nurse cells transport mRNA, protein, and organelles into the oocyte via the ring canals. At stage 10B, actin cables emerge from the cortex and elongate toward the nucleus just prior to cytoplasmic dumping, a final rapid extrusion of nurse cell cytoplasm into the oocyte. The cables reposition the nuclei away from the ring canals to prevent obstruction. We discovered that acetylated MTs co-align with actin cables throughout their growth. Disrupting MTs with nocodozole blocks actin cable elongation, while stabilizing MTs with taxol results in cable detachment from the cortex and loss of further elongation. This suggests that a dynamic MT network is required for cable elongation. Further, disrupting actin cables through loss of the actin filament bundler Quail (Drosophila Villin) distorts MT organization, suggesting codependence of the networks. To begin to understand the molecular mechanisms of actin cable-MT crosstalk, we examined the role of the MT +TIP protein EB1, that we and others have shown can impact the actin cytoskeleton. Knockdown of EB1 resulted in premature cable assembly, and in early stages of assembly, significantly increased the number of cables, consistent with a role as an actin assembly inhibitor. In addition, loss of EB1 significantly reduced the actin cable growth rate and resulted in cables with significantly increased tortuosity, but did not impact actin-MT co-alignment. To dissect the complex role of EB1 in cable growth, we are interrogating two of its binding partners, CLIP170 and the actin-MT crosslinker Pigs (a Gas2 protein). We found that both CLIP170 and Pigs localize to puncta where actin cables and MTs co-align. In contrast to EB1 knockdown, loss of either CLIP170 or Pigs resulted in a significant decrease in actin cable number and length, suggesting a role for both proteins in promoting actin assembly. We are currently testing specific hypotheses to dissect the mechanisms by which EB1, CLIP170 and Pigs are modulating actin cable assembly.

P1872/B111

Determining Mechanisms of EPS8 Function during Microvilli Growth.

I. M. Gaeta, M. M. Postema, M. J. Tyska; Vanderbilt University, Nashville, TN.

Microvilli are actin-based protrusions evolutionarily conserved from the earliest animal cells to human intestinal epithelia. In the context of the human intestine, microvilli collectively constitute the intestinal brush border and serve as the sole site of nutrient absorption within the body. Despite persistence during evolution and the imperative role of microvilli for enabling human viability, little is known about the molecular events that underlie growth of the supporting microvilli actin bundles from the cell surface. Epidermal growth factor receptor pathway substrate 8 (EPS8) is an actin binding protein previously implicated in microvilli elongation and motility, and localizes specifically to the distal tips of microvilli in both mouse intestinal tissue and cell culture models. Moreover, previous studies have shown that loss of EPS8 leads to a decrease in microvilli length. As the barbed ends of actin filaments—the physiological sites of new monomer addition—are oriented towards the distal tips of microvilli, we propose that EPS8 functions in regulating actin bundle growth. Using the brush border inducible Ls174T-

W4 cell line, we demonstrate that EPS8 actin binding activity is necessary but insufficient for robust targeting to the distal tips of microvilli. Moreover, using spinning disk confocal microscopy, we are able to visualize individual microvilli growth events in kidney epithelial LLC-PK1-CL4 cells. These studies show that EPS8 puncta can predict sites of microvilli growth, and that microvilli length rapidly decreases shortly after EPS8 is lost from the distal tips. Intriguingly, we find that not only can microvilli growth occur *de novo* from the cell surface, but that new microvilli bundles can form orthogonally or at the base of existing microvilli, with EPS8 marking the new sites of actin bundle growth. Collectively, these results demonstrate that EPS8 is one of the earliest molecules localized to sites of microvilli growth and functions to stabilize growing actin bundles.

P1873/B112

Reconstitution of the Lamellipodia to Filopodia Transition Using Purified Proteins.

C. Suarez, J. D. Winkelman, A. Harker, P. M. McCall, A. Morganthaler, G. L. Margaret, D. R. Kovar; University of Chicago, Chicago, IL.

Cells simultaneously assemble and maintain different actin filament (F-actin) networks that are involved in diverse processes such as cell motility and cell division. For example, filopodia are finger-like membrane protrusions composed of long F-actin bundles that have been proposed to sense extracellular chemical and mechanical signals to steer the cell. Two actin elongation factors, formin and VASP, localize to filopodia tips, driving their elongation. It has been hypothesized that filopodia can be generated from the lamellipodia, which consists of densely packed, branched actin filaments that are kept short by capping protein. How can filopodia emerge from this high density of capped filaments? Do different assembly factors facilitate the formation of diverse filopodia? to answer these questions, we reconstituted the actin cytoskeleton present at the leading edge of the cell in *vitro* using purified proteins. By combining micropatterning and bead motility assays with three-color Total Internal Reflection Fluorescence (TIRF) microscopy, we reconstituted the formation of filopodia-like networks (FLN) from densely-branched networks in the presence of actin, Arp2/3 complex, its activator pWA, and the bundler fascin. The addition of a saturating concentration of capping protein inhibits FLN formation, which can be rescued by the inclusion of the processive F-actin barbed-end elongator formin mDia2, and to lesser extent by VASP. Interestingly, formin-generated networks are relatively long and lacking capping protein, unlike the short VASP-generated networks. In addition, we discovered that the F-actin bundler fascin facilitates filopodia-like network formation by inhibiting Arp2/3 complex-mediated branching by 50 percent. Our biomimetic reconstituted system reveals that the combination of the F-actin bundler fascin with the actin elongation factors formin or VASP is sufficient to trigger a transition from a dense branched network of capped F-actin to a FLN. Importantly, the formation of these specific F-actin networks is established solely by the binding kinetics of these actin-binding proteins and does not require complex signaling pathways.

P1874/B113

Reconstitution of Dynamic Actin Cables from Purified Components.

L. W. Pollard, M. V. Garabedian, S. L. Alioto, B. L. Goode; Brandeis University, Waltham, MA.

A central unanswered question in biology is how cells assemble large protein structures that have precise sizes and shapes tailored to their functions and simultaneously undergo dynamic turnover. *Saccharomyces cerevisiae* actin cables provide an ideal system for addressing this question, because

their essential function in cargo transport demands that they simultaneously undergo rapid assembly and turnover while maintaining well-defined lengths. Genetic studies have identified a molecular parts list required for proper cable morphology and function in *vivo*, but a minimal set of components sufficient to assemble a dynamic cable has not yet been established, and it has remained unclear how each component contributes to cable formation. Here, using only eight purified *S. cerevisiae* proteins (actin, profilin, formin, capping protein, tropomyosin, cofilin, coronin, and AIP1), we were able to assemble linear actin structures that undergo steady-state polarized turnover while maintaining lengths similar to cables in *vivo*. Cables were polymerized at one end by formins attached to beads, in a profilin-dependent manner, and disassembled at the other end by cofilin, coronin, and AIP1. Cable assembly also required tropomyosin, which antagonized disassembly-promoting factors. Capping protein restricted actin polymerization to the formin-coated beads and limited cable network density. Remarkably, removal of individual proteins from the in *vitro* system led to cable defects similar to the phenotypes observed in *vivo* for disrupting the corresponding genes. Thus, our reconstitution system closely mirrors cellular requirements for cable formation and demonstrates that a minimal set of nanoscale components can self-organize into a dynamic, microns-long cellular structure.

P1875/B114

Mechanically Regulated Structural States of F-actin.

A. Carl[1], P. Gurel[1], A. J. Noble[2], Y. Takagi[3], J. Sellers[4], C. S. Potter[2], B. Carragher[2], G. Alushin[1]; [1]Rockefeller University, New York, NY, [2]National Resource for Automated Molecular Microscopy, Simons Electron Microscopy Center, New York Structural Biology Center, New York, NY, [3]Laboratory of Molecular Physiology, Cell and Developmental Biology Center, National Heart, Lung, and Blood Institute, NIH, Bathesda, MD, [4]Laboratory of Molecular Physiology, Cell and Developmental Biology Center, National Heart, Lung, and Blood Institute, NIH, Bethesda, MD.

The ability of cells to sense mechanical forces in their microenvironments influences cellular functions including migration, proliferation, and apoptosis. The actin cytoskeleton, a network consisting of actin filaments (F-actin), myosin motor proteins, and over 150 Actin Binding Proteins (ABPs), plays a central role in cellular mechanics. F-actin has been reported to transduce mechanical stimuli into downstream biochemical pathways (“mechanotransduction”) through force-regulated interactions with mechanosensitive ABPs. As multiple actin subunit conformations have been reported to co-exist in filament populations in the absence of force**,** we hypothesized that actin’s inherent structural plasticity facilitates the formation of force-regulated structural states which can be recognized by mechanosensitive ABPs. To test this hypothesis, we developed a novel reconstitution system utilizing surface-immobilized myosin motor proteins to study the conformational response of F-actin to compressive and tensile forces with cryo-electron microscopy (cryo-EM). Utilizing this system for cryo-electron tomography (cryo-ET) studies, we observe that F-actin adopts a super helical spiral conformation in local regions along filaments (which we term “squiggles”) in the presence of both tension and compression. An alysis of the distribution of subunit positions in tomograms suggest that squiggles form due to asymmetric longitudinal promoter spacing between the two strands that compose the filament. We furthermore observe the frequent presence of dislocated subunits in squiggles, which we posit are the initiating sites of lattice defects that propagate along a strand. In addition, to providing the first direct visualization of a force-induced rearrangement of F-actin, our studies identify a potential binding platform for mechanosensitive ABPs.

Intrinsic Constraint of the Phenotypic Plasticity of the Actin Cytoskeleton Reveals Limited Attractor States.

P. W. Gunning[1], N. S. Bryce[1], T. W. Failes[1], J. R. Stehn[1], K. Baker[2], S. Zahler[3], I. Dedova[1], G. M. Arndt[1], B. T. Goult[2], E. C. Hardeman[1], J. G. Lock[1]; [1]University New South Wales, Sydney, AUSTRALIA, [2]University of Kent, Canterbury, UNITED KINGDOM, [3]Ludwig-Maximilians-University, Munich, GERMANY.

Numerous proteins and pathways regulate F-actin organisation. In combinatorial terms, this suggests that an almost unlimited number of regulatory states are conceivable. Consequently, the potential for plasticity in F-actin phenotypes appears virtually unbounded. To estimate the actual degree of F-actin phenotype plasticity quantified by 74 parameters, we used a library of 114,400 structurally diverse compounds to induce unbiased chemical perturbations. Remarkably, we estimated the number of recurrent F-actin phenotypes that emerged to be approximately 25. This predicts that compounds with distinct molecular mechanisms induced equivalent phenotypes, suggesting that these recurring phenotypes reflect a low number of equilibrium or attractor states in actin organisation. Compounds which produce a Latrunculin A-like F-actin phenotype use at least three different pathways. Similarly both a talin activation phenotype and an anti-tropomyosin Tpm3.1 phenotype are produced by compounds using multiple pathways. This was further supported by dynamic analyses comparing phenotype trajectories over time, showing how initially divergent phenotypes ultimately converged into equivalent end-states. We propose that infrequent attractor states in the actin phenotypic landscape reflect a channelling of high perturbative diversity into low phenotypic variety. The existence of such attractor states may have provided a mechanism to suppress chaotic outcomes during the evolution of this complex, functionally integral system.

Bending of Actin Filaments into Rings by Iqgap Family of Proteins.

S. Palani, T. Lim, M. K. Balasubramanian, D. Köster; University of Warwick, Coventry, UNITED KINGDOM.

The acto-myosin cortex in cells plays a central role in providing mechanical stability, enabling vesicle transport, cell migration and cell division. This versality is achieved by interaction with many regulatory and actin binding proteins and the interplay with the plasma membrane to locally control actin filament length, stability and crosslinking to other filaments. Form and function go together as, e.g., filopodia are formed by parallel bundles of actin filaments generated by α-actinin and membrane anchored formins. Here, we report about a new module (Curly) within IQGAP family proteins that binds actin and leads to the bending of individual actin filaments into tight rings when anchored to a lipid membrane in vitro. We identified the Curly module within IQGAP1 (*H. sapiens*), Rng2 (*S. pombe*) and Iqg1 (*S. cerevisiae*). Membrane anchored Curly induces reproducible and efficient formation of F-actin rings with a characteristic curvature (0.5-1 μm^{-1}) and recognizes F-actin orientation. Interestingly, decoration of F-actin with the tropomyosin increases actin ring formation, while Fimbrin abrogates it. Addition of myosin II filaments results in further formation of actin rings by induced f-actin flow and, more importantly, in robust ring contraction. This constitutes, hence, a minimal (four components) contractile ring system. The discovery of Curly provides a new opportunity to address and control F-actin curvature in cells and in vitro and will open new approaches to generate synthetic cells capable of division and controlled shape changes.

A Novel Function of Nuclear Transport Factor Kpna1/importin Alpha5 in Neuronal Cells.

M. Yamada; University of Fukui, Eiheiji-Cho, Yoshida-Gun, Fukui Prefecture, JAPAN.

Schizophrenia, autism spectrum disorder (ASD), and attention deficit/hyperactivity disorder (ADHD) have been reported to be caused by intracellular transport deficits in neuronal cells and their migration disorder. However, the intracellular transport systems have not been studied in this context. Since importins mediate transportation from cytoplasm to nucleus, and from synapse to soma, perturbation of importin-dependent pathway may have significant neuronal consequences. Our behavioral tests using KPNA1 knockout (KO) mice revealed impairment of novel object recognition, tendency of depression, and increased sensitivity to phencyclidine (PCP), a non-competitive antagonist for NMDA glutamate receptor that causes schizophrenia-like symptoms. Coupling intracellular signals to behavioral output likely requires clarification of a novel functional role of KPNA1 in neuronal cells. In this study, DNA microarray data provided insights into the possible gene expression alterations in parts of brain, such as prefrontal cortex (PFC), and nucleus accumbens (NA) of KPNA-KO mice. Principal components analysis (PCA) of KPNA-KO mice with PCP revealed different clusters in scatter plots, suggesting higher sensitivity and/or weakness to PCP. Notably, gene expression of cytoplasmic dynein components and their associated factors was found to be reduced in KPNA-KO mice, which was further, remarkably reduced in presence of PCP. Live-cell imaging using FRAP (fluorescence recovery after photobleaching) and dual fluorescence tracking showed migration of KPNA1 both antero- and retrogradely, along with co-migration of cytoplasmic dynein. Overexpressed KPNA1 accumulated near the centrosome and around the nucleus. Our findings suggested that KPNA1 functions in intracellular transport through microtubules (MTs) and in neuronal cell migration dependent on MT traction. This unexpected and intriguing discovery, related to axonal transport, may provide new insight into neuropsychiatric disorders.

P1879/B119

Role of Coiled-coil Registry Shifts in Activation of Human Bicaudal D2 for Dynein Recruitment Upon Cargo-binding.

C. R. Noell[1], J. Y. Loh[1], E. W. Debler[2], K. M. Loftus[1], H. Cui[1], B. B. Bruss[1], K. Zhang[1], P. Goyal[1], **S. R. Solmaz**[1]; [1]SUNY Binghamton, Binghamton, NY, [2]Thomas Jefferson University, Philadelphia, PA.

Dynein adaptors such as Bicaudal D2 (BicD2) recognize cargo for dynein-dependent transport and cargo-bound adaptors are required to activate dynein for processive transport, but the mechanism of action is unknown. Here, we report the X-ray structure of the cargo-binding domain of human BicD2 and investigate structural dynamics of the coiled-coil (1). Our molecular dynamics simulations support that BicD2 can switch from a homotypic coiled-coil registry, in which both helices of the homo-dimer are aligned, to an asymmetric registry, where a portion of one helix is vertically shifted, as both states are similarly stable and defined by distinct conformations of F743. The F743I variant increases dynein recruitment in the Drosophila homolog whereas the human R747C variant causes spinal muscular atrophy. We report spontaneous registry shifts for both variants, which may be the cause for BicD2-hyperactivation and disease. We propose that a registry shift upon cargo-binding may activate auto-inhibited BicD2 for dynein recruitment (1). Furthermore, we report the x-ray structure of the C-terminal

domain of the *Drosophila* Bicaudal variant of BicD which provides experimental support for a coiled-coil registry shift, which may be the underlying cause of the observed hyperactivation of BicD in the variant (unpublished data). 1. Noell CR, Loh JY, Debler EW, Loftus KM, Cui H, Russ BB, Zhang K, Goyal P, **Solmaz** SR. J Phys Chem Lett, 2019 in press. doi: 10.1021/acs.jpclett.9b01865.

P1880/B120

Coiled-coil Regsitry Shifts in the F684I Mutant of Bicaudal Result in Cargo-independent Dynein Recruitment.

H. Cui, 13850[1], K. Trybus[2], M. Ali[2], P. Goyal[1], J. Loh[1], S. Solmaz[1], X. Aura[1]; [1]Binghamton University, Vestal, NY, [2]Vermont University, Burlington, NY.

Dynein adaptors such as *Drosophila* Bicaudal (*Dm* BicD) recognize cargo and are required to activate dynein for processive transport. In the absence of cargo, auto-inhibited BicD cannot recruit dynein, but the underlying mechanism of cargo activation is elusive. We show with single molecule processivity assays that auto-inhibition is abolished in the full-length Bicaudal mutant F684I, which activates dynein motility in the absence of cargo. To investigate the structural basis for activation, we determined the X-ray structure of the C-terminal cargo-binding domain (CTD) of *Dm* BicD-CTD/F684I. The mutant has a homotypic coiled-coil registry, in which the two helices of the homo-dimer are aligned at equal height, however, an N-terminal ~20 residue region is disordered for one of the two chains, and therefore the coiled-coil registry in that region cannot be assigned. Thus, the F684I mutation results in the formation of multiple conformations and induces flexibility. In contrast, the wild type structure has an asymmetric coiled-coil registry, in which the two chains are vertically shifted by ~ one helical turn in a portion of the coiled-coil. We propose that a coiled-coil registry shift upon cargo binding activates BicD for dynein recruitment. Interestingly, the human homolog of the Bicaudal mutant, BicD2-CTD/F743I, shows diminished binding of the cargo Nup358 compared with the wild type, while binding of the cargo $Rab6^{GTP}$ is unaffected. Therefore, we propose that a coiled-coil registry shift also modulates cargo selection for BicD2-dependent transport pathways in *mammaliae*, which are important for brain development, faithful chromosome segregation and signaling.

P1881/B121

Characterization of Human Disease Mutations of Dynein Adaptor Bicaudal D2 Provides Insights into Possible Causes for Spinal Muscular Atrophy.

C. Noell[1], J. Loh[1], E. Debler[2], K. Loftus[1], H. Cui[1], B. Russ[1], K. Zhang[1], P. Goyal[1], S. Solmaz[1]; [1]Binghamton University, Vestal, NY, [2]Thomas Jefferson University, Philadelphia, PA.

Dynein adaptor proteins such as Bicaudal D2 (BicD2) are an integral part of the dynein transport machinery as they select cargoes for transport along the minus ends of microtubules and link them to dynein motors. In the absence of cargoes BicD2 forms an auto-inhibited state that cannot recruit dynein. The importance of these transport pathways for brain and muscle development is reflected in the fact that human disease mutations cause devastating brain and muscle development diseases, including spinal muscular atrophy. Here, we use an approach that combines structural methods, molecular dynamics (MD) simulations and circular dichroism (CD) spectroscopy to establish how these disease mutations modulate the coiled coil structure of BicD2. We also present new data supporting the idea that cargo-binding induces a coiled coil registry shift in human BicD2 which activates it for dynein recruitment. Our structural analysis indicates that the human disease mutations R747C and E774G

destabilize the coiled coil structure. CD wavelength spectra indicate that these disease mutations result in misfolding. In MD simulations, the R747C disease mutation induces a transient and local coiled-coil registry shift. We thus hypothesized, that combining the disease mutation with a second mutation (F743I), which induces spontaneous coiled-coil registry shifts in MD simulations, could rescue folding and stabilize BicD2 in a registry-shifted conformer. Of note, this mutation results in increased dynein recruitment in the *Drosophila* homolog. This R747C/F743I double mutant was characterized by CD wavelength scans, which indicate that the R747C/F743I double mutation rescues folding of BicD2. The double variant has a higher melting temperature than the BicD2 wild type and the double mutation also shows comparable binding to the cargo $Rab6^{GTP}$ as the wild-type.We conclude that the human disease mutations E774G and R747C destabilize the coiled coil structure of the cargo binding domain of BicD2 and may result in context of the full length protein either in complete or partial loss of function, which may be an underlying cause for spinal muscular atrophy in these mutants. We also conclude that BicD2-CTD R747C/F743I double mutant is thermodynamically more stable than the wild type, and binds cargoes similarly to the WT. This variant may be stabilized in a registry-shifted conformer, Thus, we provide evidence that disease-causing mutations in the BicD2 coiled-coil may alter the equilibrium between registry-shifted conformers, which we propose as a mechanism of pathogenesis that may also apply to other coiled-coils.

P1882/B122

Septin 9 (SEPT9) Promotes the Retrograde Transport of Endolysosomes by Scaffolding Dynein-Dynactin Complexes.

I. Kesisova, B. K. Doyle, E. T. Spiliotis; Drexel University, PHILADELPHIA, PA.

Spatiotemporal coordination of membrane traffic is paramount for cell development and survival. Long-range transport of membrane cargos is driven by the microtubule motors kinesin and dynein. However, how cargos selectively associate with and activate motors is not well understood. Here we find that membrane-associated SEPT9, a member of the septin family of GTPases, regulates dynein-dependent transport of lysosomes by direct association with dynein and dynactin. We examined the abundance of septins on cellular membranes by density gradient fractionation and we found that SEPT9 is enriched in lysosomal fractions. Super-resolution structured illumination microcopy (SIM) showed that SEPT9 localizes on domains of Lamp1-positive endolysosomes. In the axons of cultured hippocampal neurons SEPT9 co-migrates with Lamp1-positive endolysosomes, which move with a retrograde bias toward the cell body, and SEPT9 overexpression in COS-7 fibroblasts results in perinuclear repositioning of lysosomes. Membrane relocation assays showed that ectopic targeting of SEPT9 to mitochondrial membranes is sufficient to induce perinuclear clustering of mitochondria, which is reversed by nocodazole treatment and p50/dynamitin overexpression. Similarly, coupling of SEPT9 to peroxisomes through a rapalog-induced heterodimerization assay resulted in perinuclear clustering of peroxisomes. Biochemical in *vitro* binding assays showed that recombinant SEPT9 interacts directly with native dynein/dynactin isolated from HEK-293 cells. We mapped dynein interaction to the conserved GTPase domain of SEPT9, while the N-terminal domain of SEPT9 interacts with dynactin. Interestingly, recombinant SEPT9 interacts with the N-terminal adaptor-binding region of dynein intermediate chain (DIC) (108-268aa in mouse IC1A), which does not associate with SEPT2/6/7. Strikingly, this interaction is sensitive to the nucleotide state of SEPT9 as SEPT9 association with DIC is diminished in the presence of the non-hydrolyzable GTP analog GTPγS. Collectively, our findings suggest that SEPT9 functions on the membranes of endolysosomes as a scaffold for the recruitment and potential activation of dynein. On-

going work is exploring this hypothesis and testing the role of SEPT9 in lysosome positioning under conditions of cell stress.

Dynactin P150 Promotes Processive Motility of DDB by Minimizing Diffusional Behavior of Dynein.

Q. Feng, W. Hancock; Pennsylvania State University, State College, PA.

Dynactin p150 promotes processive motility of DDB by minimizing diffusional behavior of dynein

Cytoplasmic dynein is the principal minus-end directed transport motor in cells. In *vitro*, cytoplasmic dynein motors are shown to be activated by adaptor proteins like BicD2, by forming a dynein-dynactin-BicD2 complex, DDB. A complete understanding of dynein function and regulation requires characterizing the role of the different components of the DDB complex. The dynactin subunit p150, which contains a flexible charged domain, interacts with microtubules and is proposed to act as diffusive tether that enhances processivity of dynein-dynactin. However, how dynein is activated in DDB complexes and the contribution of p150 to dynein motility in the context of the DDB complex remain unclear. We used single-molecule microscopy to analyze movement of DDB complexes along immobilized microtubules. In contrast to kinesin, DDB complexes display diverse motility behaviors that include pauses, diffusive episodes and processive runs having a range of minus-end velocities. To characterize switching between processive, diffusive and stuck states, we used Interferometric Scattering (iSCAT) microscopy to track DDB at 100 frames/s and developed a regression-based algorithm to classify switching between states. DDB spends 65 % of its time undergoing processive stepping and 4% of its time undergoing 1D diffusion along the microtubule. The role of p150 was tested by characterizing the motility in the presence of a function-blocking p150 antibody. Contradictory to predictions based on p150 acting as a diffusive tether, we found instead that blocking p150 enhanced the fraction of time DDB spends diffusing on the microtubule to 17%, and reduced the processive fractional duration to 55%. Thus, the diffusive behavior of DDB is likely due to dynein switching into an inactive (diffusive) state rather than p150 tethering DDB to the microtubule. The data suggest a model of DDB in which, rather than simply acting as a diffusive tether, interaction of dynactin p150 with the microtubule promotes or stabilizes an active conformation of dynein and therefore promotes processive minus-end motility during bidirectional transport in cells.

P1884/B124

Pac1/LIS1 Promotes an Uninhibited Conformation of Dynein That Coordinates Its Localization and Activity.

M. G. Marzo, J. M. Griswold, S. M. Markus; Colorado State University, Fort Collins, CO.

Cytoplasmic dynein is a minus end-directed microtubule motor that transports myriad cargos in various cell types and contexts. How dynein is regulated to perform all these activities with a high degree of spatial and temporal precision is unclear. Recent studies have revealed that human dynein-1 and dynein-2 can be regulated by a mechanism of autoinhibition, whereby intermolecular contacts limit motor activity. Whether this autoinhibitory mechanism is conserved throughout evolution, whether it can be affected by extrinsic factors, and its precise role in regulating cellular dynein activity remain unknown. Here, we use a combination of negative stain EM, single molecule motility assays, genetic, and cell biological techniques to show that the autoinhibitory conformation is conserved in budding yeast, and it plays an important role in coordinating dynein localization and function in cells. Moreover,

we find that the Lissencephaly-related protein, LIS1 (Pac1 in yeast) plays an important role in regulating this autoinhibitory conformation of dynein. Specifically, our studies demonstrate that rather than inhibiting dynein motility, Pac1/LIS1 promotes dynein activity by stabilizing the uninhibited conformation, which ensures appropriate localization and activity of dynein in cells.

P1885/B125

Lis1 Promotes the Formation of Activated Cytoplasmic Dynein-1 Complexes.

J. P. Gillies[1], Z. Htet[1,2], R. W. Baker[1], A. E. Leschziner[1], M. E. DeSantis[1], S. L. Reck-Peterson[1,3]; [1]University of California San Diego, San Diego, CA, [2]Harvard Medical School, Boston, MA, [3]Howard Hughes Medical Institute, Chevy Chase, MD.

Cytoplasmic dynein-1 is a molecular motor that drives nearly all minus-end-directed microtubule-based transport in human cells, performing functions ranging from retrograde axonal transport to mitotic spindle assembly. Mammalian dynein is not a processive motor on its own. Activated dynein complexes consist of one or two dynein dimers, the dynactin complex, and an “activating adaptor”, with faster velocity seen with two dimers present. Mammalian dynein in the absence of these other components adopts a conformation known as “Phi”. Phi dynein is autoinhibited and cannot interact with microtubules productively. The current model for dynein activation proposes that Phi dynein must first adopt an “Open” conformation and then ultimately a “Parallel” conformation that is observed when it is bound to dynactin and an activating adaptor. Little is known about how dynein switches between the autoinhibited Phi conformation and the Open and Parallel conformations that lead to the assembly of the activated dynein complex. The highly conserved dynein binding protein Lis1 is required for nearly all of dynein’s known functions. Lis1 increases the binding of mammalian dynein to microtubules and increases the velocity of activated dynein complexes containing the activating adaptor BicD2. How Lis1 exerts these effects is unknown. Here, using in vitro reconstitution of recombinant human proteins and single-molecule imaging, we uncovered a novel role for Lis1 in the formation of activated dynein/dynactin complexes containing two dynein dimers. Lis1 is required for increased velocity of complexes activated by proteins representing three different families of activating adaptors: BicD2, Hook3, and Ninl. Once activated dynein complexes have formed, they do not require the presence of Lis1 for sustained increased velocity. In addition, using cryo-electron microscopy we show that human Lis1 binds to dynein at two sites on dynein’s motor domain, similar to yeast dynein. We propose that the ability of Lis1 to bind at these sites may function in multiple stages of assembling the motile dynein/ dynactin/ activating adaptor complex. We also propose a unifying model for how Lis1 function is conserved from yeast to humans.

P1886/B126

Impact of a Disease-Associated DCTN4 (p62) Variant on the Dynactin/Dynein Interactome.

E. P. Mattson, T. A. Schroer; Johns Hopkins University, Baltimore, MD.

A single nucleotide variant in the dynactin component DCTN4 (rs35772018; hereafter DCTN4-018) is associated with enhanced pathology in cystic fibrosis and acute lung injury. We have shown that cells expressing DCTN4-018 exhibit defective cell migration, altered cortical actin dynamics and impaired integrin recycling, phenomena that are important for lung repair and airway health under a wide range of conditions. DCTN4 lies within the dynactin domain that allows dynein to bind to its various cargoes via coiled-coil adaptor proteins. Adaptors make direct contact with DCTN4, so we propose that the DCTN4-

018 variant (Y270C) alters dynactin binding. To identify adaptors and other dynactin-associated proteins that contribute to the DCTN4-018 phenotype we obtained the differential interactome between DCTN4-WT and DCTN4-018 using proximity-dependent biotin ligation (BioID). 018-DCTN4-BioID-3xFLAG was generated from a parent WT DCTN4 construct [provided by S.L. Reck-Peterson, along with LIC1-BioID line], and we made three HEK293 Flp-In cell lines: BioID control, WT-DCTN4-BioID, and 018-DCTN4-BioID. Similar amounts of WT and 018 DCTN4 incorporate into the dynactin complex as judged by pulldowns and biotinylation of other dynactin components, but sucrose gradient sedimentation and quantitation of DCTN4 auto-biotinylation reveal more unincorporated 018-DCTN4-BioID vs. WT. The different sizes of the free DCTN4 pool in two cell lines may yield different biotinylation levels which would complicate dataset analysis, so we also generated a dynein light intermediate chain 1 (LIC1)-BioID cell line expressing DCTN4-018 using CRISPR mutagenesis. These WT and 018 DCTN4 lines contained the same ratio of incorporated vs. free LIC1-BioID and, as expected, DCTN4 biotinylation levels were identical in the two lines. To eliminate background from proteins that might bind streptavidin beads indirectly via interactions with authentic dynactin-binding proteins, we used the DiDBiT method to enrich for biotinylated peptides. Peptides were TMT-tagged for multiplexing and relative quantitation by MS, identifying 765 and 789 proteins from the DCTN4-BioID and LIC1-BioID datasets, respectively. Dynein/dynactin components, as well as known adaptors were enriched over controls. A number of differential interactors relevant to the DCTN4-018 phenotype were also identified. Furthermore, our ability to precisely localize sites of biotinylation on dynactin components in the WT/018 DCTN4 BioID dataset allowed us to obtain novel information on dynactin structure. In summary, we have identified the first differential interactome of a disease-associated dynactin variant. Further evaluation will likely identify novel therapeutic targets for individuals expressing DCTN4-018.

P1887/B127

Dynactin Controls Movement of Different Endocytic and Post-golgi Carriers Via Distinct Protein-protein Interactions.

T. Yeh, S. Ketcham, A. Vemu, J. Bennett, B. Clarkson, T. Schroer; Johns Hopkins University, Baltimore, MD.

Dynactin is a component of the essential microtubule-based motor, cytoplasmic dynein, that allows it to associate with different intracellular cargoes. High resolution cryo-EM has revealed the structural basis by which dynactin binds dynein via cargo-associated “activating adaptor” proteins. However, the molecular contacts that underlie dynactin-adaptor binding have not been defined, and how adaptor binding is regulated remains completely unknown. We showed previously that dynactin’s p25/p27 (DCTN5/DCTN6) components are required for normal motility of transferrin (Tfn)-labeled early and recycling endosomes but not conventional late endosomes. Here, we report that p25/p27 depletion suppresses formation of tubules that recycle proteins (CD98 and CD147) entering the cell via clathrin-independent endocytosis (CIE). p25/p27 depletion, or treatment with the dynein inhibitor dynarrestin, also interferes with segregation of CIE cargoes from Tfn-positive structures. By contrast, motility and tubule formation of post-Golgi cargoes (Lumenal-GFP or GFP-Rab6a’) is enhanced by these treatments, indicating that dynein-based motility can either permit or suppress movement of different endomembranes. We used mutagenesis to investigate how different p25 structural motifs contribute to the motile behavior of these cargoes. P25 contains a cluster of lysine residues in a surface loop (K74, K75, K78) that are predicted to interact electrostastically with adaptors, as well as a conserved C-terminal alpha-helix of unknown function. Using p25 knockdown followed by rescue with various

mutants, we found that Tfn motility and/or recycling was altered by changes in either the surface loop (specifically K78A) or C-terminal helix (deletion). CIE cargo behavior was altered by K78A only. Post-Golgi carrier movement is independent of K78 and the C-terminal helix but requires K74, which we also find is required for dynein-dynactin binding to the canonical activating adaptor BICD2. Taken together, these results suggest that p25 interacts with different cargo adaptors via a series of distinct contacts that mediate cargo selection and dynein-based movement.

P1888/B128

Distinct Populations of Cortical an choring Protein Num1 Mediate Mitochondria Tethering and Dynein-based Spindle Movement.

S. Omer[1], K. Brock[2], W. Lee[1]; [1]Dartmouth College, Hanover, NH, [2]Binghamton University, Binghamton, NY.

Correct positioning of the mitotic spindle is essential for high-fidelity transmission of genetic material to daughter cells and is crucial for a wide range of processes including creation of cellular diversity during development and maintenance of adult tissue homeostasis. From budding yeast to human, spindle positioning involves attachment of the minus-end-directed motor cytoplasmic dynein to the plasma membrane, where it exerts pulling force on astral microtubules emanating from the spindle poles. Prior work has conceptualized that dynein attaches to cortical clusters containing the anchoring molecule NuMA (in human) or Num1 (in yeast), whose clustering activity is required for generation of dynein-based spindle-pulling forces. However, how clustering is regulated for proper dynein activity is unknown. Here we establish a role for Mdm36 in promoting the assembly of Num1 cortical clusters in budding yeast. Overexpression of Mdm36 dramatically enhances Num1 clustering, resulting in two morphologically distinct populations of Num1 patches that perform separate functions: one for mitochondria-tethering, whereas the other for dynein-dependent spindle-pulling function. Surprisingly, molecule counting assays revealed that the clusters mediating dynein-pulling function contain only ~ 6 copies of the Num1 protein, approximately 4 times lower than the levels in wild-type cells. Moreover, disrupting Num1 clustering (using *num1^{3E}* allele) affects mitochondria-tethering but not dynein-dependent spindle-pulling function. Additionally, we found that cluster enhancement does not correlate with an increase in cortical dynein activity, in contrast to the prevailing role of clustering for cortical dynein anchor. Our results indicate that Num1 clusters containing a small protein copy number is sufficient for dynein attachment and generation of spindle pulling forces.

P1889/B129

Linking Structure to Mechanochemistry for the Dynein-like AAA Protein Midasin.

K. J. Mickolajczyk, P. D. B. Olinares, Y. Niu, T. Walz, B. Chait, T. M. Kapoor; the Rockefeller Univeristy, New York, NY.

Midasin is an essential and highly conserved molecular machine that drives ribosome biogenesis by mechanochemically removing multiple assembly factors from the maturing preribosome. This massive (>500 kDa) AAA protein has an N-terminal region that bears resemblance to dynein, with six tandemly expressed AAA subunits, and a C-terminal region that bears resemblance to integrin, with a substrate-binding MIDAS domain. While midasin's general role in budding yeast ribosome biogenesis has been delineated, the molecular mechanism by which it converts chemical energy to mechanical force to reshape the preribosome remains unknown. Here, using a combination of structural and functional

assays with recombinant proteins, we show that despite being dynein-like in structure, midasin employs a unique mechanism for force production and transmission. Using cryo-electron microscopy in the presence and absence of the midasin-specific inhibitor Rbin-1, we show that the AAA ring of midasin is capable of undergoing large conformational changes that generate a transient site at which the distal MIDAS domain can directly bind. With truncated constructs, we show that this intramolecular binding interaction can be recapitulated in trans with nanomolar affinity. Using native mass spectrometry and single-molecule methods, we investigate how the MIDAS-ring interaction is gated by ATP and drug binding at the six available AAA sites. Overall, these data further our understanding of the midasin mechanochemical cycle.

S. L. Morris[1,2], S. Aloe[3,2], A. Onoichenco[3,2], K. Bechberger[4,2], S. König[4,2], G. Morfini[1,2], S. T. Brady[1,2]; [1]University of Illinois at Chicago, Chicago, IL, [2]Marine Biological Laboratory, Woods Hole, MA, [3]Hunter College, New York, NY, [4]Kaiserslautern University of Technology, Kaiserslauten, GERMANY.

Tau is a neuronal microtubule-associated protein which aggregates in Alzheimer's disease and other tauopathies. Tau is often described as a microtubule-stabilizing protein, but multiple lines of evidence suggest that this is not its primary function. Other roles of tau in neurons remain open to question. Studies in isolated squid axoplasm have found that aggregates of tau, or truncated tau monomers that expose the N-terminal, selectively inhibit anterograde fast axonal transport (FAT) through a mechanism dependent on amino acids 2-18. These amino acids comprise a phosphatase activating domain (PAD) which activates PP1 and GSK3β causing release of vesicles from kinesin motor protein. Whilst tau has a dynamic secondary structure it has been shown that unphosphorylated monomers adopt a "paperclip" conformation concealing the N-terminal. Post-translational modifications such as phosphorylation can stabilise more extended structures and expose domains at either the N- or C-terminals. Consequently, phosphorylation at the AT8 epitope (S199, S202, T205) in the central proline rich domain of tau also inhibits anterograde FAT through exposure of the PAD, and phosphorylation of S422 inhibits FAT in both directions by means of a currently unknown mechanism. We therefore hypothesize that tau has a physiological function in control of FAT, regulated by precise site-specific changes in its phosphorylation. Using video enhanced-differential interference microscopy in the squid axoplasm model, we show that individual pseudophosphorylation at each of the AT8 sites affects axonal transport differentially with S199E inhibiting both directions of FAT, S202E having no affect, and T205E inhibiting only anterograde FAT. In further experiments we use an antibody, TNT1, which binds specifically to the tau PAD, to test the dependence of these effects on exposure of the PAD. TNT1 successfully blocked inhibition of anterograde FAT by T205E tau but did not prevent inhibition of FAT by S199E tau, suggesting that T205E exposes the PAD but S199E does not. Combinations of phosphorylation at two sites (S199E+S202E, S202E+T205E, T212E+S214E) also inhibit FAT in both directions and could not be blocked by TNT1. These results strongly suggest that differential phosphorylation of tau can activate distinct downstream signaling pathways to affect both directions of fast axonal transport. Consistent with our hypothesis, we show that the PAD is exposed at specific sites linked to cargo delivery in developing hippocampal neurons in *vitro*.

Using Computational Approaches to Reveal Mechanisms of Molecular Motors.

L. Li; University of Texas at El Paso, El Paso, TX.

Electrostatic interactions play important roles in many biology phenomena. Therefore, a lot of efforts have been made to model the electrostatic interactions in biological systems. However, it is extremely challenging to accurately calculate the electrostatic interactions in large biological systems such as dynein and viral capsid. Dynein, a molecular motor, is important for cargo transportation and force generation in cells. Dysfunction of dynein is associated with many diseases, such as ciliopathies, lissencephaly and other neurodegeneration disorders. A novel multi-scale simulation approach was used to study dynein's motion along microtubules. The results reveal that the electrostatic interactions play significant roles in dynein's motilities and functions along microtubule. Understanding the fundamental mechanisms in molecular motors sheds light on treatment of molecular motor related diseases.

Coiled Coil Registry Shifts Modulate Cargo Selection of the Dynein Adaptor Protein BicD2.

X. Aura, H. Cui, S. Solmaz; State University of New York at Binghamton, Binghamton, NY.

Dynein adaptors such as Bicaudal D2 (BicD2) recognize cargo for dynein-dependent transport. BicD2-dependent transport pathways are important for processes such as signaling, faithful chromosome segregation and brain development. The C-terminal domain (CTD) of human BicD2 recognizes two cargoes: the nuclear pore protein Nup358 (for transport of the nucleus), and $Rab6^{GTP}$(for transport of Golgi-derived vesicles) but the underlying mechanism of how the correct cargo is selected at the correct time is elusive. In the absence of cargo, BicD2 is auto-inhibited and unable to recruit dynein. Autoinhibition is compromised by a F743I mutation in the *Drosophila (Dm)* homolog. We have determined the X-ray structure of the *Dm* BicD-CTD/F684I mutant, which has a conformation with a homotypic coiled coil registry in which the two helices of the homo-dimer are aligned at equal height, whereas the wild type structure has an asymmetric coiled-coil registry in which the two chains are vertically shifted by ~ one helical turn in a portion of the coiled-coil. The F743I mutation also induces a spontaneous coiled coil registry shift in molecular dynamic simulations of Human BicD2-CTD. A registry shift is expected to remodel the surface of the coiled coil of BicD2 which harbors binding sites for cargoes, therefore, we investigated whether a coiled-coil registry shift plays a role in cargo selection of BicD2. Notably, Nup358 binds to a larger binding site compared to $Rab6^{GTP}$ that includes a region that is expected to undergo coiled-coil registry shifts. Interestingly, the human homolog of the Bicaudal mutant, BicD2-CTD/F743I, shows diminished binding of the cargo Nup358 compared with the wild type, while binding of the cargo $Rab6^{GTP}$ is unaffected. There are differences in the electrostatic surface potential of the F743I mutant compared to the wild-type structure in the area where Nup358 binds, which may be responsible for the observed differences in cargo binding. Therefore, we propose that a coiled coil registry shift modulates cargo selection for BicD2-dependent transport pathways in Mammalia.

P1893/B133

Dynein Containing an AAA3 ATP-hydrolyzing Mutation Is Activated by Dynactin Without Lis1 Or the Cargo Adapter HookA.

R. Qiu, J. Zhang, X. Xiang; Department of Biochemistry and Molecular Biology, the Uniformed Services University - F. Edward Hébert School of Medicine, Bethesda, MD.

Dynein cargo adapters and dynactin not only link dynein to cargo but also activate dynein (reviewed by Reck-Peterson et al., 2018 and by Olenick and Holzbaur 2019). This activation requires a switch of the dynein dimer from an autoinhibited "phi" conformation to an open and then parallel conformation allowing dynein to walk on microtubule (Zhang et al., 2017). Recent studies suggest that the dynein regulator LIS1 promotes the shift of dynein from the autoinhibited phi state to an uninhibited state (Elshenawy et al., 2019; Htet et al., 2019; Marzo et al., 2019; Qiu *et al.,* 2019). In *Aspergillus nidulans*, dynein and dynactin relocate from the microtubule plus ends to minus ends near septa upon activation by the early endosome adapter HookA. This requires LIS1, and this requirement is partially bypassed by the phi-opening dynein mutations. Since the function of LIS1 is also partially bypassed by the AAA4 arginine finger mutation implicated in AAA3 ATP hydrolysis, we performed an analysis on AAA3 ATP-binding (Walker a or wA) and ATP-hydrolyzing (Walker B or wB) mutants. We found that AAA3-wA dynein locates at the hyphal-tip together with abnormally accumulated early endosomes and also at septa without early endosomes. Loss of HookA or LIS1 causes the wA dynein to accumulate at the microtubule plus ends, while loss of the Arp1 subunit of the dynactin complex causes the wA dynein to become diffused in the cytoplasm. In contrast, the AAA3-wB dynein is strongly accumulated at septa without early endosomes, and this is independent of LIS1 or HookA. However, upon loss of Arp1 of dynactin, the wB dynein mainly decorates microtubules. These results suggest several interesting points: (1) Although previous in vitro studies showed that AAA3 ATP hydrolysis is crucial for dynein motility unless tension is applied to the linker domain of dynein (Bhabha et al., 2014; DeWitt et al., 2015; Nicholas et al., 2015), blocking AAA3 ATP hydrolysis does not block dynein motility in vivo if the dynactin complex is present, (2) Intriguingly, while dynactin and cargo adapter are both needed for dynein activation in wild-type cells and cells with the phi-opening mutations, blocking AAA3 ATP hydrolysis allows the requirement for cargo adapter to be bypassed, which causes dynein to move prematurely without carrying its cargo in vivo, (3) Presence of ATP in AAA3 may possibly promote phi-opening, causing the need for LIS1 to be bypassed.

P1894/B134

Dynein Adaptors Strategically Couple ER Membrane Penetration and Disassembly of a Viral Cargo.

S. Badieyan, C. C. Spriggs, K. J. Verhey, B. Tsai, M. A. Cianfrocco; University of Michigan, an n Arbor, MI.

During entry, viruses must navigate through the host endomembrane system, penetrates cellular membranes, and undergo capsid disassembly to reach an intracellular destination that supports infection. How these events are coordinated is unclear. Here we reveal an unexpected function of a cellular motor adaptor that coordinates virus membrane penetration and disassembly. Polyomavirus SV40 traffics to the endoplasmic reticulum (ER) and penetrates a virus-induced structure in the ER membrane called focus to reach the cytosol where it disassembles prior to nuclear entry to promote infection. We now demonstrate that the ER focus is constructed proximal to the Golgi-associated BICD2 and BICDR1 dynein motor adaptors; this juxtaposition enables the adaptors to directly bind to and disassemble SV40 upon arrival to the cytosol. Our findings demonstrate that strategic positioning of the

virus membrane penetration site couples two decisive infection events — cytosol arrival and disassembly — and suggest cargo-remodeling as a novel function of dynein adaptors.

Microtubule Dynamics and its Regulation 3

P1895/B136

Clasp Mediates Microtubule Repair by Promoting Tubulin Incorporation into Damaged Lattices.

A. Aher[1], D. Rai[1], L. Schaedel[2], J. Gaillard[2], K. John[2], L. Blanchoin[2,3], M. Thery[3,2], A. Akhmanova[1]; [1]Cell Biology, Department of Biology, Faculty of Science, Utrecht University, Utrecht, NETHERLANDS, [2]Univ. Grenoble-Alpes, CEA, CNRS, INRA, Biosciences & Biotechnology Institute of Grenoble, Laboratoire de Phyiologie Cellulaire & Végétale, CytoMorpho Lab, Grenoble, FRANCE, [3]Univ. Paris Diderot, INSERM, CEA, Hôpital Saint Louis, Institut Universitaire d'Hematologie, UMRS 1160, CytoMorpho Lab, Paris, France, Paris, FRANCE.

Microtubule network in cells plays a key role in processes like cell division, motility and intracellular trafficking. It is subjected to various mechanical stresses induced by acto-myosin contractility, motor based organelle transport and morphological changes during cell motility. Microtubule lattices have always been seen as relatively stable structures that mostly undergo turnover upon depolymerization from the plus ends due to dynamic instability. However recent evidence suggests that microtubules exchange tubulin dimers at the sites of lattice defects, which can either be induced by mechanical stress or occur spontaneously during polymerization. Tubulin incorporation restores microtubule integrity; moreover, "islands" of freshly incorporated, GTP-bound tubulin can slow down microtubule disassembly and promote rescues. Microtubule repair can occur in vitro in the presence of purified tubulin. However, in cells it is likely to be regulated by specific factors, the nature of which is currently unknown. CLASP is a known microtubule-stabilizing factor, which suppresses catastrophes and induces microtubule nucleation and rescue. Since CLASP promotes recovery of tapered growing plus ends with lagging protofilaments into complete ones, it is an interesting potential candidate to promote microtubule repair. Here, we used in vitro reconstitution assays combined with microfluidics and laser microsurgery to show that CLASP2α indeed stimulates microtubule lattice repair. CLASP2α promotes tubulin incorporation into damaged lattice sites thereby restoring the integrity of the tube. Furthermore, it induces the formation of complete tubes from partial protofilament assemblies and restores the stiffness of microtubules softened by hydrodynamic flow. A single CLASP2α domain, TOG2, which suppresses catastrophes when tethered to microtubules, was sufficient to stimulate microtubule repair, indicating that catastrophe suppression and lattice repair are mechanistically similar. Our results suggest that the cellular machinery controlling microtubule nucleation and growth also protects microtubules against physiological insults.

P1896/B137

Severing Enzymes Amplify Microtubule Arrays through Lattice GTP-tubulin Incorporation.

A. Vemu[1], **E. Szczesna**[1], E. A. Zehr[1], J. O. Spector[1], N. Grigorieff[2], A. M. Deaconescu[3], A. Roll-Mecak[1]; [1]National Institute of Neurological Disorders and Stroke, NIH, BETHESDA, MD, [2]Howard Hughes Medical Institute, Brandeis University, Waltham, MA, [3]Brown University, Providence, RI.

Spastin and katanin sever and destabilize microtubules. Their function is important in basic cellular processes ranging from cell division to neurogenesis and phototropism. Paradoxically, despite their destructive activity they increase microtubule mass in cells. We combined single-molecule total internal reflection fluorescence microscopy and electron microscopy to show that the elemental step in microtubule severing is the generation of nanoscale damage throughout the microtubule by active ATP hydrolysis-dependent extraction of tubulin heterodimers. These damage sites are repaired spontaneously by guanosine triphosphate (GTP)–tubulin incorporation, which rejuvenates and stabilizes the microtubule shaft. Consequently, spastin and katanin increase microtubule rescue rates. The incorporation of GTP-tubulin into the microtubule shaft is directly responsible for the increase in rescue rates, as the same increase is not elicited by either enzyme in the presence of non-hydrolyzable ATP analog. These GTP-tubulin “islands” transiently recruit end binding protein 1 (EB1) and rescues occur preferentially at these GTP-tubulin islands. Furthermore, newly severed ends of the microtubule emerge with a high density of GTP-tubulin that protects them against spontaneous depolymerization. The stabilization of the newly severed plus ends and the higher rescue frequency synergize to amplify microtubule number and mass. Thus, severing enzymes regulate microtubule architecture and dynamics by promoting GTP-tubulin incorporation within the microtubule shaft. This microtubule-based amplification mechanism in the absence of a nucleating factor helps explain why the loss of spastin and katanin results in the loss of microtubule mass in systems that are dependent on noncentrosomal microtubule generation.

P1897/B138

Does Dendrite Identity Depend on the Presence of Minus-end-out Microtubules?

P. Thyagarajan, C. Feng, D. Lee, M. Shorey, M. Rolls; Pennsylvania State University, State College, PA.

Microtubules (MTs) are important for the development and maintenance of neurons. MTs are intrinsically polarized polymers with dynamic plus-ends and less dynamic minus-ends. In mammals, axons have uniform plus-end-out MTs while dendrites typically contain a significant proportion of minus-end-out MTs. Previous in-vitro studies suggest that loss of minus-end-out MTs causes dendrites to gain axonal features. The objective of this study is to determine if loss of minus-end-out MTs can affect dendrite identity in-vivo. We have developed a method in Drosophila neurons that eliminates minus-end-out MTs from certain regions of the dendritic arbor, leading to a subset of neurites with flipped polarity resembling axons. Using this method, we studied the effect of flipped polarity of MTs on different neuronal properties. We did not observe a significant difference in morphology between the minus-end-out and flipped neurites when we compared their length and number of branches. In contrast, MT stability and cargo distribution was affected by MT polarity. The average number of MT plus ends per unit length in the flipped neurites was about half the number in minus-end-out neurites, mirroring the increased MT stability of axons compared to dendrites. Neuropeptide-containing synaptic vesicles concentrated at tips of mixed or flipped neurites, but not minus-end-out neurites, suggesting that these axonal vesicles are distributed based on MT polarity. We also found fewer ribosomes

(dendritic marker) in flipped neurites compared to minus-end-out neurites. These data together suggest that the change in polarity can affect MT stability and localization of compartment-specific cargo, but, surprisingly, not overall shape. We further probed identity of flipped neurites by injuring them. After a dendrite is severed from the cell body, MT dynamics is increased in the cut-off piece. While minus-end-out regions of the arbor showed this response, the flipped neurites did not. All these properties together suggest that neurites with flipped MT polarity tend to lose dendritic features and gain axonal features. This study strengthens the view that MT pattern underlies neuronal polarity and particularly highlights the significance of minus-end-out MTs in defining dendrite identity.

P1898/B139

Rac1 Promotes Septin-mediated Guidance of Non-centrosomal Microtubules to Focal Adhesions.

D. G. Merenich, S. Donovan, A. Gill, P. Patel, K. A. Myers; University of the Sciences, Philadelphia, PA.

During angiogenesis, endothelial cells (ECs) utilize signaling molecules and microtubule (MT) associated proteins (MAPs) to control the dynamic and coordinated remodeling of the actin and MT cytoskeleton to become polarized. Rac1, a signaling molecule of the Rho GTPase family, promotes cell protrusion and enhances MT plus-end assembly into protrusions, thereby driving EC polarization. As ECs polarize, actin filaments assemble and become linked to focal adhesion (FA) complexes that mature at the positions where the cell interfaces with the extracellular matrix. Recent investigations have identified two distinct populations of MTs, centrosomal and non-centrosomal. Loss of centrosomal MTs had no effect on EC polarization, while non-centrosomal MTs were found to be required for EC sprouting and directed migration. Despite this discovery, how ECs distinguish different populations of MTs to drive fundamental cell functions remains unclear. Non-centrosomal MT minus-ends are known to associate with MAPs that inhibit MT disassembly, and promote plus-end MT growth. Septins are MAPs that promote actin stress fiber-mediated maturation of FAs and that spatially guide MT plus-end dynamics. Collectively, these data point to a potential mechanism used by ECs to delineate MT functions via association with septins. Here, we tested the hypothesis that Rac1 activates septin-mediated guidance of non-centrosomal MTs to promote MT growth into FAs. Live-cell fluorescence imaging of ECs revealed that MTs that penetrate FAs are predominantly non-centrosomal. Optogenetic activation of Rac1 promoted septin re-localization adjacent to peripheral FAs. Moreover, Rac1 activation prevented septin re-localization even after pharmacologic inhibition of myosin II. NC MTs consistently grew into peripheral septin resulting in growth of MTs into FAs and reduction in FA size. Lastly, activation of the MT depolymerizer MCAK reveals increased interaction with septin and FAs but inactivation of MCAK increased FA size. Taken together, these data suggest localized Rac1 activity drives the peripheral localization of septins that subsequently guides NC MT growth into FAs to promote FA disassembly. Moreover, differential regulation of MCAK activity on NC MTs aids septin targeting and growth into FAs. Future studies will further delve into the contribution of MCAK on FA targeting and to further understand MCAK activation in relation to FA turnover. Morevoer, since myosin II inhibitiom affects septin localization and MT targeting to FAs, septin recruitment of MTs will be analyzed with reference to actin stress fibers.

P1899/B140

A Clip-170-induced +Tip Network Superstructure Has Characteristics in Cells Consistent with a Liquid Condensate.

Y. O. Wu[1,2], G. Fernandes[1], A. T. Bryant[1,2], H. V. Goodson[1,2]; [1]Department of Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN, [2]Integrated Biomedical Sciences Graduate Program, University of Notre Dame, Notre Dame, IN.

Proper regulation of microtubule (MT) dynamics is critical for many cellular processes such as cell division and intracellular transport. Microtubule plus-end tracking proteins (+TIPs) dynamically track growing MT tips and play a key role in this regulation. +TIPs interact with each other in a complex web of intra- and inter- molecular interactions known as the +TIP network. Explanations for the purpose of the +TIP:+TIP interactions include localizing MT regulators to growing MT tip and relieving their autoinhibition. Our group is interested in the possibility that the +TIP network also has a physical function: we suggest that it creates a dynamic assembly that surrounds the fragile MT tip, constraining its structural fluctuations and therefore promoting MT assembly (Gupta, Bioessays. 2014). The observation that many +TIP network proteins are multivalent and contain intrinsically disordered regions suggests that the +TIP network as assembled on MT tips might constitute a liquid condensate (also known as liquid droplet or membraneless organelle). Such a condensate could potentially form a sleeve-like structure at the tip, providing an attractive model for how the +TIP network might physically promote MT polymerization. It is difficult to test this hypothesis directly. However, previous studies have shown that overexpression of the +TIP CLIP-170 induces large structures that do not co-localize with membrane markers but do contain CLIP-170 and other members of the +TIP network. We hypothesize that these overexpression-induced structures ("patches") might reflect the biological properties of the endogenous +TIP network, and so we are investigating whether they have the properties predicted for liquid condensates. Video microscopy experiments show that the GFP-CLIP-170 induced condensates can elastically deform and undergo fission and fusion. Fluorescence Recovery After Photobleaching (FRAP) experiments demonstrate that CLIP-170 dynamically exchanges both within a patch and between a patch and the cytoplasm. These results indicate that the patches have properties consistent with liquid condensates and are not simply protein aggregates. Immunofluescence experiments show that the patches contain a range of +TIP network proteins but exclude molecules found in other liquid condensates. Taken together, these results indicate that the CLIP-170 induced patches in cells are phase-separated liquid condensates consisting of +TIP network proteins, and they suggest that the endogenous +TIP network might also form liquid droplets at MT tips.

P1900/B141

Uncovering Microtubule-driven Mechanisms of Melanoma Invasion.

R. J. Ju, Y. Chhabra, N. K. Haass, S. J. Stehbens; University of Queensland, Brisbane, AUSTRALIA.

Metastatic melanoma is currently incurable and available therapies, although effective, result in resistance and recurrence. The majority of deaths are due to metastatic disease, highlighting the need for ‘migrastatics’, therapeutics which act to inhibit invasion. A recent paradigm shift positions the extracellular matrix as a key player in the metastatic cascade. Cell navigation of 3D matrix requires adaptive changes in cell and nuclear shape to fit matrix physical attributes in a process termed mechanosensing. This process incorporates dynamic remodelling of cell matrix adhesions and the cytoskeleton, to facilitate movement through confined spaces, via proteolytic matrix degradation or cell

squeezing. Microtubules play a pivotal role in both of these processes. Our data show that the microtubule-binding proteins, CLASPs, are highly overexpressed in metastatic melanoma lines where they regulate the resistance of microtubule mechanical compression during melanoma invasion in 3D collagen matrices. Using high-resolution live-cell microscopy coupled to genetic alteration and substrate microfabrication, we have identified that patient-derived Melanoma cells utilise CLASP1 and CLASP2, for differing functions to drive 3D invasion. We report paralog specific depletion of CLASPs results in strikingly different 3D invasion phenotypes. Crucially, paralog specific depletion of CLASPs ablates the ability to inter-convert between adaptive invasion strategies by interfering with microtubule-dependent functions during 3D-invasion. Furthermore, pan-depletion of CLASPs within 1205Lu melanoma cells results in 3D migration stasis and reduced cell viability following conditions of 3D confinement, which we do not observe in 2D. These findings suggest that CLASPs function in melanoma cells to facilitate biomechanically regulated cellular processes of both invasion and survival in confined environments.

P1901/B142

Effect of Cytoplasm Concentration on Cytoskeleton Dynamics.

A. T. Molines[1], J. Lemière[1], A. Serra-Marques[1], G. Goshima[2], F. Chang[1]; [1]UCSF, San Francisco, CA, [2]Nagoya University, Nagoya, JAPAN.

The cytoplasm is a very crowded environment harboring most of the metabolic reactions necessary for cellular function. Its biophysical properties are influenced by cellular metabolism. Indeed, changes in cytoplasm mechanical properties have been linked to cellular differentiation and changes in cytoplasm concentration to cell death. However, the reverse relationship has not been extensively studied. So, here we tried to address the effects of the cytoplasm biophysical properties on various dynamic processes happening inside cells from protein diffusion to cytoskeleton dynamics. Our results demonstrate the sensitivity of cellular dynamics, specifically of the cytoskeleton dynamics, to cytoplasm concentration. In fission yeast, changing cytoplasmic concentration reversibly affects all the dynamic processes we looked at from protein diffusion to complex dynamic processes such as actin and microtubule dynamics. We found that microtubule dynamics is inversely correlated to cytoplasmic concentration. Surprisingly, cytoplasmic concentration not only slowed down the microtubule growth rate but also the shrinkage rate. Moreover, the effect of cytoplasmic concentration on cytoskeleton dynamics did not seem to depend on stress pathway. We extended our observation to other eukaryotes, HeLa cells and moss, and confirmed the effect of cytoplasmic concentration on microtubule dynamics suggesting that we are probing an inherent property of the cytoplasm. Our results highlight how important the biophysical properties of the cytoplasm are to cellular metabolism in eukaryotes. This study reveals the interplay between biology and physics happening in the cytoplasm. Our assay is a first step in understanding how the biophysical properties of the cellular environment affect the biological processes it encloses.

P1902/B143

A Pushing Mechanism for Microtubule Aster Positioning in a Large Cell Type.

J. Meaders, D. R. Burgess; Boston College, Chestnut Hill, MA.

Following fertilization, microtubule (MT) sperm asters accurately position male and female pronuclei allowing for pronuclear fusion, a process essential for dictating the first division plane. Due to the relatively large sizes of zygotes compared to somatic cells, the forces that drive sperm aster migration

have been hypothesized to be due to pulling on the leading astral MTs by retrograde motility of dynein anchored either to the cell cortex or to cytoplasmic vesicles. Conversely, pushing forces from rear facing MTs growing against the cortex are have not been documented due to potential MT buckling and slipping as they grow to greater lengths. Here, we re-investigate the forces required for sperm aster centration in the large sea urchin zygote (~100 um diameter) using live confocal microscopy of astral MTs and MT plus-ends, chemical manipulation of aster sizes, inhibition of dynein, and targeted ablation of the sperm aster. We find that leading, front portions of the aster are shorter and less dense than rear, cortical facing portions of the aster. This aster geometry precludes the current cytoplasmic pulling model, which is dependent on front portions of the aster that are longer and more dense than the rear portions of the aster. Second, we find that aster migration distance and rates are equal to and limited by the length and growth rates of rear portions of the aster, with no influence from front lengths and growth rates. Rear astral MTs are also anchored to the cortex, which would antagonize pulling from dynein along front astral MTs. Ciliobrevin treatment, which was previously reported to inhibit aster migration in this system, causes immediate disruption of sperm aster integrity, complicating interpretations of ciliobrevin as a probe for dynein function. Therefore we inhibit dynein by injecting the CC1 subunit of p150 and follow aster migration. CC1 injection does not abrogate sperm aster migration despite inhibiting normal mitotic spindle formation indicating that dynein is not essential for aster migration in the sea urchin zygote. Finally, using the UV light inducible MT depolymerizing agent, caged-combretastatin, we show that ablation of rear astral MTs halts aster migration, while ablations of front and side astral MTs does not block aster migration. Collectively, our data indicates that a pushing mechanism by rear, cortical facing MTs can drive aster migration in a large cell type.

P1903/B144

Multi-component in *Vitro* Reconstitution Induces Robust Microtubule Treadmilling.

M. Zanic, G. Arpag, E. J. Lawrence; Vanderbilt University, Nashville, TN.

Dynamic instability, in which a microtubule end switches between phases of growth and shrinkage, is the hallmark behavior of microtubules. Microtubule treadmilling, in which the plus end grows while the minus end shrinks, is also observed in cells when minus ends are detached from nucleating centers. While microtubule dynamic instability has been widely studied in *vitro*, the conditions that lead to microtubule treadmilling are not well understood. To elucidate the mechanisms underlying microtubule treadmilling, we first characterized microtubule dynamics in *vitro* with purified tubulin over a range of tubulin concentrations, and analytically calculated a net assembly/disassembly rate at both polymer ends. Our population-level results predicted that microtubules assembled with tubulin alone can treadmill, albeit with minus ends leading, consistent with earlier reports. We then used an in *vitro* assay that allows observation of treadmilling on a single-microtubule level. In conditions predicted for treadmilling, we observed a significant fraction of microtubules that could be classified as treadmilling, with the majority exhibiting minus-end directionality. However, not only was the treadmilling direction different from that observed in cells, the overall flux rates of these microtubules were an order of magnitude smaller than measured cellular rates. We hypothesized that this discrepancy is due to the regulatory effects of Microtubule Associated Proteins (MAPs) in cellular environments. To test this hypothesis, we explored the combined effects of MAPs on microtubule assembly flux rates using computer simulations, constrained by published experimental observations. Our in *silico* experiments predicted that a combination of four MAPs (EB1, XMAP215, CLASP2 and MCAK) could promote plus-end-leading treadmilling with high flux rates. Finally, we tested the predictions of our computational model

using the multi-MAP in *vitro* microtubule assembly assay, and found that with this minimal in *vitro* system, we could indeed reconstitute robust and fast plus-end-leading treadmilling, consistent with observations in cells.

P1904/B145

The Effect of Tubulin Arginylation on Cellular Microtubules.

B. MacTaggart, A. Kashina; University of Pennsylvania, Philadelphia, PA.

Microtubules are involved in a host of cellular processes required for development and health, including cell division, cell morphology, cell motility, and intracellular transport. These functions require morphologically and dynamically different microtubule populations, and this diversity is often conferred by post-translational modifications. Different tubulin modifications are enriched in specific microtubule-based structures and can regulate the dynamics, stability, and protein interactions of the microtubules they decorate. One tubulin modification that has been identified but not well studied is arginylation. Arginylation is the post-translational addition of arginine to glutamate and/or aspartate residues within a protein by arginyl transfer enzyme 1 (ATE1). In mice, *Ate1* deletion causes abnormal cardiac and neurological development, resulting in embryonic lethality starting at E12.5. Many of the observed phenotypes appear to be the result of impaired cytoskeletal function. Accordingly, cellular studies have shown that *Ate1* deletion causes cytoskeletal defects, including reduced cell motility and adhesion. These processes are known to involve microtubules, but the role of tubulin in these defects has not yet been explored. Previously, tubulin arginylation has been identified by mass spectrometry of whole mouse embryos and by in *vitro* arginylation reactions. Here, mass spectrometry of taxol purified microtubules from mouse embryonic fibroblasts (MEFs) has identified arginylation on several residues in both α- and β-tubulin, in regions that have the potential to alter electrostatic interactions and thus to regulate microtubule dynamics and/or stability. MEFs with *Ate1* knockout (*Ate1*$^{-/-}$) show a significant reduction in end binding 1 (EB1) comet velocity compared to wildtype MEFs, suggesting that lack of arginylation results in slower microtubule growth rate. Additionally, *Ate1*$^{-/-}$ MEFs show an increased fraction of depolymerization resistant microtubules compared to wildtype, suggesting that lack of arginylation results in an increased population of stable microtubules. Together these results demonstrate that arginylation plays a role in regulating the dynamics and stability of cellular microtubules.

P1905/B146

Kinetochore Proteins Function Post-mitotically to Influence Dendrite Regeneration and the Neuronal Cytoskeleton.

I. Hertzler; Pennsylvania State University, State College, PA.

The kinetochore is a complex of highly conserved proteins that is responsible for proper chromosome segregation during mitosis. Until recently there has not been reason to study these proteins outside of cell division, much less in post-mitotic neurons. By comparing RNAseq data from control and injured neurons, we found that a set of kinetochore genes was upregulated 6 hours after dendrite injury but not after axotomy in Drosophila ddaC neurons. We subsequently discovered that knocking down some of these proteins post-mitotically with RNAi in *vivo* caused a deficit in dendrite regeneration without impairing axon regeneration. However, normal morphology of these cells was not impaired with these knockdowns. To understand how kinetochore proteins might impact dendrite regeneration, we

examined microtubule dynamics in neurons, as the kinetochore is the link between microtubules and chromatin. In neurons with kinetochore components knocked down, microtubule dynamics in axons was normal but in dendrites was enhanced. This phenotype of more dynamic microtubules was present in dendrites of two neuron types following kinetochore protein knockdown. The enhanced microtubule dynamics was independent of cell stress, as it was not rescued by a JNK inhibitor. We conclude that a set of kinetochore proteins is repurposed in post-mitotic neurons to modulate the microtubule cytoskeleton in dendrites as well as promote dendrite regeneration.

P1906/B147

Regulation of Kinetochore Function by the Ras/pka Pathway in *Saccharomyces Cerevisiae*.

S. B. Shah, C. Bolton, P. Elizalde, H. Alsufyani, J. S. Choy; the Catholic University of America, Brookland, DC.

Faithful chromosome segregation during cell division over generations is required for the health and survival of organisms. This process is mediated by two major events: (1) stable attachments between the microtubules (MTs) nucleated from the spindle pole body (SPB) and sister chromatid kinetochores (KTs) assembled at the centromeres; (2) partitioning of sister chromatids to daughter cells. Dam1C and Ndc80C are the two major KT complexes that physically bind to the incoming MT. The heterodecameric Dam1 complex (Dam1C) is an efficient microtubule stabilizer and forms the outermost part of a kinetochore. Oligomers of Dam1c form rings that embrace the depolymerizing plus ends of MT's during anaphase to ensure chromosomes remain stably bound as they move to the opposite spindle poles. We previously reported for the first time that PKA directly acts on KT function and chromosome segregation by phosphorylating Dam1 at S31, a subunit of the Dam1C. However, the function of Dam1 phosphorylation by PKA remains unclear. It is well established that the Aurora B kinase (Ipl1p in yeast) is a major regulator of MT-KT attachments by phosphorylating multiple KT subunits. Interestingly, we found that phosphomimetic *dam1S31D* rescues the temperature sensitivity (ts) of *ipl1* mutants. Thus, PKA may work together with Ipl1 in modulating MT-KT attachments. Furthermore, cell imaging experiments revealed that phosphorylation of S31 contributes to resolution of aberrant attachments that occur prior to entering metaphase. We are working to determine how phosphorylation of S31 influences KT-MT dissociation and to identify additional KT subunits that are PKA targets. Our new work will help to build a better understanding of how PKA functions in chromosome segregation and provides a model for how extrinsic factors such as nutrients can modulate chromosome segregation.

A Role of DRG2 in Brain Cell and a Mouse Model of the Alzheimer Disease.

D. Kang[1], S. BATSAIKAHN[1], M. Kim[1], H. Park[2], **I. Han**[1]; [1]University of Ulsan, Ulsan, KOREA, REPUBLIC OF, [2]Ulsan, Ulsan, KOREA, REPUBLIC OF.

Our previous study indicated abnormal behaviors of microtubule dynamics and phosphorylation of tau S202 in the developmentally regulated GTP binding protein 2(DRG2) KD HeLa cells. Alzheimer disease (AD) is characterized to be "tauopathies" by the abnormally phosphorylated tau protein. Here, we initiate to find a link between DRG2 and AD. The depletion of DRG2 in BV-2 microglial cell line, which is associated with AD plaques containing β-amyloid (Aβ), leads to decrease Aβ and Fe65(*Apbb1*) expression. The expression of Aβ is down-regulated in the hippocampi of the *DRG2* KO mice. We also show that DRG2 expression was increased in the hippocampi from streptozotocin-induced Alzheimer

animal model. Taken together, our results suggest that DRG2 is associated with deposition of Aβ in AD. (Supported by the Grant NRF-2017R1D1A3B04030339 of Korea)

P1908/B149

Dynamics of Meiotic Spindles in Mouse Oocytes.

C. Kelleher; Harvard University, Cambridge, MA.

In mouse oocytes, meiosis arrests in metaphase II for up to 12 hours, awaiting the arrival of a sperm to trigger anaphase. While the morphology and global properties of the meiotic spindle are maintained during this time, the period of arrest is nevertheless highly dynamic, as individual microtubules continuously polymerize and depolymerize, molecular motors slide microtubules along each other, and microtubule bundles -- locally dense regions -- form and dissolve. Previous work has shown that, for Xenopus laevis spindles reconstituted in vitro, these processes can be described by a coarse-grained continuum model, in which the microtubules that make up the spindle are treated as an (active) liquid crystal. In this poster, we will present the results of our attempts to apply these concepts to the meiotic spindles in living mouse oocytes, and discuss the applicability of continuum theories in this case.

P1909/B150

Computer-based Simulation of the Heterodimer Interface in Microtubules to an alyze the Impact of Phosphorylation of Ser^{165} in Alpha-tubulin.

V. Maddula[1], **S. A. Rotenberg**[2], M. Nagan[3]; [1]Adelphi University, Garden City, NY, [2]Queens College - CUNY, Flushing, NY, [3]SUNY-Stony Brook, Stony Brook, NY.

Previous studies with human breast cells demonstrated that phosphorylation of alpha-tubulin at Ser^{165} by protein kinase C results in marked changes in microtubule dynamics that included a prolonged elongation phase and increased rate of elongation (*Cytoskeleton* 71:257-272, 2014). As verified with site-direct mutants of alpha-tubulin (S165D, S165N), microtubule growth correlated with dramatically increased cell motility and other hallmarks of the epithelial-mesenchymal transition. Ser^{165} in alpha-tubulin occurs near the heterodimer interface and is within 10Å of the exchangeable GTP on beta-tubulin and Glu^{254}, the catalytic residue (on alpha-tubulin) that hydrolyzes the exchangeable GTP. It is generally believed that the growing end of a microtubule is capped by several units of GTP-bound beta-tubulin. Our hypothesis is that phosphorylation at Ser^{165} (as given by the S165D mutant) perturbs the alignment of Glu^{254} with respect to the exchangeable GTP thereby preventing its hydrolysis and consequently giving rise to persistent polymer growth. In the present study, molecular simulations were performed with cryoEM structures of microtubules (PDB 3J6E) into which a mutation had been introduced at Ser^{165}. The objective was to identify whether the S165D mutant alters the intramolecular distance between the catalytic residue Glu^{254} and bound GTP. The results revealed that S165D produced only a slight decrease in the intermolecular distance. However, the impact by S165D was stronger with respect to the distance between Ser^{165} and the loop-helix defined by Gln^{256}/Ala^{247}; this sub-structure was pulled into the heterodimer cleft and formed a H-bond at the GTP binding site with Gln^{451} in beta-tubulin that suggested weaker GTP binding. These results indicated that phosphorylation at Ser^{165} causes structural alterations at the heterodimer interface. However, further study is required to establish whether these perturbations affect GTP binding and/or hydrolysis.

P1910/B151

Actomoysin Dynamics Modulate Microtubules Deformation and Growth during T Cell Activation.

I. Rey Suarez[1], S. Kerr[2], K. Do[3], H. Shroff[4], A. Upadhyaya[3]; [1]University of Maryland - Biophysics Program, College Park, MD, [2]University of Colorado - Physics Department, Boulder, CO, [3]University of Maryland - Physics Department, College Park, MD, [4]National Institutes of Health/NIBIB, Bethesda, MD.

The activation of T lymphocytes is an essential step in the adaptive immune response. T cell activation involves the binding of T cell receptors (TCR) with antigen on the surface of antigen presenting cells (APC), which leads to the spreading of the T cell onto the APC and formation of the immunological synapse (IS). Proper formation and maturation of the IS requires the polarization of the T cell and coordination between different cytoskeletal systems. T cell spreading is characterized by remodeling of the actomyosin cytoskeleton and reorientation of the microtubule-organizing center (MTOC) towards the activating surface. Despite extensive research, the interactions between the different cytoskeletal components during T cell activation are not well understood. In this work, we imaged multiple distinct fluorescently labeled cytoskeletal structures in Jurkat T cells using instant structured illumination microscopy (iSIM) and TIRF microscopy. We found that microtubules (MT) filaments were more dynamic at the peripheral actomyosin rich region of the cell-substrate contact compared to the central actin-depleted zone. Microtubules in actin rich zones also displayed more deformed shapes as indicated by their local curvature distributions. We used small molecule inhibitors to explore the role of different cytoskeletal modulators and molecular motors that regulate the forces responsible for the deformations. We found that formin inhibition reduced MT growth rates and reduced the deformation of MT filaments. Inhibition of ROCK kinase using Y27632 resulted in a further reduction of MT deformation, suggesting that actomyosin contractility plays an important role in defining MT shapes. We found that MT tip growth speed is slower when passing through actin rich regions as compared to actin poor regions. These differences disappeared in cells treated with Arp2/3 inhibitor CK666, suggesting that branched actin networks impose a physical barrier to growing microtubules. Our results indicate an important mechanical coupling between the actomyosin and microtubule systems where different actin structures influence microtubule dynamics in distinct ways.

P1911/B152

SSNA1 Stabilizes Microtubule Dynamics in *Vitro*.

E. J. Lawrence, M. Zanic; Vanderbilt University, Nashville, TN.

Sjogren's Syndrome Nuclear Autoantigen 1 (SSNA1) is a microtubule-associated protein that has been implicated in cilia assembly, cell division and axonal branching; however, the effect of SSNA1 on microtubule dynamics is not known. We employed in *vitro* reconstitution techniques with purified protein components combined with TIRF microscopy to investigate the effects of human SSNA1 on microtubule dynamics. Using Alexa 488-labeled SSNA1, we show that SSNA1 binds and bundles GMPCPP-stabilized microtubules. Interestingly, when incubated with dynamic microtubules, SSNA1 preferentially localizes to newly-formed microtubule lattices indicating that SSNA1 co-polymerizes with soluble tubulin. Furthermore, we find that SSNA1 suppresses microtubule growth and catastrophe (the transition from growth to shrinkage), and promotes rescue (the transition from shrinkage to growth). To further probe the anti-catastrophe activity of SSNA1, we polymerized dynamic microtubules with or without SSNA1 and then depleted the available soluble tubulin concentration by either dilution or by stathmin-mediated tubulin sequestration; in both cases, SSNA1 was able to robustly protect

microtubules against catastrophe. Our results indicate that SSNA1 is a potent microtubule stabilizer that prevents microtubules from undergoing catastrophe. The microtubule stabilizing activity likely underlies the role of SSNA1 in cilia function, cell division and neuronal development.

P1912/B153

Mammalian CLASP1 and CLASP2 Act in a Functional Hierarchy to Support Microtubule Nucleation, anchoring, and Plus-end Dynamics.

A. Sanders, R. Thoppil, K. Chang, S. Narasimhan, I. Kaverina; Vanderbilt University, Nashville, TN.

Microtubule (MT) plus-end tracking proteins CLASPs regulate MT dynamics and nucleation. Mammalian paralogs CLASP1 and CLASP2 are highly similar, however, unique functions of each protein or mutual regulatory interactions have not been studied extensively. Here, we show that CLASP1 and CLASP2 have different functions relating to nucleation and anchoring of non-centrosomal MTs, as well as MT plus end dynamics. Our data indicate that in cells CLASP1 promotes robust localization of CLASP2 to MT plus ends via a direct protein-protein interaction. Accordingly, CLASP2 acts downstream of CLASP1 in those functions that depend on MT plus end positioning, in particular the support of MT nucleation and MT plus end dynamics. Interestingly, we found that while these two functions are related, CLASP1 is more efficient in supporting MT nucleation, while CLASP2 is critical in regulating MT growth rates. At the same time, CLASP2 has a unique cellular location at the Golgi membrane, where CLASP1 is not found. We find that Golgi-associated CLASP2 pool is necessary for anchoring of nascent Golgi-derived MTs (GDMTs) to the Golgi membrane. In summary, our data dissect functional hierarchy between mammalian CLASP paralogs and determines specific functions of these two proteins in MT dynamics and organization.

Tubulins and Associated Proteins 2

Expression Levels of α- and β-tubulin Reveals Collusion between Subunits.

L. Wethekam, J. Moore; University of Colorado an schutz Medical Campus, Aurora, CO.

The microtubule cytoskeleton undergoes major reorganizations during mitosis, process extension and ciliogenesis. To do this, cells must rapidly increase the supply of tubulin heterodimers, and, accordingly, the levels of α- and β-tubulin protein monomers. Therefore, a fundamental question is how cells control levels of α- and β-tubulin so that the stoichiometry heterodimer is maintained. Previous work has provided insights into how α- and β-tubulin are individually regulated. However, these studies have not addressed whether there is a mechanism that coordinates regulation between α- and β-tubulin subunits to maintain stoichiometry for heterodimer assembly. We address this question using the budding yeast model system, generating tools to control the copy number and expression of α- or β-tubulin genes. We monitor total α- and β-tubulin levels in the cell as well as the amount of heterodimer and observe impacts on microtubule dynamics and function during mitosis. Our findings demonstrate when β-tubulin protein levels are decreased by knocking out one gene copy, α-tubulin protein levels decrease in response. However, β-tubulin protein levels do not respond when α-tubulin is decreased by knocking out one gene copy. Additionally, we provide evidence for toxicity associated with excess β-tubulin in cells. Our results support a model in which the cell only maintains a level of α-tubulin protein that is needed for the appropriate level of β-tubulin and necessary to prevent detrimental effects associated with excess β-tubulin.

Parthenolide Destabilizes Microtubules by Forming Cysteine Adducts on Tubulin.

T. Hotta, T. L. Blasius, K. Verhey, R. Ohi; University of Michigan, an n Arbor, MI.

Tubulin is subjected to various post-translational modifications such as acetylation, methylation, phosphorylation, polyglutamylation, and detyrosination. Tubulin detyrosination has been studied for nearly 4 decades, but the carboxypeptidase that targets tubulin (TCP) was only recently identified as vasohibin (VASH) and its associated small vasohibin binding protein (SVBP). Prior to the identification of VASH-SVBP, tubulin detyrosination was studied using broad spectrum carboxypeptidases (*eg.*, carboxypeptidase A) and a sesquiterpene lactone, parthnolide (PTL), that was reported to block tubulin detyrosination in cells. However, PTL exhibits polypharmacology and has been commonly used as an anti-cancer and anti-inflammatory drug through modulation of cytochrome c and nuclear factor-κB activities. We found that PTL treatment induced cell rounding and destabilized microtubules during both mitosis and interphase. However, PTL does not inhibit the tubulin detyrosination activity of VASH1-SVBP in *vitro*. Rather, we demonstrate that PTL affects the biochemical properties of tubulin through a non-specific cysteine-targeting mechanism. First, PTL induces mobility shifts of tubulin during SDS-PAGE. Second, PTL induces tubulin aggregation. Third, mass spectrometry analysis revealed that PTL formed covalent adducts with cysteine residues within both alpha- and beta- tubulin. Importantly, we demonstrate that PTL also forms adducts on tubulin when added to cells in culture. We suggest that PTL induces microtubule destabilization by reducing the polymerization-competent pool of tubulin in cells through adduct formation. Finally, we demonstrate that the recently introduced TCP inhibitor, epoY, is a potent inhibitor of VASH both in *vitro* and in *vivo*. Altogether, our results suggest that PTL targets tubulin through a non-specific mechanism, and we strongly encourage the use of epoY instead of PTL when studying tubulin detyrosination.

P1915/B156

Studying of a Connection between α,β-tubulin Conformations and Microtubule Dynamics.

K. Dudnyk, L. Rice; UT Southwestern Medical Center, Dallas, TX.

Microtubules (MTs) are αβ-tubulin polymers that are essential for chromosome segregation and intracellular organization. MTs are always in a state of dynamic instability, which means MTs constantly switch between growing and shrinking phases. The dynamic properties of MTs essential for their function. However, the molecular mechanisms underlying microtubule dynamics are incompletely understood. αβ-tubulin cycles through different conformations during MT growth and shrinking. Individual αβ-tubulins display a 'curved' conformation, but adopt different 'straight' conformations after binding to MT end. We are studying the relationship between the αβ-tubulin conformation cycle and microtubule dynamics using site-directed mutagenesis of αβ-tubulin. The core helices of α- and β-tubulin are positioned differently during the conformational cycle. These helices may operate as a structural relay to transmit information from one end of the fold to the other. In a prior study, we showed that a T238A mutation at the bottom of the core helix of β-tubulin reduced catastrophe frequency and MT shrinking rate, with little effect on growth rate. We were not able to determine if a similar mutation in α-tubulin yielded similar effects, because the muted site is not conserved between α and β tubulin. As a next step, we want to study mutation at positions that equivalently buried in both α and β tubulin. We a targeting a cluster of residues that are positioned around the core helix and that are

conserved between α - and β - tubulin. We will present an update on our progress. Ultimately, these studies are likely to provide new insights into the role of the ab-tubulin conformation cycle and whether both α- and β- tubulin contribute comparably.

P1916/B157

Binding Affinity of Tau Repeat Regions with Neuronal Specific β-tubulin Isotypes.

A. Kunwar; Indian Institute of Technology Bombay, Mumbai, INDIA.

Tau is a microtubule-associated protein which is abundantly expressed in neurons. Tau plays an important role in the assembly and stabilization of microtubules which are formed by polymerization of α and β tubulin subunits. The C-terminal domain of Tau consists of four repeat regions R1, R2, R3 and R4 which bind to microtubules to stabilize them. It is known that the detachment of tau from the microtubules leads to the formation of cytoplasmic insoluble aggregates which forms the basis of various neurodegenerative diseases. Microtubules are made up of αβ tubulin subunits. Seven α-tubulin and nine β-tubulin isotypes have been reported to be present in humans till date. These tubulin isotypes show residue composition variations mainly at C-terminal region and bind to motor proteins and anti-mitotic drugs differently. These tubulin isotypes show tissue specific expression as their relative proportion varies significantly in different type of cells. These isotypes show differential microtubule dynamics as well as differential binding affinity towards anti-mitotic drugs and motor proteins. However, the relative binding affinities of tau repeat regions with neuronal-specific tubulin isotypes are not completely known due to lack of their structural information. Using a combination of molecular modelling, molecular docking and molecular dynamics simulations we have explored the relative binding affinity of tau repeat regions with neuronal-specific tubulin isotypes.

Regulation of Tpx2 by Importins-ab.

M. Safari, M. King, S. Petry; Princeton University, Princeton, NJ.

The microtubule based mitotic spindle is responsible for equally partitioning the genome with each cell division. This process is enabled by equal rapid and accurate spindle assembly, which begins with MT nucleation. Targeting Protein for XKlp2 (TPX2) promotes MT nucleation around chromosomes and promotes branching MT nucleation, where MTs form on the lattice of a pre-existing MTs. TPX2 is regulated by importins-α/β, but the molecular nature of this regulation remains unclear. Here we demonstrate that TPX2 interacts with importins-α/β with nanomolar affinity as a 1:1:1 mono-dispersed trimer. Furthermore, importin-α mediates this high affinity interaction and does so via one of two nuclear localization sequences (NLS) - one of which (at aa123-126) was previously not annotated. Interestingly, both importin-α and importin-β associate with TPX2 via dispersed, weak, Van der Waals interactions. These interactions appear to be the molecular driving forces of importin-mediated inhibition of TPX2 phase separation. Lastly inhibition of phase separation is correlated with loss TPX2-mediated branching microtubule nucleation. Collectively our study elucidates the molecular architecture of a complex essential for cell division, provides insight into molecular forces of phase separation, and supports an underappreciated mechanism of regulation involving weak interactions.

P1918/B159

Interactions between Ca^{2+}& Microtubule-actin Crosslinking Factor 1 (MACF1) in Cytoskeletal Remodeling & Cell Adhesion Dynamics.

T. Lin, T. Lin, P. TSAI, C. HSU, D. LI, F. CHEN, P. HSU, F. TSAI; National Taiwan University, Taipei, TAIWAN.

Microtubule-actin crosslinking factor 1 (MACF1) is a cytoskeletal crosslinking protein that interacts with F-actin and microtubules. Although there are two putative Ca^{2+}-binding EF hands at its C-terminus, whether and how Ca^{2+} interacts with MACF1 remains elusive. We thus explored how intracellular and extracellular Ca^{2+} regulated cytoskeletal remodeling and cell adhesion respectively. In the intracellular aspect, we studied how Ca^{2+} regulated MACF1-microtubule interaction using GFP-tagged & N-terminus truncated MACF1 proteins with various mutations or deletions on their EF hands. These proteins revealed distinct affinities to microtubules and also to each other in different Ca^{2+} concentrations. We are currently using fluorescent live-cell imaging to investigate their underlying molecular mechanisms. In the extracellular part, our scratch wound-healing assays demonstrated that MACF1 knockdown in cancer cells increased cell-cell coordination in addition to their speed reduction. Together with literature reports that MACF1 knockdown reduced focal adhesion dynamics while increasing levels of adherens junctions & tight junctions-related proteins, we hypothesized that MACF1 induced epithelial-mesenchymal transition (EMT) via directly switching the balance from cell-cell adhesion to cell-matrix adhesion. To verify this hypothesis, we are currently using EGTA to remove extracellular Ca^{2+} and induce E-cadherin internalization to examine how MACF1 alters the dynamics of cell-cell adhesion. Finally, because of the huge size of MACF1 (~600KD), it is not feasible to over-express MACF1. Thus we will use CRISPR to label the endogenous MACF1 molecule with fluorescent proteins, so its dynamic regulation on cytoskeletons and adhesion molecules could be delineated in temporal and spatial manners. With these approaches we will elucidate how MACF1 regulate cytoskeletons and cell adhesion, with the hope to develop novel therapeutic strategies against EMT- and/or adhesion-related diseases in the near future.

P1919/B160

Coordination of the Ndc80 and Ska Complexes at the Human Kinetochore-microtubule Interface.

R. Wimbish[1], K. F. DeLuca[1], J. Himes[1], J. Mick[1], I. Sanchez[2], J. Arulanandam[2], J. G. DeLuca[1]; [1]Colorado State University, Fort Collins, CO, [2]Wellcome Trust Centre for Cell Biology, University of Edinburgh, Edinburgh, UNITED KINGDOM.

Successful segregation of chromosomes during mitosis requires the formation of stable, force-transducing attachments between kinetochores and spindle microtubules. Equally importantly, cells must regulate the strength of kinetochore-microtubule interactions in order to correct erroneous attachments that would lead to chromosome mis-segregation. The kinetochore-associated NDC80 complex is the hub of the kinetochore's microtubule binding activity, and its Hec1/Ndc80 subunit harbors the key microtubule binding site in its globular calponin-homology domain. Hec1/Ndc80 is also a major contributor to attachment strength regulation: its N-terminal "tail" domain is a target for Aurora kinase phosphorylation to promote "release" of incorrect attachments, and dephosphorylation by mitotic phosphatases to strengthen attachments. In addition to the NDC80 complex, the spindle and kinetochore-associated (Ska) complex, comprised of Ska1, Ska2, and Ska3, is a critical factor in stabilizing attachments. How the Ska complex is recruited to kinetochores, and what domain(s) of the NDC80 complex are required for these factors to stabilize kinetochore-microtubule attachments in cells, remain open questions. Here, we investigate how Ska is recruited to kinetochores and which domains of the

NDC80 complex are required for Ska to enhance NDC80-microtubule binding. Using a combination of in *vitro* and in-cell techniques, we find that the Ndc80/Hec1 tail domain is dispensable for kinetochore recruitment of the Ska complex, as well as for Ska-mediated enhancement of NDC80-microtubule binding. In contrast, we find that the Hec1/Ndc80 coiled-coil/loop domain is required for these functions, and all components of the Ska complex localize along the NDC80 complex central coiled-coil domain in cells. Furthermore, we find that the phospho-state of the Hec1/Ndc80 tail has no effect on Ska recruitment to kinetochores, and that kinetochore-microtubule attachments are robustly formed independently of the Ska complex in cells that are blocked of Hec1/Ndc80 tail phosphorylation. However, we demonstrate that the Hec1/Ndc80 tail is not explicitly required for kinetochore-microtubule attachments, but is required for proper spindle maintenance and force generation at the kinetochore, offering a more unified view of Hec1/Ndc80 tail function across organisms.

P1920/B161

Distribution of Posttranslational Modifications Dy/dc2 of A-tubulin C-terminal Tail during Mitosis.

M. P. Gebbie, K. Hill, R. Ohi; University of Michigan, an n Arbor, MI.

Microtubules (MTs) are a major cytoskeletal polymer critical for a broad range of cellular processes including cell division, cell migration, and intracellular trafficking in eukaryotic cells. MTs are polymerized from the protein tubulin, a heterodimer of the proteins α-and β-tubulin. However, heterogenous MT populations can be generated inside cells by incorporation of various isotypes, and post-translational modifications (PTMs). How MTs can achieve functional diversity is not fully understood, but one hypothesis is that the ability to carry out diverse functions is enhanced by PTMs. We are specifically focused on a modification of the C-terminal tail of α-tubulin (α-CTT), where the C-terminal tyrosine (Y) is cleaved by VASH1-SVBP leaving the α-CTT detyrosinated (dY). dY-MTs can be further process to dC2 by an unknown carboxy peptidase, and this proteolysis event is thought to be irreversible. This modification is reversed by Tubulin Tyrosine Ligase (TTL) adding tyrosine to the CTT. Deregulation of dY-Y cycle has been shown to impact tumorigenesis and neuro-development. To study the function of TTL, we deleted *TTL* in HeLa cells by genome editing. By immunoblot analysis, clonal isolate 13 (dTTL13) lacks TTL detected and shows enrichment of dY-MTs during all cell cycle phases. Sequencing of the targeted exon 2 identified InDels at three loci introduced by CRISPR/Cas9 gene editing. Because dY-MTs are believed to be more stable than Y-MTs, we examined mitotic progression, a process that is impeded by overly stable MTs, in dTTL13 cells. To examine mitotic progression, we determined the percent mitotic errors, defined as mis/unattached chromosomes during metaphase, and lagging chromosomes in anaphase, for both WT and dTTL13 HeLa cells. dTTL13 shows increased micronuclei relative to WT HeLa, as a result of mitotic errors that coincide with increased dY and dC2-MTs. To further examine the correlation between increased dY-MTs, hyperstable MTs, and chromosome segregation, we challenged dTTL13 cells with sub-lethal doses of taxol, a MT-stabilizing drug. We observed that treatment of dTTL13 cells with taxol increased mitotic errors of dTTL13, suggesting that dY-MTs impair chromosome segregation by elevating MT stability. Current efforts are directed towards defining how dY-MTs prevent accurate chromosome segregation.

P1921/B162

A Structural and Mechanistic Model for the Regulation of LRRK2'S Interaction with Microtubules.

J. Salogiannis; University of California San Diego, San Diego, CA.

Parkinson's Disease (PD) is the second most prevalent neurodegenerative disease, affecting ~10 million people worldwide. One of the most commonly mutated genes in PD is **L**eucine **R**ich **R**epeat **K**inase **2** (*LRRK2*). Autosomal dominant mutations in *LRRK2* cause familial PD, while *LRRK2* mutations are also associated with sporadic PD. LRRK2 is a large protein with multiple domains, including a kinase and GTPase domain. A unifying theme for *LRRK2* and many other PD genes is that they function in intracellular trafficking. For example, LRRK2 co-localizes with microtubules, an association that is enhanced by the majority of familial PD mutations and has been shown to disrupt trafficking in model systems. We set out to determine the structure of LRRK2, how LRRK2 interacts with microtubules, and why interactions with microtubules could be detrimental. Using pure components in an in vitro reconstituted system we show that LRRK2 directly binds microtubules. Furthermore, low nanomolar concentrations of LRRK2 inhibit the motility of the microtubule-based motor kinesin-1. Using cryo-electron microscopy, we solved a 3.5Å structure of the catalytic half of LRRK2, which contains its kinase and GTPase domains. Using cryo-electron tomography we solved an 18Å structure of the microtubule-associated filaments formed by LRRK2 in cells. Based on these structures, we built an atomic model of microtubule-associated LRRK2. This model led us to hypothesize that the conformational state of LRRK2's kinase domain is critical for filament formation on microtubules. In support of this model, we find that kinase inhibitors favoring a closed-kinase conformation negatively impact kinesin motility, while kinase inhibitors favoring an open-kinase confirmation relieve the inhibition of kinesin motility caused by LRRK2. In cells, we observe similar trends; with kinase inhibitors that favor an open conformation reducing LRRK2 microtubule-associated filament formation and those favoring a closed conformation enhancing LRRK2 filaments formation. We also find that LRRK2's kinase activity towards the GTPase Rab10 is stimulated by microtubules in vitro. Together, our work leads us to propose that PD-linked LRRK2 uses microtubules as an intracellular scaffold to act as a roadblock for molecular motors and phosphorylate Rab proteins.

P1922/B163

Structural and Functional an alysis of EB1 as a Novel RNA Binding Protein.

.Vaishali, L. Dimitrova-Paternoga, J. Hennig, A. Ephrussi; EMBL, Heidelberg, GERMANY.

RNA binding proteins (RBPs) play crucial roles in regulating almost all aspects of the RNA life cycle in a cell. Many RBPs have been identified over the years that have a modular organization and comprise a set of canonical RNA binding domains. Recently, high throughput studies have led to the identification of a large number of proteins with putative RNA binding activity in *Drosophila* embryos, despite lacking a canonical RNA binding motif (Sysoev et al., 2016; Wessels et al., 2016). Using a structural-functional approach, we are studying the RNA binding activity of some of these newly discovered RBPs, with the aim of identifying their mechanism of RNA binding and its physiological significance in the cell. Initially, we selected a number of factors known to be involved in cytoskeletal regulation or cell cycle, or to have a specific subcellular localization. One of the candidates we found to interact with RNA in *vitro* is EB1, a master regulator of microtubule plus-end dynamics. In *vitro* assays such as EMSA and NMR titrations performed with EB1 and RNA oligoA and oligoU showed a positive interaction between the protein and the RNAs, and allowed us to map the RNA-protein interaction surface to the microtubule-binding

surface and linker region of EB1. Moreover, the presence of RNA inhibits EB1 binding to polymerized microtubules in a co-sedimentation assay. RIP-Seq with GFP labelled EB1 from *Drosophila* oocytes showed an enrichment for transcripts involved in cell communication, metabolism, cell cycle, localization and cytoskeletal organization. Further validation of candidate RNAs using single molecule FISH is ongoing.

P1923/B164

Reconstitution and Function of Tubulin Methylation by SETD2.

S. Kearns, M. Cianfrocco, K. Verhey; University of Michigan, an n Arbor, MI.

Reconstitution and Function of Tubulin Methylation by SETD2 Sarah Kearns[1,2,*], Michael Cianfrocco[2,3], and Kristen Verhey[4] [1.] Chemical Biology Program, University of Michigan, an n Arbor U.S.A. [2.] Life Sciences Institute, University of Michigan, an n Arbor U.S.A. [3.] Department of Biological Chemistry, University of Michigan, an n Arbor U.S.A. [4.] Department of Cellular and Developmental Biology, University of Michigan, an n Arbor U.S.A. * Corresponding author: skearns@umich.edu Microtubules form one of the major components of the eukaryotic cytoskeleton. Assembled from dimers of alpha and beta tubulin, microtubules are involved in a wide variety of cellular functions that range from transporting cargo, forming the mitotic spindle, and creating primary cilia and flagella. How microtubules achieve this functional diversity is partially driven by a “Tubulin Code” of tubulin isotypes and post-translational modifications (PTMs). So far, PTMs including, but not limited to, detyrosination, polyglutamylation, and acetylation are found enriched on specialized microtubule structures and their enzymatic writers and erasers have been identified. Recently, methylation has joined the ranks as a tubulin modification. This mark occurs on spindle and midbody microtubules, and is written by canonically histone methyltransferase SET Domain-containing Protein 2 (SETD2). The role of SETD2 in a histone methylating context has been well studied and linked to cancer phenotypes, but this new finding suggests that tubulin methylation, or lack thereof, drives cancer independently. To investigate SETD2’s tubulin methylation activity and cellular output, we are combining biochemical, kinetic, single-molecule, and structural studies. An active truncated construct of SETD2, which contains the catalytic SET domain to the C-terminal SRI domain, methylates both histone and tubulin. A cancer-driving mutation in the SET domain ablates all SETD2 activity regardless of substrate, but a mutation found in the SRI domain reduces tubulin methylation suggesting a domain-dependent substrate activity. Performing mass spectrometry on both purified recombinant single-isotype tubulin and SETD2-modified recombinant tubulin has identified sites of methylation, indicating that we have reconstituted in *vitro* methylation of tubulin. Additionally, our work suggests that SETD2 methylation may preferentially occur on tubulin dimers instead of polymerized microtubules. This provides a target for structural studies using cryo-electron microscopy. Subsequent structure determination will elucidate how the histone methyltransferase SETD2 is able to recognize and modify tubulin in an SRI-domain dependent way, and how methylation impacts the cytoskeletal and mitotic spindle structure.

Assembly and Disassembly of Primary Cilia

SCF^{Fbxw5} Facilitates Ciliogenesis by Ubiquitylation of Kif2c/MCAK.

J. Schweiggert[1], G. Habeck[2], F. Mikus[1], A. Razov[1], K. Meese[1], S. Hess[3], S. Hata[1], K. Knobeloch[3], F. Melchior[1]; [1]University of Heidelberg, Heidelberg, GERMANY, [2]University of Helsinki, Helsinki, FINLAND, [3]University of Freiburg, Freiburg, GERMANY.

Members of the kinesin-13 family of proteins are microtubule depolymerases that play important roles in various cellular processes such as spindle formation, chromosome segregation and ciliogenesis. Not surprisingly, these proteins are frequently overexpressed in different cancer types often associated with poor patient prognosis. Despite the importance of their correct abundance, remarkably little is known about how they are maintained and regulated by the ubiquitin proteasome system. Using comprehensive substrate screening on protein microarrays, we identified Kif2c as a target of the multi-subunit ubiquitin E3 ligase SCF^{Fbxw5}. By combining different in *vitro* and in *cellulo* assays, we could establish a strong and direct binding of Kif2c to the substrate receptor Fbxw5. Complete reconstitution of the SCF-dependent ubiquitylation reaction in *vitro* shows that Kif2c is polyubiquitylated by the E3 ligase complex in a highly efficient manner predominantly forming K48 linkages. Accordingly, knockdown of Fbxw5 in RPE-1 cells leads to a general stabilization of Kif2c with a most drastic increase of Kif2c levels at centrosomes after serum starvation. Live-cell imaging revealed that centrosomal levels of Kif2c are already elevated directly after exit of mitosis, suggesting that the regulation is not taking place in G_0 but rather during or before mitosis. In line with a negative role of Kif2c in the generation of primary cilia, knockdown of Fbxw5 leads to a block of ciliogenesis in serum-starved cells, a defect that can be completely reverted by simultaneous knockdown of Kif2c. Thus, we propose that regulation of Kif2c by SCF^{Fbxw5} before mitotic exit is important to reduce its centrosomal levels in order to allow proper formation of primary cilia in G_0.

Non-canonical Hedgehog Pathway Induces Ciliogenesis Via Promoting the Activation of Autophagy and Ofd1 Centriolar Translocation.

T. Akhshi, W. Trimble; Hospital for Sick Children/ University of Toronto, Toronto, ON, CANADA.

Primary cilia are microtubule-based structures protruding from the basal body at the surface of most animal cells. Cilia are critical signaling hubs during embryonic development and their absence leads to a variety of severe disorders collectively known as ciliopathies. Canonical Hedgehog (Hh), depends on the presence of primary cilia and involves the binding of Hh ligand to Patched1 (Ptch1), allowing Smoothened (Smo) to accumulate at the primary cilium to activate Gli transcription factor. However, non-canonical Hh pathways do not require primary cilia and in some Smo activates other effectors such as $G\alpha_i$ and liver kinase B1 (LKB1). Despite the importance of cilia, our knowledge of upstream regulators of ciliogenesis is very limited, although autophagy has been implicated. Here we describe a non-canonical Hh pathway as a novel regulator of ciliogenesis. We show that under conditions of low cell density and in serum-rich conditions, Hh activation can unexpectedly activate autophagy via activating LKB1, and induce cilia formation. By depleting various autophagy regulators, we show that Hh-induced ciliogenesis also relies on autophagy, although activation of autophagy is insufficient for ciliogenesis. Using different Smo agonists that enforce different conformations on Smo, we show that in addition to

autophagy, which removes centriolar satellite OFD1, Smo activation of $G\alpha_i$ promotes dynein-mediated translocation of a portion of OFD1 to the centrioles which is also required for Hh-mediated cilia formation. This work reveals that physiological stimuli can promote ciliogenesis, and that autophagic degradation of OFD1 must be accompanied by its translocation and concentration at the centrosome/basal body for ciliogenesis.

Centriolar Satellites Are Important for Cilium Assembly, Function and Cell Migration.

E. Odabasi, H. Zirhlioglu, E. Firat-Karalar; Koc Univesity, Istanbul, TURKEY.

Centriolar satellites have recently emerged as key regulators of centrosome/cilium biogenesis, and their mutations are linked to ciliopathies. However, their precise functions and mechanisms of action remain poorly understood. In our recent study, we generated kidney epithelial cells lacking satellites by genetically ablating PCM1 and investigated the cellular and molecular consequences of satellite loss. Satellite-less kidney epithelial cells still formed full-length cilia but at significantly lower levels. Using these cells, we identified the first satellite-specific functions at cilia, specifically in regulating ciliary content, Hedgehog signaling, and epithelial cell organization in three dimensional cultures. However, other satellite-linked functions, namely proliferation, cell cycle progression and centriole duplication, were unaffected in these cells. Quantitative transcriptomic and proteomic profiling revealed that loss of satellites scarcely affects transcription, but significantly alters the proteome. GO-term analysis of biological processes shows that actin cytoskeleton, cell migration and adhesion are affected in satellite-less cells. In the light of this information, we performed wound healing assay and we observed that satellite-less cells are slower to close the wound. Our findings show that satellites have role in efficient cilium assembly and function as well as cell migration.

P1927/B169

Defining the Role of Rab34 GTPase in the Assembly and Function of Primary Cilia.

D. K. Breslow, A. K. Ganga, M. C. Kennedy, K. E. Oliver; Yale University, New Haven, CT.

Ciliary membrane trafficking is critical to cilium formation and function but remains incompletely understood. Here we describe the role in ciliogenesis of Rab34, a poorly characterized member of the Rab family of GTPases, which have widespread roles in intracellular trafficking. We identified Rab34 in a genome-wide screen for regulators of Hedgehog signaling, and we show here that Rab34 localizes to the Golgi, mother centriole, and cilium and is required for cilium formation. An alysis of Rab34 KO cells indicates that Rab34 is dispensable for some early steps in ciliogenesis but necessary for elaboration of the ciliary membrane and subsequent axoneme extension. By identifying novel mutant alleles of Rab34 that alter nucleotide binding and GTPase activity, we find that ciliogenesis is dependent upon both GTP binding and hydrolysis by Rab34. In particular, GTP-locked mutants of Rab34 localize to the mother centriole and dominantly inhibit cilium formation. Furthermore, when inducibly expressed in ciliated cells, these mutants provoke cilium resorption. Thus, Rab34 is required not only for cilium assembly but also for cilium maintenance. To investigate regulators and effectors of Rab34, we identified Rab34-interacting proteins by affinity purification and mass spectrometry. These purifications have revealed a ciliary trafficking complex as a candidate Rab34 effector and a candidate GTPase activating protein (GAP). Taken together, our findings lead us to propose a model in which Rab34 regulates formation and maintenance of the ciliary membrane through dynamic interaction with ciliary trafficking factors. More

broadly, our studies on Rab34 illustrate the value of genome-wide screening approaches to study cilia and suggest a new gene that may be mutated in ciliopathies.

P1928/B170

Casein Kinase 2 Opposes TTBK2 Function in Regulating Cilium Stability.

A. Loukil, **S. Goetz**; Duke University, Durham, NC.

Primary cilia are critical mediators of cellular signaling pathways. The biogenesis of these microtubule-based structures is a multi-step process of which Tau Tubulin Kinase 2 (TTBK2) is a key regulator. TTBK2 is essential for the initiation primary cilia assembly, acting upstream of the intraflagellar transport (IFT) machinery, and embryos homozygous for null mutations to *Ttbk2* fail to assemble cilia. Additionally, embryos with hypomorphic alleles of *Ttbk2* exhibit shorter cilia with perturbed localization of IFT proteins, revealing that TTBK2 is also required to regulate cilia stability. Although TTBK2 is at the nexus of cilia regulation, the molecular pathway in which it functions remains largely undefined. To identify additional proteins that function in the TTBK2-dependent ciliogenesis pathway, we performed screens for both physical and functional TTBK2 interactors. Through these approaches, we identified Casein Kinase 2 Alpha 1 (CSNK2A1) as a negative regulator of TTBK2. We showed that *Csnk2a1* knockout in *Ttbk2* hypomorphic mutant cells rescued defects in cilia formation and length. CSNK2A1 was localizes to the centrosome and enriched at the mother centriole, where it partially co-localizes with TTBK2. We also found that CSNK2A1 physically interacts with TTBK2. CSNK2A1 is required to regulate cilia length and stability: cilia of *Csnk2a1* knockout cells are longer than those of controls, and exhibit instability, particularly at the tip. Live imaging revealed more frequent breakage events in *Csnk2a1*-depleted cells compared to control cells. The composition of these mutant cilia was also perturbed with an abnormal accumulation of IFT proteins, preferentially at the distal part of the cilium. De novo mutations of *Csnk2a1* are linked to a newly characterized disorder, Okur-Chung neurodevelopmental syndrome. Patients diagnosed with this autosomal dominant disorder have dysmorphic facial features and a range of neurodevelopmental abnormalities. We found that stable over-expression of these *Csnk2a1* variants in wild-type cells also led to ciliary tip breakages, similar to those observed in the *Csnk2a1*-depleted cells. From these studies, we identify a new role of CSNK2A1 in cilia stability and trafficking that opposes TTBK2 function. We expect to unveil new mechanisms involved in cilia integrity and trafficking, which will help uncover the impact of cilia instability in human disease and reveal new roles of primary cilia in neural function and homeostasis.

P1929/B171

A Novel TrappII Complex Protein C7orf43/TRAPPC14 Functions in Ciliogenic Vesicle Tethering to the Mother Centriole.

A. Cuenca, **H. Zhao**, C. Insinna, Q. Lu, C. J. Westlake; NIH/NCI, Frederick, MD.

The Rab11-Rab8 cascade functions in early stages of ciliogenesis. Rab11 traffics the guanine nucleotide exchange factor (GEF) Rabin8 to the centrosome to activate Rab8, needed for ciliary growth. Rabin8 also requires the Transport Particle Protein complex (TRAPPC) proteins for centrosome recruitment during ciliogenesis. Here, we identify C7orf43, detected in Rabin8 mass spectrometry analysis, and show its requirement for ciliation in human cells and zebrafish embryos. C7orf43 directly binds to Rabin8, and its knockdown diminishes Rabin8 ciliogenic centrosome accumulation. Interestingly, C7orf43 co-sediments with TRAPPII complex subunits and directly interacts with TRAPPC proteins. Our findings establish that

C7orf43 is a TRAPPII-specific complex component, referred to as TRAPPC14. Additionally, we show that TRAPPC14 is dispensable for TRAPPII complex integrity, but mediates Rabin8 interaction with the TRAPPII complex. Finally, we demonstrate that TRAPPC14 interacts with distal appendage proteins FBF1 and CEP83, which we show function in GFP-Rabin8 centrosome accumulation, supporting a role for the TRAPPII complex in tethering preciliary vesicles to the mother centriole during ciliogenesis.

P1930/B172

Primary Cilium Assembly Is Initiated by a Rab11 Effector Switch Regulated by Akt Signaling.

V. Walia[1], A. Cuenca[1], **S. Perera**[1], M. Vetter[2], C. Insinna[1], Q. Lu[1], D. A. Ritt[1], D. K. Morrison[1], E. Lorentzen[2], C. J. Westlake[1]; [1]NCI/NIH, Frederick, MD, [2]Aarhus University, Aarhus, DENMARK.

One of the earliest cilia assembly initiating events reported to date is the Rab11-dependent vesicular transport of Rabin8, a Rab8 GEF, to the mother centriole leading to Rab8 activation and cilium growth. This preciliary trafficking of Rabin8 is observed within minutes of serum starvation, which is used to stimulate cilia growth in cultured cells, yet, the serum factors associated are unknown. Here, we report the identification of the serum mitogen lysophosphatidic acid (LPA) as a negative-regulator of ciliogenesis initiation. We demonstrate that LPA, through the LPA receptor 1 (LPAR1), regulates Rab11-Rabin8 interaction and ciliogenesis trafficking via downstream Akt activation, independent of effects on cell proliferation and the cell cycle. Rab11 interaction analysis led to the discovery that Akt directly stabilizes Rab11 binding to its effector WDR44/Rabphilin11, which is shown to negatively regulate Rabin8 preciliary trafficking. Consistent with these observations expression of a WDR44, Akt-site phospho-mimetic, blocks ciliogenesis in human cells and zebrafish embryos. We further characterized Rabin8 preciliary trafficking regulation, demonstrating that FIP3, another Rab11 effector, is required to switch from a Rab11-WDR44 complex to the ciliogenic Rab11-FIP3-Rabin8 complex. Finally, we demonstrate that Akt regulates additional ciliogenic processes downstream of the Rab11 effector switch associated with Rab8-dependent cilia growth. Together, this study uncovers a previously unknown mechanism whereby serum mitogen signaling regulates preciliary trafficking to the mother centriole and ciliogenesis initiation via signaling through the Akt pathway.

P1931/B173

Membrane Tubulation Orchestrates Emergence of the Developing Cilium Via Microtubules Revealed by 3-d Ultrastructure Imaging.

C. Insinna-Kettenhofen[1], Q. Lu[1], I. Teixeira[1], A. Harned[1], E. Semler[1], J. Stauffer[1], V. Magidson[1], A. Tiwari[2], A. K. Kenworthy[2], K. Narayan[1], C. J. Westlake[1]; [1]National Cancer Institute, NIH, Frederick, MD, [2]Vanderbilt University School of Medicine, Nashville, TN.

Cystokeleton and membrane organization is essential for proper assembly of the microtubule-based cilium that occurs, in part, intracellularly in many cells types including photoreceptors and fibroblasts. Yet, the sequence of steps coordinating early ciliogenesis remains poorly understood, and in particular how the developing intracellular cilium membrane fuses with the cell surface membrane for its signaling function is completely unknown. Ciliogenesis requires initial membrane trafficking to the mother centriole (MC) distal appendages followed by docking of vesicles, which will fuse into a larger ciliary vesicle (CV), a pre-requisite step before axonemal growth. Further CV reorganization into the ciliary sheath double membrane is followed by fusion of the latter with the plasma membrane and emergence of the cilium outside the cell. Here, we demonstrate that F-BAR domain containing proteins PACSINs

coordinate membrane reorganization with EHD1 during early ciliogenesis. PACSINs function with EHD1 at the CV step to uncap the mother centriole, and remarkably, stimulate the formation of membrane tubules that contain the ciliary membrane growth regulator Rab8. Correlative light and electron microscopy was performed with Focused Ion Beam Scanning Electron Microscopy (FIB-SEM) to generate 3-D ultrastructure images of the developing cilia and reveal that these membrane tubules connect the CV and ciliary sheaths to the plasma membrane forming an extracellular membrane channel (EMC). Live cell imaging in both human cells and developing zebrafish embryo demonstrated that these tubules originate from the intracellular developing ciliary membranes, and depend on PACSINs and microtubules for their formation. Interestingly, these tubular membranes were also observed forming from the ciliary pocket membrane suggesting a role in trafficking in mature cilia. This work sheds new light on the mechanism of how the developing cilium emerges from inside the cell and exposes the ciliary membrane to the extracellular environment highlighting the importance of the interplay between membrane trafficking and the cytoskeleton during ciliogenesis.

P1932/B174

Single-molecule Tracking Reveals Complex Motility of Transmembrane Proteins in the Chemosensory Cilia Of*C. Elegans*.

J. van Krugten, N. B. Danné, **E. J. G. Peterman**; Vrije Universiteit, Amsterdam, NETHERLANDS.

Cilia are vital for the cell's ability to sense its environment and rely on a process called intra flagellar transport (IFT) for their development, maintenance and function in signal-transduction. In IFT, motor proteins transport ciliary components along the polarized microtubule axoneme of the cilium. Among the cargoes of IFT are transmembrane proteins involved in signal transduction. As a model system, we study *C. elegans* chemosensory cilia, which we study using fluorescence microscopy with single-molecule sensitivity. First, we demonstrate that IFT machinery and ciliary components, including TRPV transmembrane channel protein OCR-2 are redistributed away from the ciliary tip upon external chemical stimulation, in a robust, extensive and reversible way. To elucidate the dynamics underlying this dramatic protein redistribution, we performed single-molecule imaging of OCR-2 in live *C. elegans*. Advanced analysis of the single-molecule trajectories shows that, in dendrite and transition zone, active transport is the prevailing motility mode of OCR-2. In the proximal and distal segments, however, motility is a much more complex, location-specific interplay between active transport, normal diffusion and sub diffusion. At the tip, confinement of the membrane proteins plays an important role. Together, our data and analysis demonstrate an intricate interplay between modes of transportation that ensure the proper ciliary distribution of OCR-2. These insights in the dynamics of cellular signal-transduction contributes to a wider understanding of IFT dynamics and to cilia as chemosensory organelles.

Ciliary/flagellar motility

P1933/B175

Characterization of a Novel Ciliary Protein, CFAP70.

N. Shamoto, K. Narita, T. Kubo, T. Oda, S. Takeda; Yamanashi University, Yamanashi, JAPAN.

Cilia- and flagella-associated protein 70 (CFAP70) is a 150 kDa protein discovered by our transcriptome analysis in mice. Little is known about this protein, except for the tetratricopeptide repeat (TPR)

domains concentrated on the C-terminus, which is known to mediate protein-protein interactions, and present in many components of the intraflagellar transport (IFT) complex. We characterized the mouse CFAP70 and *Chlamydomonas* homolog FAP70 with particular interests on the ciliary localization and function. RT-PCR of various mouse tissues demonstrated the association of CFAP70 with motile cilia and flagella, and the immunohistochemistry showed a staining pattern being different from the punctate signals of IFT subunits. A stepwise extraction of proteins from porcine tracheal cilia showed that CFAP70 bound tightly to the ciliary axoneme. Fluorescence microscopy of the cultured ependyma expressing fragments of CFAP70 demonstrated that the N-terminus rather than the C-terminus with the TPR domains was more important for the ciliary localization. When CFAP70 was knocked down in cultured mouse ependyma, reductions in cilia beating frequency were observed. Consistent with these observations, a *Chlamydomonas* mutant lacking the FAP70 showed defects in outer dynein arm (ODA) activity and a reduction in flagellar motility. Cryo-electron tomography revealed that the N-terminus of FAP70 resided stably at the base of the ODA. However, there are no obvious changes in the *FAP70*-null mutant axoneme. These results collectively demonstrate that CFAP70 is a novel regulatory component of the ODA in motile cilia and flagella. Furthermore, binding of CFAP70 to the axoneme takes places at the N-terminus being independent of TPR domain.

P1934/B176

Evolution of Multicellularity - Lessons from Ciliary Waves of a Giant Single-celled Cilate *Stentor Coeruleus*.

S. Shekhar[1], H. Guo[2], S. P. Colin[3], W. Marshall[4], E. Kanso[5], J. H. Costello[6]; [1]Brandeis University, Waltham, MA, [2]University of Michigan, an n Arbor, MI, [3]Roger Williams University, Bristol, RI, [4]UCSF, San Francisco, CA, [5]University of Southern California, Los an geles, CA, [6]Providence College, Providence, RI.

Early multicellular organisms have long been suggested to have evolved from unicellular organisms which can form colonies to achieve mutual benefit. While many unicellular protists (e.g. ciliates) are known to rapidly switch between a solitary unicellular state and colonial multicellular-like states, the rules governing these transitions and the benefits they endow the organisms are still poorly understood. We have developed *Stentor coeruleus*, a giant (~1 mm) unicellular ciliate, as a model organism to investigate unicellular to multicellular transition. *S. coeruleus* beat their oral cilia in a metachronal wave to swim as well as to generate microcurrents that transport dissolved nutrients and smaller prey cells critical for nutrition. These ciliary flows are characterized by symmetric vortices on either side of the oral opening. Further, these organisms can spontaneously self-assemble into hemispherical colonies with oral openings radially radiating outwards. Using a combination of high-speed imaging, particle image velocimetry and computational fluid dynamics, we show that individuals in a colony cooperate to generate faster feeding current as compared to their solitary counterparts. The combined flows can act over longer distances and transport greater amounts of fluid per individual organisms, and thus giving a direct survival benefit to individuals in a colony vs solitary ones. The advantages endowed by their colonial organization can thus potentially provide fundamental insights into the selective forces favoring early evolution of multicellular organization.

P1935/B177

Identifying and Mapping the Protein Composition of the Central Pair Apparatus through Proteomics.

D. Dai[1], M. Ichikawa[2], K. Peri[1], R. Rebinsky[1], K. H. Bui[1]; [1]McGill University, Montreal, QC, CANADA, [2]Nara Institute of Science and Technology, Ikoma, JAPAN.

The central pair (CP) apparatus is a robust yet elusive component of the axonemal structure in motile cilia and flagella. The presence of the CP distinguishes the motile cilia from its non-motile counterpart, the primary cilia. The CP plays fundamental roles in conferring structural integrity, flexibility and regulation of ciliary beating. It consists of two bridged microtubules termed C1 and C2. Both C1 and C2 are decorated with multiple protein complexes that are unique and specific to each microtubule. The protein composition and organization of the CP have yet to be addressed in full. This is in part due to previous approaches which relied on existing Chlamydomonas mutants to identify CP proteins one by one. In this study, we looked to identify new CP proteins and localize all the new and currently known CP proteins in a more comprehensive fashion using a proteomic approach. The proteomic composition of the entire CP was identified by comparing mass spectrometry (MS) of wild type cells and pf15 cells, which is missing the entire CP structure. To map CP proteins into sub-structures, Chlamydomonas reinhardtii strains of different CP components, were subjected to MS analysis. Mutants missing parts of CP structure: pf16 (C1-less strain), pf6 (missing C1a complex) and cpc1 (lacking C1b complex), were used to generate MS profile of each CP protein and, consequently, for mapping into sub-structures based on known proteins. Flagella were purified from wild type and mutants; pf15, pf16, pf6 and cpc1, treated with 0.6M NaCl twice to remove dynein motor complexes, and analyzed by MS. MS was performed by in-gel digestion 3 times for each strain and statistical analysis was performed. Comparison between wild type and pf15 MS results revealed over 40 new CP protein candidates in addition to well-characterized CP proteins. By comparing these results to subsequent mutant MS results, those proteins were further mapped to the sub-structures surrounding the CP. We believe that our approach has provided further insights into the composition and localization of new proteins of the CP.

P1936/B178

Multi-scale Spatial Heterogeneity in the Airway Multiciliated Epithelium Underlies Directed Flow Generation.

G. Ramirez-SanJuan[1], A. Mathijssen[2], M. He[3], L. Jan[1], W. Marshall[3], M. Prakash[2]; [1]University of California San Francisco/ Stanford University, San Francisco, CA, [2]Stanford University, Stanford, CA, [3]University of California San Francisco, San Francisco, CA.

Flow generation is essential for the development and physiology of organisms across the tree of life. Flows required for processes that range from swimming in single cell organisms to mucus clearance in humans are generated by arrays of motile cilia. To generate large scale fluid flows, motile cilia must coordinate their activity across entire tissues. The mechanisms of fluid transport have been studied extensively at the level of the individual cilium and collectively moving metachronal waves. However, the connection between local cilia arrangement and the patterns of flow they generate remains largely unexplored. Here, we image the mouse airway multiciliated epithelium from the sub-cellular (nm) to the organ scales (mm), characterizing quantitatively its ciliary arrangement and the flow generated. Locally we measure heterogeneity in both cilia organization and flow structure, but we find that fluid transport is coherent and globally directed across the trachea. To examine this result, we developed a hydrodynamic model and explore systematically the flows generated by diverse ciliary architectures.

Surprisingly, we find that disorder enhances particle clearance, whether it originates from fluctuations, heterogeneity in multiciliated cell arrangement or ciliary misalignment. Thus, disorder in ciliary arrays provides a mechanism to generate globally directed flows that are highly correlated in space and time. Altogether our results shed light into how multi-scale patterning of an array of multi ciliated cells determines its emergent dynamics. Furthermore, this work is also applicable to understand the origin of human airway pathologies, which are the third leading cause of deaths worldwide.

P1937/B179

Ccdc113 / Ccdc96 Complex Links N-drc, Rs3 and Idas G Tailand Is Essentialfor Proper Cilia Beating.

A. Schröfel[1], R. Bazan[2], E. Joachimiak[2], M. Poprzeczko[2], G. Pigino[1], D. Włoga[2]; [1]Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, GERMANY, [2]Nencki Institute of Experimental Biology, Polish Academy of Sciences, Warsaw, POLAND.

A proper ciliary beating requires the coordinated activity of numerous axonemal complexes. While the protein composition and a role of the major axonemal complexes is well established, little is known about the minor complexes and linkers, which connect the major complexes and likely regulate or coordinate their activity and/or mediate signal transduction. We identified a structure that connects the N-DRC, the tail of the IDA g, and the base of the RS3, and showed that it is composed of the evolutionarily conserved proteins, Ccdc113 and Ccdc96. The ciliary localization of Ccdc96 and Ccdc113 is interdependent and loss of Ccdc113 or Ccdc96 alters cilia beating. We propose that the Ccdc113/Ccdc96 complex transmits signals from N-DRC and RS3 to IDA g and thus, regulates its activity and the cilium beating pattern. Additionally, we observe that the density of the Ccdc113/Ccdc96 complex contributes to an elongated linker structure that, passing through the N-DRC, the MIA complex, and the IC-LC complex of IDA f connects all major components of the 96-nm repeat.

P1938/B180

Changes in the Helical Symmetry of the Axoneme of *Chlamydomonas* Flagella Coupled with Ca^{2+} Concentrations.

K. Oiwa[1,2], H. Iwamoto[3], H. Sakakibara[1]; [1]Advanced ICT Res Inst, NICT, Kobe 6512492, JAPAN, [2]Grad Sch Life Sci, Univ Hyogo, Harima, Hyogo, JAPAN, [3]Japan Synch Rad Res Inst, SPring-8, Harima, Hyogo, JAPAN.

X-ray diffraction allows the extraction of structural information from unfixed biological materials that remain functional in an aqueous environment and allows dynamic or time-resolved measurements on the structures of biological materials. It is particularly useful when the target molecules to be investigated are periodically arranged because X-rays scattered by periodic arrays interfere with each other to generate strong signals. An axoneme with its highly ordered structures is, therefore, a suitable target for X-ray diffraction. Using *Chlamydomonas* as the useful model system for the structural analysis of eukaryotic cilia and flagella, we have explored the spatial arrangement of axonemal components and helical symmetry of the axoneme under physiological conditions by small-angle X-ray fiber diffraction. The axonemes were oriented in a physiological solution by continuous shear-flow and were exposed to intense and stable X-rays generated in the synchrotron radiation facility SPring-8 BL40XU. When the diffraction patterns were viewed along the meridian, the peaks of the meridional reflections were sharp and well-separated from each other and could be indexed to a basic axial repeat of 96 nm, which was the periodicity of the radial spokes and inner dynein arms. The reflections were observed up to the 12th (at 1/8 nm^{-1}) and 24th (at 1/4 nm^{-1}) orders. The use of a variety of mutants lacking specific axonemal

components allows us to assign the reflections to the structures since diffraction patterns from mutant axonemes exhibited a systematic loss/attenuation of meridional/layer line reflections. Next, we explored the spatial arrangement and dynamics of axonemal components under various [Ca^{2+}]. At the low [Ca^{2+}], 24-nm meridional reflections split each into the layer lines, suggesting changes in the helical nature of nine doublet microtubules in the axoneme. At the high [Ca^{2+}], the intensity of layer lines decreased. This change found in wt axonemes was also observed in the central pair-less mutant, *pf18*. Furthermore, the dependency of the change in diffraction patterns upon [Ca^{2+}] was similar to that of the waveform changes observed in *Chlamydomonas*. These results suggest the possibility that [Ca^{2+}] changes the helical arrangement of doublet microtubules in an axoneme and modulates the coordinates of dynein arms and the adjacent doublets. This work was supported by Grant-in-Aids for Scientific Research (C), the Japan Society for the Promotion of Science (JSPS, grant numbers 26440089 and 17K07376 to K.O.), and the Takeda Science Foundation and Hyogo Science and Technology Association (K.O.).

Centrosome Assembly and Functions 2

P1939/B182

A Perinuclear Microtubule-Organizing Center Controls Plasma Membrane Growth and Basement Membrane Secretion by Engaging a Novel Paradigm for Microtubule Assembly.

T. L. Megraw[1], Y. Zheng[1], C. Zheng[1], R. A. Buchwalter[1], E. M. White[1], J. V. Chen[2]; [1]Florida State University, Tallahassee, FL, [2]University of California, Santa Barbara, Santa Barbara, CA.

Non-centrosomal microtubule-organizing centers (ncMTOCs) are a prevalent feature of differentiated cell types. ncMTOCs are diverse in their sites of subcellular assembly, yet little is known of their structures, regulation, and what functions they serve in the specialized cell types where they are found. Here we show a unique molecular architecture for the ncMTOC in fat body cells, a Drosophila differentiated cell type that has critical secretory functions that we show are controlled by the ncMTOC. We show that a prominent ncMTOC is assembled at the nuclear surface in the fat body, which is the functional equivalent of vertebrate liver and adipose tissue. This ncMTOC has several novel features and mechanisms of MT assembly that distinguish it from centrosomes and other MTOCs. Firstly, this MTOC is remarkable in its complete lack of dependence on gamma-tubulin, the broadly employed MT nucleator at centrosomes and ncMTOCs. Secondly, we show that the Nesprin Msp300 establishes the MTOC on the nuclear surface together with the spectraplakin Shot. This complex recruits the MT minus-end regulators Patronin (CAMSAP homolog) and Ninein, which function redundantly to establish MT nucleation at the nuclear surface. Thirdly, Patronin + Ninein recruit the MT polymerase Msps (XMAP215 homolog) to generate the radial MTs upon which membrane trafficking occurs. We further show by co-IP that Patronin and Msps reside together in a complex. Overall, this MT regulatory axis involving Patronin + Ninein to stabilize or anchor MT minus ends while recruiting the MT polymerase Msps to assemble the radial MT array, anchored at the nucleus by Msp300 + Shot, and functioning independently from gamma-tubulin, represents a novel paradigm for MTOC structure and function. Surprisingly little is known about the cell biological or physiological functions that diverse ncMTOCs serve in the variety of cell types where they are found. Here we show that the fat body perinuclear ncMTOC controls membrane trafficking, impacting plasma membrane homeostasis. The microtubule arrays radiating from the perinuclear ncMTOC coordinate dynein motor-dependent endocytic trafficking

to maintain proper plasma membrane growth, representing the first example of microtubule-mediated control of plasma membrane growth as far as we are aware. Importantly, the uncontrolled plasma membrane overgrowth that results from disruption of the ncMTOC causes extracellular entrapment of large secreted complexes like collagen within the convoluted membrane folds, a phenomenon comparable to liver fibrosis.

P1940/B183

CK2-dependent Phosphorylation Regulates ZYG-1/PLK4 Stability and Centrosome Number.

M. Song[1], J. DiPanni[1], J. Medley[1], L. Schira[1], B. Shaffou[1], B. Sebou[1], A. Petrelli[1], E. Cramer[1], N. Fellows[1], C. Wu[1], M. Kabara[2], M. Song[1]; [1]Oakland University, Rochester, MI, [2]Michigan State University, East Lansing, MI.

Spindle bipolarity is critical for genomic integrity and centrosome number often determines bipolarity in mitosis. Tight control of centrosome assembly is, therefore, vital for the fidelity of cell division. The kinase ZYG-1/Plk4 is a key centrosome regulator and ZYG-1/Plk4 protein levels appear to be regulated through opposing activities between kinases and phosphatases in *C. elegans* embryos. Our prior work showed that Casein Kinase II (CK2)-dependent phosphorylation influences centrosome-associated ZYG-1 levels and CK2 acts as a negative regulator of centrosome assembly. We thus postulated that CK2 directly phosphorylate ZYG-1 and CK2-dependent phosphorylation influences ZYG-1 stability and centrosome-associated ZYG-1. To test our hypothesis, we used in *silico* tools and identified serine 279 (S279) and several adjacent serine residues within ZYG-1 as putative CK2 target sites. S279 is located within a linker domain (L1) between the kinase domain and cryptic polo box in ZYG-1. The L1 domain is known to be critical for ZYG-1 loading to centrosomes and its interaction with another centrosome factor SAS-6. Using CRISPR/Cas9 genome editing, we mutated these serine residues to alanine (A: non-phosphorylatable) or aspartic acid (D: phospho-mimetic), and tested for the effects of site-specific phosphorylation of ZYG-1 in the early *C. elegans* embryo. Our data show that non-phosphorylatable ZYG-1 mutations restore centrosome duplication and embryonic viability to hypomorphic *zyg-1* mutants, whereas phospho-mimetic mutations aggravated *zyg-1* phenotypes. We also observe that phospho-mutants of ZYG-1 at multiple residues (4A and 4D) exhibit much stronger effects than single-site mutation at S279. Consistent with our hypothesis, non-phosphorylatable mutations result in elevated ZYG-1 levels and supernumerary centrosomes in early *C. elegans* embryos. In contrast, phospho-mimetic ZYG-1 mutations lead to the reduced centrosomal ZYG-1 levels and often to a centrosome duplication failure. We also show that blocking the 26S proteasomal activity leads to a partial rescue of centrosome duplication to the phospho-mimetic ZYG-1 mutant, consistent with our hypothesis that phosphorylated ZYG-1 is subject to proteasomal destruction. Finally, our in *vitro kinase* assay indicates that CK2 may directly phosphorylate ZYG-1 at multiple sites. Together, our results suggest that CK2-dependent ZYG-1 phosphorylation at multiple sites contributes to ZYG-1 stability via the 26S proteasomal degradation. Thus, ZYG-1 phosphorylation by CK2 provides an additional mechanism to maintain ZYG-1 activity, leading to one and only one centrosome duplication during the early *C. elegans* cell division.

P1941/B184

Identification and Characterization of Sas-6 as an Mps1 Substrate for Centriole Biogenesis.

S. T. Nguyen, H. A. Fisk; the Ohio State University, Columbus, OH.

The faithful segregation of chromosomes during mitosis is essential for maintaining genetic stability. Improper segregation leads to aneuploidy and contributes to genetic instability and tumorigenesis, common features in cancer. The centrosome is an organelle composed of a pair of centrioles made up of triplet microtubules organized in a cylindrical structure that has nine-fold symmetry. Centrosomes function as the poles of the mitotic spindle to ensure equal segregation of chromosomes and safeguard against genetic instability. Like DNA, centrosomes are duplicated once and only once per cell cycle, wherein the two centrioles of a single centrosome each serve as the template to nucleate their own daughter centrioles in the centriole assembly pathway. Once the daughter centrioles are assembled, the two mother/daughter pairs separate from each other to form two centrosomes that go on to organize the mitotic spindle. Failure to regulate this process can lead to the amplification of centrosomes and increases the likelihood of aberrant spindle formation in mitosis and the improper segregation of chromosomes. The protein kinase Mps1 is necessary for the spindle assembly checkpoint and contributes to centriole assembly in animals. We have previously shown that preventing the degradation of Mps1 at centrosomes led to the overproduction of centrioles, though the exact mechanism remains to be seen. Mps1 phosphorylates the centrosomal protein Centrin2 and targets it to the centrosome, but whether Centrin2 is the only centrosomal substrate of Mps1 is not known. To address this question, we have looked at several centrosomal proteins involved in the centriole assembly pathway for interactions with Mps1. We have found that Sas-6, a protein involved in the formation of the cartwheel base of the centriole and the source of its nine-fold symmetry, is a substrate of Mps1. By mass spec, we have identified 5 in vitro Mps1 phosphorylation sites in Sas-6. Single site mutations to non-phosphorylable or phospho-mimetic residues does not affect the localization of Sas-6 or its ability to recruit the microtubule nucleating protein gamma-tubulin. While mutating all five sites similarly does not affect Sas-6 localization or function, we found that the Sas-6 5D phospho-mimetic mutant display defects in the overproduction of centrioles during an extended S-phase arrest. These results support the identification of Sas-6 as a novel and relevant substrate of Mps1 and will require further research to unravel their interactions and effects on the regulation of centrosome duplication.

P1942/B185

Genetic an alysis of a SAS-6 Mutant Suggests an Instructive Role for the Mother Centriole in Centriole Assembly.

S. Guagliardo[1], N. DeVaul[1], G. Fabig[2], T. Mueller-Reichert[2], K. F. O'Connell[1]; [1]National Institutes of Health, NIDDK, Bethesda, MD, [2]Technische Universität, Dresden, GERMANY.

Centrioles are nine-fold symmetric barrel-shaped organelles that exist as mother-daughter pairs and participate in the assembly of bipolar spindles as well as in the formation of cilia and flagella. In canonical duplication, centrioles are precisely duplicated through a process that involves the formation of a new daughter next to each preexisting mother centriole. It is well established that mother centrioles provide spatial control by recruiting initiation factors, but current evidence is inconclusive about whether the mother provides any additional assistance. Arguments against this are supported by the finding that centrioles are able to form in the absence of a mother centriole, called de novo. Additionally, SAS-6, the protein responsible for forming the centriole scaffold, has been shown to

possess the ability to self-oligomerize with nine-fold radial symmetry in vitro, providing a mechanism for which daughter centrioles could self-assemble. However, de novo centrioles are often structurally defective and lack numerical control, suggesting that the mother centriole may play a more instructive role in centriole assembly. Here we describe a missense (D9V) mutation in *C. elegans* SAS-6 that specifically compromises the ability of centrioles to act as mothers. The SAS-6(D9V) protein can be assembled into structurally-defective centrioles (D9V centrioles) that organize normal-sized centrosomes and spindle poles. Importantly, D9V centrioles are fully capable of initiating daughter centriole formation, as evidenced by their ability to recruit near-normal levels of an essential assembly initiation protein, SAS-7, as well as by their ability to reliably form daughters when exposed to a cytoplasmic pool of wild-type SAS-6 protein. However, in the presence of a cytoplasmic pool of SAS-6(D9V) protein, D9V mother centrioles frequently fail to form daughters. In contrast, under these same conditions, wild-type mothers efficiently form daughters, demonstrating that SAS-6(D9V) protein is assembly competent. Together these data indicate that centriole duplication failure associated with SAS-6(D9V) arises in part from a defect in a post-inititation role of the mother centriole, and suggest some type of molecular communication between the mother centriole and the assembling daughter.

Regulation of Centriole De Novo Biogenesis.

C. Nabais, D. Pessoa, J. de-Carvalho, P. Duarte, J. Carneiro, I. A. Telley, M. Bettencourt-Dias; Instituto Gulbenkian De Ciencia, Oeiras, PORTUGAL.

In proliferating cells, centrosome formation via canonical duplication is spatially, temporally and numerically regulated by the presence of mature centrioles. However, in several eukaryotic cell-types, centrioles assemble de novo*,* yet very little is known regarding the regulation of this process, in part because previous studies lacked the appropriate techniques to look into this process in live samples. Overexpression of Polo-like kinase 4 (Plk4) triggers de novo assembly of multiple centrioles in the cytosol of unfertilised *Drosophila melanogaster* eggs. We have established an ex vivo assay for high-resolution confocal live-imaging of centriole assembly within small cytosolic explants from unfertilised fly eggs, allowing us to investigate how this process is spatially and temporally regulated. Surprisingly, we found that both canonical duplication and de novo pathways co-occur within the same cytoplasmic explant, at their own temporal kinetics suggesting that either process does not inhibit the other. We followed centriole de novo biogenesis in time and determined where and when centrioles formed in the droplets. Comparing our observations to stochastic models demonstrated that recently formed centrioles do not impact the location where new centrioles assemble de novo, at high Plk4 levels. We observed that after an initial temporal delay, centrioles assemble at a high rate (0.15-0.75 min^{-1}) that accelerates over time. Our experimental results indicate that this burst in biogenesis is not due to a cell-cycle dependent mechanism but, instead, Plk4 concentration - and presumably its activation - are the main driving force regulating the process. In agreement, altering Plk4 concentration delays the onset of centriole biogenesis. Altogether, our results show that Plk4 local concentration is critical in controlling the onset of centriole de novo formation and its temporal kinetics.

A Novel Assay to Screen Sirna Libraries Identifies Protein Kinases as Required for Chromosome Transmission.

M. Liskovykh[1], N. V. Goncharov[1], N. Petrov[1], V. Aksenova[2], G. Pegoraro[1], L. L. Ozbun[1], W. C. Reinhold[1], S. Varma[1], M. Dasso[2], H. Masumoto[3], W. C. Earnshaw[4], V. Larionov[1], N. Kouprina[1]; [1]National Cancer Institute, Bethesda, MD, [2]National Institute for Child Health and Human Development, Bethesda, MD, [3]Kazusa DNA Research Institute,, Chiba, JAPAN, [4]Wellcome Centre for Cell Biology, Edinburgh, UNITED KINGDOM.

One of the hallmarks of cancer is chromosome instability (CIN), which leads to aneuploidy, translocations and other chromosome aberrations. However, in the vast majority of human tumors the molecular basis of CIN remains unknown, partially because not all genes controlling chromosome transmission have yet been identified. To address this question, we have developed an experimental high-throughput imaging (HTI) siRNA assay that allows the identification of novel *CIN* genes. Our method uses a human artificial chromosome (HAC) expressing the *GFP* transgene. When this assay was applied to screen a siRNA library of protein kinases we identified *PINK1*, *TRIO*, *IRAK1*, *PNCK,* and *TAOK1* as potential novel genes whose knockdown induces various mitotic abnormalities and results in chromosome loss. The HAC-based assay can be applied for screening different siRNA libraries (cell cycle regulation, DNA damage response, epigenetics, transcription factors) to identify additional genes involved in CIN. Identification of the complete spectrum of *CIN* genes will reveal new insights into mechanisms of chromosome segregation and may expedite the development of novel therapeutic strategies to target the *CIN* phenotype in cancer cells.

P1945/B188

Evidence That Centrioles Duplicate Via an Inheritable Organelle Zone.

M. G. Aydogan[1,2], F. Y. Zhou[3], M. Mofatteh[1], J. Bohlen[1,4], J. W. Raff[1]; [1]University of Oxford, Oxford, UNITED KINGDOM, [2]University of California, San Francisco, San Francisco, CA, [3]Ludwig Institute for Cancer Research, Oxford, UNITED KINGDOM, [4]German Cancer Research Center, Heidelberg, GERMANY.

During the cell cycle, organelles must undergo biogenesis to increase in amount and be inherited into daughter cells. Although the molecular mechanisms that regulate organelle biogenesis is under active investigation, current knowledge of how their inheritance works is limited. Our recent studies in *Drosophila* embryos have revealed essential aspects of how centriole biogenesis is regulated as a function of time (Aydogan et al. 2018 and 2019). However, the spatial control over how a mother centriole initiates the growth of its daughter, and whether this information is inherited to the next generation, remains unclear. Here we present our recent evidence that centrioles may acquire a permanent, inheritable metabolite pool that is required for the sustained duplications of centrioles in flies. Live-imaging experiments using spinning disk confocal microscopy showed that cartwheel assembly proteins Sas-6 and an a2/STIL are present in excess on the mother centriole prior to the formation of the daughter. Further investigation with Airyscan super-resolution microscopy demonstrated that the excess Sas-6 and an a2 form a metabolite pool that is associated with, but separate than, the overall structure of mother centrioles. Our results suggest that this metabolite pool is permanently maintained on the mother centriole throughout the cell cycle, but is replenished and inherited to the daughter centriole presumably when the daughter separates from its mother to become a new mother itself. We reasoned that this metabolite pool might function to serve as buffer that limits the parameters of

daughter centriole growth (such as rate or period), and/or to help mark a permanent, inheritable site on the mother centriole that allows efficient duplication of the daughter centriole. In order to investigate this hypothesis, we first looked at whether the size of this metabolite pool is correlated with parameters of centriole growth, and found that this was not the case. To more directly test this, we developed a novel computational script that allows looking at the same parameters distinctly on old and new mother centrioles, but we again observed no significant difference between the two. In agreement with these findings, we found that old and new mothers recruit similar amounts of Plk4, an essential kinase that homeostatically controls the rate and period of centriole growth. Furthermore, unlike Sas-6 and an a2, we found that Plk4 is absent from the metabolite pool, potentially suggesting that this pool does not necessarily serve as buffer to limit aspects of daughter centriole growth. These indicate that the metabolite pool associated with centrioles in cycling cells may form a permanent, inheritable organelle zone on the mother centriole that allows efficient duplication of the daughter centriole.

P1946/B189

A Molecular Mechanism for Assembly of the Pre-procentriole.

T. A. McLamarrah[1], **G. C. Rogers, 85724**[1], J. M. Ryniawec[1], S. Speed[2], D. W. Buster[1], C. J. Fagerstrom[2], B. J. Galletta[2], N. M. Rusan[2]; [1]University of Arizona, Tucson, AZ, [2]National Institutes of Health, Bethesda, MD.

Centriole duplication begins with the accumulation of several assembly factors at a single asymmetric spot on mother centrioles, which eventually gives rise to a procentriole. Specifically, this involves the hierarchical recruitment of a conserved set of centriole proteins, including Polo-like kinase 4 (Plk4)/ZYG-1 and an a2/SAS-5/STIL, followed by the cartwheel protein Sas6. Recruitment of these proteins occurs during late mitosis in *Drosophila* cells, first forming a nebulous structure known as the 'pre-procentriole' and later, during the subsequent S-phase, assembles into a procentriole containing a central cartwheel and a cylinder of microtubule bundles. Because the pre-procentriole is the progenerative platform for nascent centriole growth, our study focuses on determining the molecular details of its composition, structure and assembly, which are largely unknown. Initially, Plk4 decorates the surface of mitotic centrioles due to its interaction with a centriole-targeting factor. Next, an a2/STIL is recruited and stimulates Plk4 kinase activity. In turn, an a2/STIL's C-terminal STAN domain is phosphorylated by Plk4, generating a high-affinity phospho-binding site for Sas6 loading. Although the assembly steps immediately preceding Sas6-loading appear clear, the mechanism underlying the upstream pre-procentriole recruitment of an a2/STIL is not. In contrast to proposed models of an a2/STIL recruitment, we recently showed that loading of *Drosophila an* a2 onto procentrioles is actually independent of Plk4 binding, but does require Plk4's catalytic activity. We have discovered that the amyloid-like domain of Sas4, a centriole surface protein, binds Plk4 and an a2. Sas4 binding facilitates phosphorylation of an a2's N-terminus which increases an a2's affinity for Sas4. Consequently, an a2 accumulates at the procentriole to induce daughter centriole assembly. We propose a new multi-step pathway for the initial assembly of the pre-procentriole and provide insight into how Sas4 may define the site of daughter centriole assembly.

P1947/B190

Inner Nuclear Membrane Proteins Lem2 and Sad1 Regulate Localized Nuclear Envelope Remodeling during Mitosis to Insert the Fission Yeast Centrosome.

A. J. Bestul[1], Z. Yu[1], J. R. Unruh[1], S. L. Jaspersen[1,2]; [1]Stowers Institute for Medical Research, Kansas City, MO, [2]University of Kansas Medical Center, Kansas City, KS.

Making sure the centrosomes in a cell have access to the chromosomes to ensure the correct division of nuclear material is vital during mitosis. In fission yeast, the centrosome (called the spindle pole body, SPB) is assembled in the cytoplasm adjacent to the nuclear envelope (NE). To access the chromosomes during mitosis, fission yeast breaks down the NE. However, this NE breakdown is highly localized, restricted to underneath the SPB and allows insertion of the SPB into the NE. How this process of localized NE disassembly occurs is not well understood, particularly since fission yeast lack many components of the lamin network thought to trigger NE breakdown in metazoans. Here, we utilized structured illumination microscopy (SIM) to visualize the organization of SPB and NE proteins during mitosis in *Schizosaccharomyces pombe* to understand how localized and highly regulated NE breakdown occurs. The high spatial resolution of SIM allows us to delineate between proteins that are localized to the SPB core and proteins that localize to a ring around the SPB. Further analysis of protein localization using single particle averaging methods allowed us to determine if NE proteins are enriched in nuclear regions near the SPB, suggesting a function in NE breakdown and/or remodeling. We further examined the function and hierarchical recruitment of proteins to the SPB region to better understand their role in localized NE breakdown and SPB insertion. Our data supports the idea that Lem2 and Sad1 play important, non-redundant roles in the control of membrane organization at the SPB, acting as upstream regulators of membrane remodeling.

P1948/B191

Cep57 Interacts with Cep63 to Construct the Inner Layer of Pericentriolar Matrix and Provide a Platform for Plk4-dependent Centriole Biogenesis.

Z. Wei[1], T. Kim[1], J. Ahn[1], E. Ryu[2], J. Bang[2], J. Park[1], K. Lee[1]; [1]Laboratory of Metabolism, National Cancer Institute, NIH, Bethesda, MD, [2]Korea Basic Science Institute, Ochang, KOREA, REPUBLIC OF.

Cep57, initially identified as an intracellular trafficking mediator of FGF-2, has been characterized as a part of a pericentriolar complex containing Cep63 and Cep152. A recent study demonstrated that Cep63 and Cep152 form a heterotetrameric complex that self-assembles into a cylindrical higher-order assembly around a centriole. This assembly process is critical for subsequent recruitment of Polo-like kinase 4 (Plk4), a key regulator for centriole duplication, to the future procentriole assembly site. How Cep57 interacts with the Cep63-Cep152 complex and contributes to the structure and function of the Cep63-Cep152 self-assembly remains unknown. Here we showed that depletion of Cep57 delocalizes Cep63 from centrosomes and cripples Sas6 recruitment to the procentriole assembly site. An alyses with cells derived from Cep57-knockout mouse embryonic fibroblasts confirmed this finding. Subsequent coimmunoprecipitation analyses with transfected lysates revealed that the N-terminal region of Cep57 interacts with the N-terminus of Cep63. Consistently, cells expressing a Cep57 mutant defective in Cep63 binding failed to properly recruit Cep63 and Sas6 to centrosomes. In disagreement with the previous report, PCNT did not significantly interact with Cep57 under the conditions where Cep63 interacted with it efficiently. Furthermore, Cep57 failed to directly interact with Cep152 but rather associated with the latter via Cep63, suggesting that Cep63 mediates the formation of a trimeric Cep57-

Cep63-Cep152 complex. Immunostaining analyses showed that Cep57 localizes to the inner face of pericentriolar Cep63 signals but at the outskirts of centriolar tubulin signals. Intriguingly, the C-terminal domain of Cep57 has been shown to possess a capacity to directly bind to microtubules. Taken together, we propose that the Cep57-Cep63 interaction is critical to link the Cep63-Cep152 assemblies to the outskirts of Cep57-associated centrioles. We further speculate that this multilayered organization is important to generate a higher-order architectural platform that serves to orderly arrange various pericentriolar components in a confined subcentrosomal space and intricately regulate Plk4-dependent centriole biogenesis.

P1949/B192

Regulation of Plk4- Dependent Centriole Duplication by the Cullin4/DDB1/VprBP E3 Ubiquitin Ligase Complex.

A. Kratz, X. Holtkotte, S. Freiss, **I. Hoffmann**; DKFZ, F045, Heidelberg, GERMANY.

Centrioles play important functions for the assembly of both centrosomes and cilia. Centriole formation is triggered by and dependent on polo-like kinase 4 (Plk4). Overduplication of centrioles is prevented by degradation of interphase Plk4 mediated by the SCF SLIMB/β-TrCP E3 ubiquitin ligase complex which recognizes a phosphodegron after Plk4 autophosphorylation of multiple residues within a 24- amino acid region. However, a β-TrCP binding site mutant of Plk4 is only modestly stabilized implying the existence of additional E3 ubiquitin ligases that regulate Plk4 levels. We find that the Cullin(CUL)4A/B-DDB1/VprBP E3 ligase complex targets Plk4 for degradation. The DDB1/VprBP complex binds to and ubiquitylates Plk4. Depletion of each VprBP, CUL4A/B or DDB1 causes centrosome amplification, leading to the formation of multipolar mitotic spindles. Furthermore, we show that the interaction between Plk4 and CUL4-DDB1 is independent of Plk4 kinase activity and that VprBP and DDB1 interact specifically with polo-boxes 1 and 2 of Plk4, suggesting that DDB1 promotes Plk4 ubiquitylation independently of the β-TrCP recognition motif. Thus, the SCF SLIMB/β-TrCP pathway which targets Plk4 for ubiquitylation on the basis of its phosphorylation state and the CUL4A/B-DDB1-VprBP ligase which selects Plk4 for ubiquitylation by binding to the conserved PB1-PB2 domain appear to be complementary ways to control Plk4 abundance to prevent centriole overduplication.

P1950/B193

The Relationship between Rab11-endosomes and the Centrosome during Abscission.

N. Krishnan, M. Nunez, E. Curtis, H. Hehnly; Syracuse University, Syracuse, NY.

During interphase, Rab11-GTPase-containing endosomes recycle endocytic cargo. However, little is known about Rab11 endosomes in mitosis. Previous work has identified that Rab11 endosomes are utilized during the final stage of cell division, termed abscission, where they are directed into the cytokinetic bridge and dock adjacent to a proteinaceous structure called the cytokinetic midbody. My laboratory has identified that Rab11-endosomes interact with a specific sub-structure of the centrosome, mother centriole appendages. Mother centriole appendages functionally define the “older centriole” of the centriole pair. Our studies herein identify the relationship between Rab11-endosomes and the centrosome throughout the cell cycle. Strikingly, upon anaphase exit, the oldest spindle pole (containing the oldest centriole) and youngest mitotic spindle poles both maintain a population of Rab11-endosomes, but the oldest pole maintains a significantly larger population of endosomes. Using Fluorescent Recovery After Photobleaching (FRAP) we find that bleaching the Rab11-binding protein,

FIP3, at the oldest spindle pole presents with a significantly different recovery rate when compared to the youngest. These studies suggest that spindle pole age may be modulating Rab11-endosome function during cytokinesis. After the cytokinetic furrow has ingressed, formation of a second endosome compartment in each daughter cell occurs proximal to the cytokinetic bridge where the spindle poles remain at the distal ends. The oldest spindle pole then moves proximal to the bridge carrying with it its population of endosomes, where it meets the second endosome compartment. When this pole is adjacent to the bridge, then the youngest pole moves towards the bridge to meet its second endosome compartment. Once both spindle poles are proximal to the bridge, abscission occurs. Rab11-null cells result in transferrin receptor positive endosomes that are unable to track with spindle poles during abscission and result in abscission failure. We present a model where the centrosome may direct Rab11-endosomes into the cytokinetic bridge to initiate abscission.

P1951/B194

Phase Separation Induced by Plk4 Autoactivation and Noncatalytic Domain Clustering Drives Centriole Biogenesis.

J. Park[1], L. Zhang[1], T. An dresson[2], F. DiMaio[3], K. Lee[1]; [1]National Cancer Institute, NIH, Bethesda, MD, [2]National Cancer Institute, NIH, Frederick, MD, [3]University of Washington, Seattle, WA.

As the main microtubule (MT)-organizing center in animal cells, the centrosome plays a pivotal role in various cellular processes, such as spindle formation, chromosome segregation, and cell division. Tight control of centriole duplication is critical for normal chromosome segregation and the maintenance of genomic stability. Polo-like kinase 4 (Plk4) is well characterized as a key regulator of centriole biogenesis. However, how Plk4 dynamically promotes its symmetry-breaking relocalization and achieves its procentriole-assembly state remains unknown. Here we demonstrated that Plk4 promotes its own ring-to-dot localization conversion by autophosphorylating and transmuting the physicochemical properties of its noncatalytic cryptic polo-box (CPB), thereby causing it to rapidly coalesce into a nanoscale spherical condensate with a distinct constituent phase. An alyses of the crystal structure of a phospho-mimicking, condensation-proficient CPB mutant revealed a disordered loop at the CPB PB2 tip predicted to become an intrinsically disordered region (IDR). Mutations in the putative IDR eliminated phospho-CPB-dependent Plk4 condensation, Plk4's symmetry-breaking ring-to-dot relocalization, and its ensuing centriole biogenesis. In a related experiment, CPB phosphorylation also promoted Plk4's dissociation from the Cep152 tether while binding to downstream STIL, thus allowing Plk4 condensate to serve as an assembling body for centriole biogenesis. Thus, we propose that Plk4 is an unparalleled kinase that harnesses its KD-dependent autophosphorylation onto its CPB to induce phospho-CPB-dependent physicochemical condensation. This unique capacity enables Plk4 to phase-separate into a matrix-like body that can amass downstream components critical for procentriole assembly.

P1952/B195

Dynamic Remodeling of Microtubule-Organizing Centers and Their Requirements for Zika Virus Proliferation.

R. A. Buchwalter[1], S. C. Ogden[2], C. Hammack[2], C. Cabrera[1], J. A. Salerno[1], E. Weiland[1], J. V. Chen[1], H. Tang[2], T. L. Megraw[1]; [1]Florida State University, Department of Biomedical Sciences, Tallahassee, FL, [2]Florida State University, Department of Biological Science, Tallahassee, FL.

The 2015-2016 outbreaks of the Zika virus (ZIKV) in the Americas resulted in a public health crisis due to its links to microcephaly and additional birth defects collectively known as congenital Zika syndrome. ZIKV is a member of the single-stranded RNA Flavivirus family, which includes Dengue and West Nile viruses, that are mainly transmitted to humans through mosquitos. Inherited forms of microcephaly are due to recessive mutations mostly in centrosome protein-encoding genes. However, the functional link between centrosomes and the development of microcephaly remains unclear. The centrosome and the Golgi Apparatus are involved in the formation and anchoring of microtubules in human cells, and they function as microtubule organizing centers (MTOCs). Due to the connection to the centrosome in the inherited forms of microcephaly, we investigated how the cell's MTOCs and their MTs are used by ZIKV to facilitate viral infection and replication. During the Flavivirus infection cycle, the ER rearranges to form a compact structure called a viroplasm that is responsible for virus replication and assembly, and MTs contribute to its formation. We show that the ZIKV viroplasm is toroidal shaped, and MTs form a cage-like structure around the viroplasm and in a dense bundle located at its hollow inner core. We also found a close association between the centrosome and the Golgi MTOC with the viroplasm. The Golgi surrounds the outside of the viroplasm. In addition, the centrosome and a Golgi cluster is located at the hollow core of the ZIKV viroplasm, and the combined MTOCs' activities are elevated at this core. As both MTOCs localize to the area of ZIKV replication in infected cells, we tested the requirement of the centrosome and the Golgi MTOC for viroplasm formation during infection. Viroplasm formation still occurs in cells without the centrosome and without the Golgi MTOC; however, efficiency of infection and viral release may be affected. Though we observe a viroplasm in cells without centrosomes, the formation of its inner core is disrupted. In addition to the host MTOCs' involvement, we investigated which ZIKV factors contribute towards viroplasm organization. Viral proteins play a role in the subcellular rearrangements that occur during infection, and we investigated if individual ZIKV proteins affect the viroplasm development. We have found that a single ZIKV protein was sufficient to assemble a viroplasm-like structure complete with a toroidal shape surrounding the centrosome/Golgi MTOC complex.

P1953/B196

Superresolution Microscopy Reveals Coupling between Mammalian Centriole Subdistal Appendages and Distal Appendages.

W. Chong[1], W. Wang[2], T. Chang[1], T. Chiu[1], Y. Liu[1], M. Tsou[3], T. Yang[4,5], **J. Liao**[1]; [1]Institute of Atomic and Molecular Sciences, Academia Sinica, Taipei, TAIWAN, [2]Institute of Biochemistry and Molecular Biology, National Yang Ming University, Taipei, TAIWAN, [3]Cell Biology Program, Memorial Sloan-Kettering Cancer Center, New York, NY, [4]Department of Electrical Engineering, National Taiwan University, Taipei, TAIWAN, [5]Graduate Institute of Biomedical Electronics and Bioinformatics, National Taiwan University, Taipei, TAIWAN.

The unique feature of the mammalian mother centriole is the existence of distal appendages (DAPs) and subdistal appendages (sDAPs) at its distal end. Specifically, the structure of sDAPs and their relationship with DAPs are less well understood despite their obvious presence. Here, we use super-resolution microscopy to map the molecular architecture of the sDAP protein complex. In addition to the ordered organization relatively consistent with the hierarchical relationship known from genetic studies, we find unexpected features, including two-layer arrangements of ODF2 and CEP89, with one layer associated with DAPs and the other layer associated with sDAPs. Depleting DAPs by CRISPR-Cas9 knock-out of CEP83 removes the distal layer of ODF2; while sDAP depletion by knocking out CEP128 removes the proximal layer of ODF2 and CEP89. Thus, these two proteins play dual roles in DAPs and sDAPs. Furthermore, DAP depletion relaxes the longitudinal occupancy of ninein to span over the space of potential DAP sites and sDAP sites, suggesting that sDAP localization is partially dictated by the structure of DAPs. sDAPs also set the distal border of γ-tubulin at the G0 phase, where γ-tubulins are confined around the mother centriole. Microtubules (MTs) broadly occupy space around the centrioles, with some extending from DAPs and sDAPs. Depleting sDAPs eliminates a subset of MTs originated from the location close to the sDAP region, providing direct evidence of the MT anchoring role of sDAPs. Together, super-resolution microscopy enables the structural and functional understanding of sDAPs, surprisingly illustrating the coupling between DAPs and sDAPs and assuring that DAPs and sDAPs are not entirely independent.

P1954/B197

Material Aging Causes Centrosome Weakening and Disassembly during Mitotic Exit during Mitotic Exit.

V. Tran, J. Woodruff; UT Southwestern Medical Center, Dallas, TX.

Centrosomes are membrane-less organelles that must resist microtubule-mediated forces for mitotic chromosome segregation. During mitotic exit, however, centrosomes are deformed and fractured by those same forces, which is a key step in centrosome disassembly. How the mechanical properties of centrosomes are tuned during the cell cycle is not known. Here, we used optically-induced flow perturbations to determine the molecular basis of centrosome deformation resistance and fracture resistance in *C. elegans* embryos. Induced flows caused time-dependent deformation and eventual fracture of the centrosome scaffold. Centrosome resistance to these flows peaked in metaphase, then declined sharply in anaphase, ~150s prior to natural disassembly. This mechanical transition depended on PP2A phosphatase and correlated with the departure of PLK-1 (Polo Kinase homolog) and SPD-2 (Cep192 homolog) from centrosomes. Acute inactivation of PLK-1 or SPD-2 made the centrosome scaffold weak and brittle in metaphase and led to premature disassembly. In vitro, PLK-1 and SPD-2

protected centrosome scaffolds from force-induced disassembly, suggesting that they directly reinforce the centrosome scaffold. In anaphase, centrosomes undergo material aging, whereby they lose PLK-1 and SPD-2andtransition from a strong, ductile state to a weak, brittle state that enables centrosome disassembly. Thus, centrosome mechanical properties are tuned via compositional balance of PLK-1 and SPD-2 versus PP2A.

Cell Polarity Dependent Centrosome Separation in the *C. Elegans* Embryo.

A. Bondaz[1], L. Cirillo[1], P. Meraldi[1], **M. Gotta**[2]; [1]University of Geneva, Geneva, SWITZERLAND, [2]University of Geneva, University of Geneva, SWITZERLAND.

In animal cells, faithful chromosome segregation depends on the assembly of a bipolar spindle driven by the timely separation of the two centrosomes. Here we took advantage of the highly stereotypical cell divisions in *C. elegans* embryos to identify new regulators of centrosome separation. We find that at the two-cell stage the somatic AB cell initiates centrosome separation later than the germline P1 cell. This difference is strongly exacerbated by the depletion of the kinesin-13 KLP-7/MCAK, resulting in incomplete centrosome separation at NEBD in AB but not P1. Our genetic and cell biology data indicate that this phenotype depends on cell polarity via the enrichment in AB of the mitotic kinase PLK-1, which itself limits the cortical localization of the dynein-binding NuMA orthologue LIN-5. We postulate that the timely separation of centrosomes is regulated in a cell type dependent manner.

P1956/B199

CPAP Is Essential for Centriole Biogenesis but Not for Their Maintenance and PCM Organization.

K. Lukasik, D. Kong, J. Loncarek; Laboratory of Protein Dynamics and Signaling, NIH/NCI/CCR, Frederick, MD.

Centrosomes are major microtubule organizing centers in human cells. They are comprised of a microtubule-based core, centriole, and a surrounding pericentriolar material (PCM). CPAP is a centrosomal protein which mediates centriole initiation, elongation and PCM recruitment, and is localized to three distinct centrosomal fractions. One fraction is localized in mother centriole lumen, the second on procentrioles, and the third in pericentriolar material. Here we explore the functional interdependency of three different fractions of CPAP during centriole initiation, elongation, centriole disengagement and mitosis. We employ genetics and various modalities of microscopy including Stochastic optical reconstruction microscopy (STORM), to analyze the intra-centrosomal distribution and functional requirements of specific CPAP fractions. Using siRNA and an auxin-degradable system, we generated centrioles which lacked specific fractions of CPAP, allowing us to analyze them separately. We found that three CPAP fractions localize to the centrosome independently and are functionally independent. We find that neither PCM nor mother-centriole luminal CPAP fraction is needed for the process of procentriole duplication, elongation and disengagement. In addition, the removal of the PCM CPAP fraction does not affect the localization of inner and outer PCM components during interphase and in mitosis. Further, cytosolic and centrosome-dependent microtubule nucleation activity and mitotic progression were not perturbed in the absence of the PCM component of CPAP. Finally, a chronic depletion of CPAP to ~5% of its control physiological level appeared inconsequential for the maintenance of mature centrioles and centrosomes. In summary, we show functional independency of three centrosomal CPAP fractions, which corroborate the original reports suggesting that CPAP in

human cells is dispensable for the assembly of mitotic centrosomes but is critical for centriole structuring.

Characterizing the Role of Mps1 and Erk in MAPK Mediated Centrosome Amplification.

J. L. Thomas, H. A. Fisk; the Ohio State University, Columbus, OH.

The MAPK signaling pathway is a phosphorylation cascade, consisting of RAS, RAF, MEK, and ERK, and is involved in a number of cellular processes including cell proliferation, differentiation, and growth. A number of constitutively active (CA) MAPK mutations have been identified in many cancers. However, the role of the MAPK proteins in the centrosome cycle is not well understood. Centrosome amplification has been shown to lead to genomic instability, both of which are common hallmarks of cancer. Previous work has shown that cancers containing CA B-RAF mutations contain supernumerary centrosomes and overexpression of CA B-RAF results in centrosome amplification. Additionally, CA BRAF dependent centrosome amplification has been linked to stabilization of a protein called Mps1, a dual functionality kinase that has roles in both the mitotic checkpoint and centrosome cycle. It has been demonstrated that MAPK signaling is important for localization of Mps1 at the mitotic checkpoint; however, less is known about how MAPK signaling interacts with Mps1 at the centrosome. We therefore aim to further characterize the relationship between Mps1 and MAPK signaling to better understand how supernumerary centrosomes form in cancer cells. To address this question, we assessed the localization of MAPK proteins, identified protein-binding partners, and generated mutations to increase the activity of MAPK proteins and assessed their effect on centrosome amplification. We have found that phospho(p)- and total ERK localizes to centrosomes in both interphase and mitotic cells and that localization is increased under prolonged S-phase arrest. Further, the amount of pERK accumulated at centrosomes increased more than two-fold when arrested in prolonged S-phase. Mps1 and ERK1/2 show reciprocal co-immunoprecipitation (IP), but MEK and B-RAF do not co-IP with Mps1. In order to explore the relationship between ERK and Mps1 on centrosomes, a mutant version of ERK, ERK L75P, S153D, demonstrating increased phosphorylation activity was generated. ERK L75P, S153D caused an increase in centrosome amplification over wildtype ERK in an Mps1-dependent manner. In conclusion, we have found that (p)ERK localizes to centrosomes, which is enhanced during a prolonged S-phase. ERK binds to Mps1 and ERK L75P, S153D causes Mps1-dependant centrosome amplification. This work greatly adds to the mechanistic understanding of how the MAPK pathway contributes to centrosome amplification in cancer. Further, given that our findings suggest that Mps1 is essential for MAPK induced centrosome amplification, Mps1 may be used as a potential therapeutic target in treating patients with activating mutations in the MAPK pathway.

P1958/B201

Disruption of Centriolin Impairs Differentiation in Rhabdomyosarcoma Cells.

A. Cornett, C. Boyle, V. Ursu, K. DeMars, Z. Gromley, A. Gromley; Lincoln Memorial University-DeBusk College of Osteopathic Medicine, Harrogate, TN.

Rhabdomyosarcoma is the most common soft tissue cancer in children, arising from defects in myoblast differentiation. Previous studies have suggested that this differentiation process may be controlled by primary cilia, structures in the myoblasts that arise from the centrosome. However, it is not clear what factors in the primary cilia are required for the regulation of this process. Centriolin is an integral

component of both the centrosome and the primary cilia, suggesting that this protein may play an important role in myogenesis. In an attempt to identify centriolin's role in differentiation of rhabdomyosarcoma cells, the CRISPR/Cas9 gene editing system was used to eliminate the centriolin gene in cultured rhabdomyosarcoma cells and normal skeletal muscle cells, and the ability of these cells to differentiate was assayed. Immunofluorescence staining with antibodies against myosin heavy chain was used to indicate differentiation, and centriolin antibody was used to verify loss of this protein. Initial findings suggest that centriolin may play an essential role in differentiation, as disruption of centriolin leads to fewer cell aggregates and the absence of myogenic morphological characteristics, both indicators of ineffective differentiation. To determine the fate of the cells following loss of centriolin, Ki67 levels were examined. Ki67 levels were determined to be lower in both rhabdomyosarcoma cells and normal skeletal muscle cells lacking centriolin, indicating these cells are arrested and that this may play a role in the cells' inability to properly differentiate. Future studies are aimed to identifying the molecular mechanisms underlying centriolin's role in regulating this process.

P1959/B202

Emerging Role of Genetic Modifiers in the Etiology of Primary Microcephaly.

S. Seema Waseem[1,2,3], A. Moawia[1,2,4], M. S. Hussain[1,2,3], S. M. Baig[4], A. A. Noegel[2,3], P. Nuernberg[1,3]; [1]Cologne Center for Genomics, University of Cologne, Cologne, GERMANY, [2]Institute for Biochemistry I, University of Cologne, Cologne, GERMANY, [3]Center for Molecular Medicine Cologne (CMMC), University of Cologne, Cologne, GERMANY, [4]Human Molecular Genetics Laboratory, Health Biotechnology Division, National Institute for Biotechnology and Genetic Engineering (NIBGE), Faisalabad, PAKISTAN.

Introduction Primary microcephaly (PM) is a neurodevelopmental defect characterized by a reduction in the cerebral cortex and mild intellectual disability (ID). The incidence for PM is 1/10,000 depending on ethnicity and the rate of consanguinity. There are approximately 25 genes known to cause PM. Besides small cerebral cortex and ID, several studies also report on the severe phenotypes of PM like short stature, extreme ID, speech impairment, salivation and seizures. But the underlying molecular mechanism for severity of such phenotypes is still unexplained. Up to now, little attention has been paid to genetic modifiers in case of PM that could be the culprit for severity of PM phenotypes. To address this question, we recruited families with PM from Pakistan. In our cohort, some of the families show significant interfamilial phenotypic variability. Here we report on a PM family with affected members in two different loops. Affected members of both loops of the same family differ in their phenotypes. Affected siblings in loop 2 show reduced height, severe ID, salivation, and speech impairment along with PM, but the patients in the loop 1 have only PM. Therefore, in this study we aim to unravel the novel role of genetic modifiers in causing the severity of phenotype in PM **Results** Sequencing of two patients each from both loops with customized gene panel "Mendeliome" (TruSight One gene panel from Illumina) demonstrated a novel homozygous *CENPJ* mutation (c.3586G>A; p.Asp1196Asn) in affected siblings of both loops and a reported heterozygous mutation of *PCNT* (c.5767C>T; p.Arg1923*) underlying microcephalic primordial dwarfism detected only in patients of loop 2 suggesting a role for *PCNT* as a genetic modifier. This data was further supported by observing severe cellular phenotypes like abnormal numbers of centrioles, large centrosome-nucleus distance, fragmented/supernumerary centrosomes as well as abnormal shape of nucleus, disorganized microtubules networks and reduced amount of CENP-J as well as PCNT detected by both immunofluorescence and western blotting in primary fibroblasts derived from patient of loop 2 only. Whereas, fibroblasts of patient from loop 1 did not show the cellular phenotypes observed in loop 2 except with reduced amount of CENP-J and

abnormal number of centrioles but less severe as compared to the cells from loop 2. Therefore, we propose that genetic factors may contribute to modify the severity of the *CENPJ* phenotype and, although based on suggestive cellular evidence, *PCNT* could function as one of such factors **Perspectives** This research could provide scientific community with new insights for consideration of genetic factors when analyzing the data into account for PM. In addition, it could also help in delineating the underlying pathways in the etiology of PM

P1960/B203
Microtubule-dependent Cytoplasmic MTOCs are Necessary for Spindle an choring and Ppositioning During Oocyte Meiosis**.**
A. Balboula; University of Missouri, Columbia, MO.

During oocyte meiosis I (MI), the spindle is assembled at a central position prior to its timely migration towards the cortex. Such asymmetrical positioning of the spindle following migration is crucial to extrude a small polar body (PB) and thereby retain a large proportion of the cytoplasm necessary to support early embryonic development. Remarkably, how these critical events-— spindle positioning and migration—are regulated during MI remains controversial and largely unknown. In mitotic cells, spindle positioning relies on centrosome-mediated astral microtubules (MTs). Interestingly, mammalian oocytes lack classic centrosomes and instead contain numerous MT organizing centers (MTOCs), whose only known function is to assemble the spindle. Whether MTOCs have other functions during MI is largely unknown. We fluorescently labeled MTOCs using AURKA-GFP or Cep192-GFP followed by time-lapse confocal microscopy. Interestingly, we observed two different sets of MTOCs: those that are known to form spindle poles (polar MTOCs; pMTOCs) and those that remain free in the cytoplasm (cytoplasmic MTOCs; cyMTOCs). The role of cyMTOCs during MI is unknown. We confirmed that these fluorescently-labeled structures in the cytoplasm are indeed MTOCs as evidenced by their co-immunostaining with γ-tubulin and their ability to nucleate MTs when exposed to taxol. Using time-lapse confocal microscopy, we found that pMTOCs have similar kinetics and behaviors to the cyMTOCs; suggesting that the latter might connect to pMTOCs. Importantly, using super-resolution microscopy, we found that cyMTOCs are connected to both the oocyte cortex and pMTOCs (at spindle poles) through MT connections suggesting that cyMTOCs anchor pMTOCs to regulate spindle positioning. To investigate this hypothesis, we used 2-photon laser ablation to deplete cyMTOCs followed by time-lapse confocal imaging of live oocytes. Strikingly, depletion of cyMTOCs results in severe defects in spindle positioning and spindle pole integrity. Our results suggest a novel model for spindle positioning during MI, in a large cell with short astral MTs, where MTs emanating from pMTOCs attach to cyMTOCs; which in turn act as amplifying sites for MT nucleation, anchoring pMTOCs to the cell cortex.

M2I-1, an Inhibitor of CDC20 and MAD2 Interaction, Increases Cancer Cell Lines Sensitivities to Anti-mitotic Drugs through Mcl-1s Pathway.

N. Dang; Institute for Cell and Molecular Biosciences, Newcastle University, Newcastle Upon Tyne, UNITED KINGDOM.

Background: Drugs such as taxanes, epothilones, and vinca alkaloids are widely used in the treatment of breast, ovarian, and lung cancers but come with major side effects such as neuropathy and loss of neutrophils and as single agents have a lack of efficacy. M2I-1 (MAD2 inhibitor-1) has been shown to disrupt the CDC20-MAD2 interaction, and consequently, the assembly of the mitotic checkpoint complex (MCC). **Results**: We report here that M2I-1 can significantly increase the sensitivity of several cancer cell lines to anti-mitotic drugs, with cell death occurring after a prolonged mitotic arrest. In the presence of nocodazole or taxol combined with M2I-1 cell death is triggered by the premature degradation of Cyclin B1, the perturbation of the microtubule network, and an increase in the level of the pro-apoptotic protein MCL-1s combined with a marginal increase in the level of NOXA. The elevated level of MCL-1s and the marginally increased NOXA antagonized the increased level of MCL-1, a pro-survival protein of the Bcl-2 family. **Conclusion**: Our results provide some important molecular mechanisms for understanding the relationship between the mitotic checkpoint and programmed cell death and demonstrate that M2I-1 exhibits antitumor activity in the presence of current anti-mitotic drugs such as taxol and nocodazole and has the potential to be developed as an anticancer agent.

P1962/B205

Klp2 and Ase1 Synergize to Maintain Meiotic Spindle Stability during Metaphase I.

F. Dong, 230031; the university of science and technology of China, HeFei, CHINA.

The spindle apparatus segregates bi-oriented sister chromatids during mitosis but mono-oriented homologous chromosomes during meiosis I. It has remained unclear if similar molecular mechanisms operate to regulate spindle dynamics during mitosis and meiosis I. Here, we employed live-cell microscopy to compare the spindle dynamics of mitosis and meiosis I in fission yeast cells and demonstrated that the metaphase spindle length is ~two-fold longer in meiotic I cells than in mitotic cells and that the spindle elongates faster during meiosis I than mitosis. We further demonstrated that the conserved kinesin-14 motor Klp2 plays a specific role in maintaining metaphase spindle length during meiosis I, but not during mitosis. Moreover, the maintenance of metaphase spindle stability during meiosis I requires the synergism between Klp2 and the conserved microtubule crosslinker Ase1 as the absence of both proteins causes exacerbated defects in metaphase spindle stability. The synergism is not necessary for regulating mitotic spindle dynamics. Hence, our work reveals a new molecular mechanism underlying meiotic spindle dynamics and provides insights into understanding differential regulation of meiotic and mitotic events.

P1963/B206

One Stone Two Birds-Regulation of Cell Division by Nuclear Transport Factors.

C. Chen[1], **T. Huang**[1], C. Chen[2], C. Cédric Grauffel[3], Y. Pien[2], Y. Shimamoto[4], C. Lim[5], S. Tsai[2], K. Hsia[1]; [1]Institute of Molecular Biology, Academia Sinica, Taipei, TAIWAN, [2]Department of Life Science, National Taiwan University, Taipei, TAIWAN, [3]Institute of Biomedical Sciences, Academia Sinica, Taipei, TAIWAN, [4]2Center for Frontier Research, National Institute of Genetics, Shizuoka, JAPAN, [5]3Institute of Biomedical Sciences, Academia Sinica, Taipei, TAIWAN.

In conjunction with transport factors such as Importin-α/-β, the small GTPase Ran plays a crucial role in the delivery of macromolecules between the nucleus and cytoplasm during interphase. Importantly, assembly of the mitotic spindle is also orchestrated by the Ran pathway. Ran functions by modulating the interaction between transport factors and the spindle assembly factors (SAFs) that control many aspects of microtubule behavior, such as microtubule nucleation, stabilization and bundling. First, our work provides molecular details of how transport factors regulate the NuMA, one of SAFs, functioning facilitating assembly of higher-order microtubule structures, further illuminating how Ran-governed transport factors regulate diverse SAFs and accommodate various cell demands. Secondly, we further report a Ran pathway-independent attenuation mechanism that allows transport factor, Importin-α, to suppress the vesicle fusion mediated by p115 (a vesicular tethering factor) and required for mitotic Golgi disassembly. During early mitosis, Ran releases Importin-α from SAFs (e.g. NuMA), activating the mitotic functions of these SAFs and in turn promoting mitotic spindle assembly. Thus, the Importin-α liberated by RanGTP can instead interact with a Golgi associated protein, GM130, thereby suppressing p115-mediated vesicle-Golgi fusion and allowing Golgi disassembly. Altogether, our findings illuminate that the Ran and kinase-phosphatase pathways regulate multiple aspects of mitosis coordinated by nuclear transport factors (e.g. spindle assembly, Golgi disassembly).

P1964/B207

A Mitotic Screen in Indian Muntjac Cells Reveals a Role for Augmin in Kinetochore Fiber Maturation.

A. C. Almeida[1], D. Drpic[1], A. Pereira[1], J. Damas[2], H. A. Lewin[3], D. M. Larkin[2], H. Maiato[1]; [1]Instituto de Investigação e Inovação em Saúde, i3S, Porto, PORTUGAL, [2]Royal Veterinary College, London, UNITED KINGDOM, [3]University of California, Davis, CA.

Accurate chromosome segregation during mitosis is essential for life and relies on the activity of hundreds of proteins. However, due to technical limitations or limitations of the available model systems, some of their functions might have been overlooked. Here we propose to establish a unique placental mammal model system that combines the powerful genetic tools and low chromosome number of fission yeast and Drosophila melanogaster, with the exceptional cytological features of a rat kangaroo cell. This system is based on hTERT-immortalized fibroblasts from a female of the Indian Muntjac, a small deer which has the lowest known chromosome number (n=3) in mammals. Due to centromere-telomere and centromere-centromere tandem fusions during evolution, Indian Muntjac chromosomes are large and morphologically distinct, with one pair of acrocentric chromosomes (chromosomes 3+X) containing an unusually large compound kinetochore. Here we used an siRNA library to perturb the function of mitotic proteins in this system and investigated the respective mitotic phenotypes using spinning-disk confocal live-cell recordings and super resolution STED microscopy. With these approaches, combined with western blot analysis, we were able to confirm and investigate 56 RNAi phenotypes. The vast majority revealed that the molecular landscape required for mitosis is

conserved with other placental mammals, including humans, validating the Indian muntjac as a powerful model system. However, due to some specific features associated with the large kinetochore size of Indian muntjac, we uncovered a role for the Augmin complex, which has been implicated in microtubule-dependent microtubule amplification, in k-fiber maturation. This project contributes with a detailed phenotypic analysis of mitosis in Indian muntjac, offering a powerful resource open to the cell division community. Ultimately, this systematic analysis discloses overlooked functional roles for known mitotic proteins, while opening questions that were not addressable in more complex eukaryotic model systems.

P1965/B208

PLK1 Is Required for Normal Chromosome Compaction and Microtubule Organization in Mouse Oocytes.

T. M. Little, P. W. Jordan; Johns Hopkins University, Baltimore, MD.

Errors in meiosis can result in genetic mutation and chromosome missegregation. Mammalian meiosis is sexually dimorphic and presents unique temporal challenges for oogenesis. Oocytes initiate meiosis during embryogenesis, then enter a prolonged late prophase (dictyate) arrest. Immediately prior to ovulation, oocytes will undergo nuclear envelope breakdown, chromosome condensation, and then homologous chromosomes segregate to complete meiosis I. Therefore, oocytes remain arrested at dictyate for long periods of time, which varies depending on when an oocyte is matured for ovulation. It is critical for oocytes to maintain their capacity to condense and segregate their chromosomes during dictyate arrest, but it is known that these events can be compromised, particularly in oocytes that have remained arrested for longer periods of time. Several cell cycle kinases have been linked with roles in coordinating events during meiotic resumption, including polo-like kinases (PLK). Mammals express four kinase-proficient PLKs, (PLK1-4). Studies assessing the role of mammalian PLK1 have previously relied on RNA knockdown and kinase inhibition approaches, as *Plk1* null mutations are embryonically lethal. To further study the role of PLK1 in mammalian meiosis, we have developed a *Plk1* conditional knockout mouse line. This novel genetic model specifically mutates *Plk1* in during meiotic prophase I, prior to the dictyate arrest. *Plk1* conditional knockout females are infertile, despite having a normal number of oocytes that successfully undergo nuclear envelope breakdown. A significant portion of these oocytes fail to maintain chromosome compaction, with defective cohesin and condensin localization. At the point of metaphase I, *Plk1*-depleted oocytes form either a monopolar microtubule organizing center or an abnormally small bipolar spindle, with aberrant localization of microtubule organizing center components. We conclude that PLK1 is essential for the post-resumption stages of oogenesis.

P1966/B209

Whole Exome Sequencing Implicates *CEP120* in Human an euploidy Conception Risk.

K. Tyc[1], **W. El Yakoubi**[1], A. Bag[1], J. Landis[2], Y. Zhan[2], N. Treff[2], R. Scott[3], X. Tao[2], K. Schindler[1], J. Xing[1]; [1]Rutgers the State Unversity of NJ, Piscataway, NJ, [2]Foundation for embryonic Competence, Basking Ridge, NJ, [3]Reproductive Medecine Associate of New Jersey, Basking Ridge, NJ.

Human infertility is a significant public health problem in the world that affects women, men and couples. In United States, surveys estimate that around 10-15% of the population struggle with infertility. In females, around the half of infertility cases are due to distinct phenotypes (i.e., physical abnormalities, polycystic ovarian syndrome, Perrault syndrome, etc), and at least 35% of cases have an

underlying genetic basis. Thus, determining the genetic drivers of infertility is important for a greater insight into the origins of this issue. The key event important for human reproduction is Meiosis, a specialized type of cell division producing female and male gametes through segregation of homologous chromosomes and sister chromatids during two subsequent meiotic divisions. Compared to male meiosis, female meiosis is highly error prone. Mis-segregation of chromosomes leads to the formation of around 20% of aneuploid eggs in young females and this rate drastically increases with advanced maternal age. Although advancing maternal age is an established contributing factor, some women undergoing in *vitro* fertilization (IVF) procedures have extreme aneuploid conception rates for their age. These observations indicate that other factors, such as maternal genetic variants, also contribute to infertility, irrespective of age. To identify genetic variants that could affect female egg quality we performed whole-exome sequencing on women that produced a high proportion of aneuploid blastocysts as determined by preimplantation genetic testing for aneuploidy following IVF. In these women, we identified an enrichment of coding variants of genes involved in cytoskeleton and microtubule formation. Using a mouse oocytes model, we validated the biological significance of a variant rs2303720 within the *Centrosomal protein 120* (CEP120) during meiotic maturation. We found that ectopic expression of CEP120 p.Arg947His caused decreased spindle microtubule nucleation efficiency and increased the incidence of aneuploidy at metaphase II. Importantly, this *CEP120* variant encodes a protein that has a dominant negative function. This study is the first step in identifying genes and mutations contributing to the risk of maternal aneuploidy and could allow prescreening of patients that have better chances to benefit from preimplantation genetic testing.

P1967/B210

Phospho-dependent Regulation of Competitive Interactions among Assembly Factors during Centriole Duplication in *C. Elegans*.

P. Sankaralingam, K. O'Connell; National Institute of Diabetes and Digestive and Kidney Diseases, NIH, Bethesda, MD.

Centrioles are microtubule-based organelles that aid in bipolar spindle formation and serve as basal bodies for nucleating cilia. Centriole duplication is a tightly controlled event in dividing cells that happens only once each cell cycle and mis-regulation of this process has been linked to diseases such as cancer and primary microcephaly. Studies in *C. elegans* have identified a set of core conserved centriole proteins: SPD-2, ZYG-1, SAS-5, SAS-6, and SAS-4. The overall theme of centriole assembly is conserved across genera, with only minor variations. Although general details of the assembly process have been worked out, the molecular aspects of the process are still not completely understood. The factors that trigger centriole duplication, the critical substrates of the kinase ZYG-1, and the importance of substrate phosphorylation are some of the intense areas of research. Unfortunately, difficulty in procuring recombinant core centriolar proteins in soluble form has hampered in *vitro* studies designed to address these questions. We here show that ZYG-1, SAS-6, SAS-5 and SAS-4 can be obtained in their functional form from *E. coli*. Although each of the proteins were insoluble initially, we were able to efficiently refold them in *vitro* under standardized conditions. Based on biophysical and functional studies, these proteins have attained their native conformation. Using the recombinant proteins, we discovered a novel interaction between ZYG-1 and SAS-5 and mapped the regions necessary for their binding. We find that while ZYG-1 can phosphorylate SAS-4, -5, and -6 in vitro, SAS-5 appears to be the preferred substrate. Further we find that many of the phosphorylated residues in SAS-5 are conserved among nematodes. Of particular interest, some of these residues are part of a larger conserved motif in the N-

terminus. Surprisingly, we found that this motif is required to mediate interaction of SAS-5 with both SAS-4 and ZYG-1, and that the precise pattern of phosphorylation within this domain, dictates the choice of ZYG-1 or SAS-4 as a binding partner. Using Cas9-mediated mutagenesis, we show that blocking phosphorylation of these residues results in sporadic centriole duplication failure and embryonic lethality. We hypothesize that phosphorylation of SAS-5 by ZYG-1 within this motif is necessary to specify a mutually exclusive mode of interaction of SAS-5 with ZYG-1 and SAS-4, and that this phosphorylation-dependent interaction contributes to the fidelity of centriole duplication.

P1968/B211

From Parts to Processes: in *Vitro* Reconstitution of Branched Microtubule Nucleation.

A. Tariq, L. Green, J. G. Jeynes, C. Soeller, R. Chait, **J. G. Wakefield**; University of Exeter, Exeter, UNITED KINGDOM.

Eukaryotic cell division requires the mitotic spindle, a microtubule (MT)-based structure which accurately aligns and segregates duplicated chromosomes. The dynamics of spindle formation are determined primarily by correctly localising the MT nucleator, γ-Tubulin Ring Complex (γ-TuRC), within the cell. A conserved MT-associated protein complex, Augmin, recruits γ-TuRC to pre-existing spindle MTs, amplifying their number, in an essential cellular phenomenon termed “branched” MT nucleation. Here, we purify endogenous, GFP-tagged Augmin and γ-TuRC from *Drosophila* embryos to near homogeneity using a novel one-step affinity technique; **cl**eavable **A**ffinity **P**urification (cl-AP). We demonstrate that, in *vitro*, while Augmin alone does not affect Tubulin polymerisation dynamics, it stimulates γ-TuRC-dependent MT nucleation. We also show the combined nucleating activity of mitotic Augmin-γ-TuRC is greater when complexes are isolated from mitotic, rather than cycling cells, suggesting this phenomenon is regulated in *vivo in* a cell cycle-dependent manner. We also assemble and visualise the MT-Augmin-γ-TuRC-MT junction using light microscopy, conclusively demonstrating the polarity-specific nature of the interaction. Our work therefore reconstitutes branched MT nucleation. It also provides a powerful synthetic approach with which to investigate the emergence of cellular phenomena, such as mitotic spindle formation, from component parts.

P1969/B212

The Value of Drawing in Scientific Practice: New Representations of Cell Division and Process Epistemology.

G. An derson, J. Dupre, **J. G. Wakefield**; University of Exeter, Exeter, UNITED KINGDOM.

Modern scientific practice reflects the current value the research community places on quantifying biological (cellular) phenomena and in representing it within a mechanical framework. However, the philosophical thesis that all living systems should be envisaged dynamically raises pressing questions about how they can be best represented, qualitatively. Here, we describe a collaborative project between a philosopher of biology, an artist and a cell biologist, focusing on the process of cell division. A series of ‘Drawing Labs’ and one-to-one sessions between the artist, the cell biologist and their research group, designed to uncover implicit and accumulated understanding, and reinforced by discussion with the philosopher, has resulted in the generation of drawings which attempt to represent the whole process of cell division in one connected image. This, in turn, has led us to reappraise the value of drawing in biological practice. We have begun to reincorporate observational, experiential and imaginative exercises and practices within microscopy-based methodologies, arguing that a more

holistic scientific approach can yield new knowledge of those processes and stimulate new and relevant hypotheses.

P1970/B213

Dual Spindle Assembly in Mammalian Zygotes Is Independent of the Presence of Centrioles.

I. Schneider[1], M. de Ruijter-Villani[2], J. M. Hossain[1], S. R. Correia[1], J. Reichmann[1], J. Ellenberg[1]; [1]EMBL, Heidelberg, GERMANY, [2]Utrecht University, Utrecht, NETHERLANDS.

Dual spindle assembly in mammalian zygotes is independent of the presence of centrioles in mammals, the genetic material from each parent is replicated in a separate pronucleus after fertilization of the egg. For a long time, it was unknown why the two sets of parental chromosomes still occupy separate compartments when united in one nucleus after the first division of the zygote. Recently, we discovered that in the first murine embryonic mitosis two individual bipolar spindles form around each zygotic pronucleus, which independently congress chromosomes during pro-metaphase and only later align to segregate the two parental genomes in parallel. The formation of exactly two bi-polar spindles in one cell furthermore suggested that spindle assembly is not entirely driven by self-organization of many randomly distributed cytoplasmic microtubule organizing centers (MTOCs) as in the oocyte, but that chromosomal nucleation is likely to play an important role in the zygote. Before defining this mechanism further, we wondered if dual spindle assembly and the chromosomal nucleation pathway are indeed generally relevant for mammals. This is especially important to address in non-rodent species where zygotes inherit centrioles from the sperm and thus have only two MTOCs in contrast to the many present in murine embryos. To answer this question, we set up the in *vitro* maturation and fertilization of oocytes and mRNA microinjection to express GFP marker proteins in zygotes in the bovine model system, where two centrioles are inherited from the sperm like in humans. We then imaged the behavior of chromosomes and microtubules throughout the first mitotic division using an inverted light-sheet microscope developed in the group. Very interestingly, we found that despite the presence and incorporation of centrioles into the spindle, also in bovine zygotes two separate microtubule arrays frequently form around the pronuclei. Taken together, these results show that dual spindle formation is conserved both in species with multiple or only two MTOCs, and makes it very likely that a microtubule nucleation pathway originating from chromosomes plays an important role in the first embryonic division of mammals in general. By perturbing microtubule polymerization at the onset of spindle formation in mouse zygotes, we have indeed found evidence of a chromosomal nucleation pathway. We will present new data, where we further explore the nature of this nucleation as a key process that ensures faithful chromosome segregation at the beginning of mammalian life.

Air Pollution and Chromosomal Segregation: the Effect of Particulate Matter in the Spindle Assembly Checkpoint, Trough Overexpression of the Long Non-Coding RNA *NORAD*.

M. Santibáñez-Andrade, Y. Sánchez-Pérez, R. Morales-Bárcenas, C. García-Cuellar; Instituto Nacional De Cancerología (INCan) Mexico, Mexico City, MEXICO.

Background: Air pollution represents a worldwide problem, impacting in human health predominantly in major cities, where traffic or industry activities releases gases and solid particles in the air. Particulate matter of 10 micrometers or less in diameter (PM_{10}) is considered as an agent related to cardiopulmonary diseases, including lung cancer. Chromosomal segregation is controlled by the long

non-coding RNA (lncRNA) *NORAD*, as well as by spindle assembly checkpoint (SAC), in which proteins such as MAD1, MAD2, BUBR1, AURORA B and SURVIVIN orchestrate a mitosis-delay signal in order to ensure genomic instability. Alterations in SAC causes aneuploidy, a feature associated to carcinogenesis. Although PM_{10} are associated to the generation of chromosomal alterations, the impact in chromosomal segregation mechanisms has not been characterized. The **aim** of this study is to evaluate the effect of PM_{10} in the expression of the lncRNA *NORAD*, as well as the effect in the expression of SAC genes and in the control of chromosomal segregation/mitosis, using the A549 cell line (lung cancer) as our model. **Materials and methods:** Synchronized A549 cells were exposed to PM_{10} (10 µg/cm^2) for 24 h to evaluate the expression of the genes *NORAD, MAD1L1, MAD2L1, BUB1B, AURKB y BIRC5* by RT-qPCR. To serve as controls of SAC activation, cells were exposed to taxol (100nM) and doxorubicin (0.25 µg/mL). Finally, *NORAD* was inhibited by siRNAs in all treatments. **Results:** PM_{10} increases the expression of *NORAD* (53%), MAD1L1 (61%), MAD2L1 (48%), BUB1B (36%), AURKB (41%) and BIRC5 (37%) in A549 cells, compared with non-treated cells ($p<0.05$). Taxol caused an increase in mRNA levels of these genes, while doxorubicin caused only an increase in *NORAD* expression (188%). *NORAD* inhibition decreased the expression of *MAD1L1, MAD2L2 y BUB1B* in presence of PM_{10}, taxol or doxorubicin. This effect was not seen in AURKB y BIRC5. **Conclusion:** Particulate matter PM_{10} induces overexpression of the lncRNA *NORAD*, as well as the overexpression in SAC components (*MAD1L1, MAD2L2 y BUB1B*), predisposing to the generation of aneuploid cells.

P1972/B215

Myl5 Associates with the Mitotic Spindle and Is Required for Cell Division.

I. Ramirez, J. Torres; University of California, Los an geles, CA.

Cell division is a highly regulated process that ensures the proper distribution of genetic material to daughter cells. The mitotic microtubule spindle is a structure that is critical for chromosome congression and chromosome segregation, which is important for the fidelity of cell division. We recently performed a screen for mitotic microtubule interacting proteins and identified a Novel Myosin Light Chain 5 (Myl5) as a putative mitotic microtubule binding protein. Here, I present data on the characterization of Myl5 and its role in cell division. Myl5 is a myosin regulatory light chain that is upregulated in late stage cervical cancer patients and has been shown to promote metastasis. I discovered that Myl5 is essential for mitotic spindle assembly and proper cell division. Myl5 localizes to the spindle poles during mitosis and co-localizes with spindle pole proteins and Myo10 in a cell cycle dependent manner. Depletion of Myl5 led to spindle assembly defects and lagging chromosomes. Additionally, the localization of Myl5 to the spindle poles depended on microtubules and Myo10. These results elucidate a novel function for Myl5 in early spindle assembly and chromosome segregation. I have proposed a model where Myl5 is a component of the Myo10 complex, which functions to ensure the fidelity of chromosome segregation. This study is the first to highlight how Myl5 misregulation could drive carcinogenesis.

Distinct Modes of Chromosome Lagging in Meiosis-i Predict an euploidy in Mouse Oocytes.

A. I. Mihajlović, C. Mehrotra, G. FitzHarris; CRCHUM, Montreal, QC, CANADA.

The incidence of chromosome segregation errors that cause aneuploidy in the first meiotic division (MI) increases with age and is considered a major contributing factor of age-related decline in female fertility. A frequently observed segregation defect in aged oocytes is lagging anaphase chromosomes,

though the extent to which these directly contribute to aneuploidy in mouse oocytes is unclear. To understand the importance of lagging chromosomes in generation of aneuploidy, we combined live and fixed confocal fluorescence microscopy to monitor chromosomal behavior and examine their attachments to spindle-microtubules during MI. Live imaging revealed an increased incidence of lagging chromosomes during anaphase in old versus young oocytes (58.8% vs. 26.7%). Surprisingly, not all lagging chromosomes had common origin and exhibited identical behavior. Rather, we identified two distinct types of lagging chromosomes that we refer to as 'canonical', that originated from aligned bivalents, and 'non-canonical' that originated from mildly misaligned bi-oriented bivalents. Importantly, the presence of 'canonical' lagging chromosomes, reminiscent of those found in mitotic cells, strongly correlated with aneuploidy outcome of anaphase, while the presence of 'non-canonical' ones showed no correlation. Interestingly, the examination of chromosome attachment status shortly before anaphase revealed that in both young and old oocytes, the proportion of incorrect/merotelic attachments, considered responsible for producing lagging chromosomes, was negligible. However, the proportion of chromosomes lacking stable microtubule attachments remained constantly high (20-30%) throughout entire MI in old oocytes. At the onset of anaphase, all chromosomes in both groups become stably attached to microtubules, suggesting that a large proportion of chromosomes in old oocytes rapidly stabilize their attachments just prior to anaphase. We propose that this sudden formation of stable microtubule attachment might be highly error-prone thus giving rise to 'canonical' lagging chromosomes that would be responsible for aneuploidy in old oocytes.

S6k1 Drives Polycystic Kidney Downstream of Mtor by Perturbing Oriented Cell Division.

M. Bonucci[1,2], N. Kuperwasser[1,2], S. Barbe[1,2], V. Koka[1,2], D. de Villeneuve[1,2], C. Zhang[1,2], N. Srivastava[3], X. Jia[4], M. P. Stokes[4], F. Bienaimé[1,2], M. Pontoglio[1,2], F. Terzi[1,2], B. Delaval[5], M. Piel[3], M. Pende[1,2]; [1]Institut Necker Enfantes Malades INSERM U1151, Paris, FRANCE, [2]Université Paris Descartes, Sorbonne Paris Cité, Paris, FRANCE, [3]Institut Curie, PSL Research University, CNRS, UMR 144,, Paris, FRANCE, [4]Cell Signaling Technology INC, Danvers, MA, [5]CRBM, CNRS, Univ. Montpellier, Centrosome, Cilia and Pathologies Lab, Montpellier, FRANCE.

mTOR activation is essential and sufficient to cause polycystic kidneys, as observed in Tuberous Sclerosis Complex (TSC) and other genetic disorders. However, the mechanistic targets of mTOR responsible for cyst formation remain to be established. In disease models, a sharp increase of proliferation and cyst formation correlates with a dramatic loss of oriented cell division (OCD). Surprisingly, combining mouse models and 3D kidney epithelial cells culture, we find that OCD distortion is intrinsically due to S6 kinase 1 (S6K1) activation. The concomitant loss of S6K1, in *Tsc1* mutant mice, restores OCD but does not decrease hyperproliferation, leading to non-cystic harmonious hyper growth of kidneys. mTOR/S6K1 hyperactivity alters centrosome positioning in mitotic cells. Mass spectrometry-based phosphoproteomics for novel S6K1 substrates reveals targets involved in cell adhesion and the actomyosin cortex. Among them is Afadin, a known component of cell-cell junctions required to couple intercellular adhesions and cortical cues to spindle orientation. Afadin is directly phosphorylated by S6K1 and abnormally accumulates with E-cadherin at the apical surface in *Tsc1* mutant cells. Phospho-mutant Afadin rescues sphere formation in *Tsc1 and Afadin* knockout cells. By revealing two distinct branches regulating the rate and orientation of cell division downstream of mTOR, our data may reconcile the need of both cellular alterations at the onset of cystogenesis.

P1975/B218

A *Drosophila* Gene, Cg10126, Is Required for Normal Mitotic Spindle Elongation, Bipolarity and Chromosomal Stability.

B. Setu, S. Spencer; Saint Louis University, Saint Louis, MO.

Our lab is interested in epidermal growth factor receptor (EGFR)-directed cell proliferation and differentiation in developing *Drosophila*. In a screen for transcriptional targets of EGFR activity, we identified a *Drosophila* gene, CG10126, that is upregulated 10-fold in response to EGFR activation. CG10126 is orthologous to human Calcyphosine (CAPS), whose expression is upregulated in many human cancers. Subsequent work from our lab showed that CG10126 is localized to the mitotic spindle and is required for normal levels of mitosis. From these observations, we hypothesized that CG10126 might be required for spindle stability and integrity. To test this hypothesis, we knocked down CG10126 using RNAi in cultured S2 cells followed by immunocytochemistry. We then compared spindle length and phenotypes between control and knockdown cells. During analysis, we observed a significant decrease in mitotic spindle length and an increase in the number of abnormal spindle phenotypes among cells with reduced CG10126 compared to control. These results suggest CG10126 is essential for mitotic spindle stability and integrity in *Drosophila* and suggests that CAPS might also affect spindle formation and mitosis in humans.

P1976/B219

Characteristics of Spindle Assembly Checkpoint Gene Expression.

D. E. Weidemann, E. L. Esposito, E. Baybay, J. M. Rogers, C. M. Morton, S. Hauf; Virginia Tech, Blacksburg, VA.

p.p1 {margin: 0.0px 0.0px 6.0px 0.0px; font: 11.0px 'Times New Roman'; color: #404040} the mitotic checkpoint or spindle assembly checkpoint (SAC) is a signaling pathway that safeguards proper chromosome segregation. The core of the checkpoint mechanism is a network of protein-protein interactions. Proper functioning of the SAC depends on adequate protein concentrations and appropriate stoichiometries between these proteins. This makes it important to understand the underlying gene expression and its quantitative parameters. Not much is known about SAC gene expression in any organism. We have systematically mapped genetic regions that are necessary for the expression of SAC genes in fission yeast (*S. pombe*). Short upstream regions are sufficient for wild type-like expression and may consist of a core promoter only. The *mad1* and *mad2* genes, coding for proteins forming a tight complex, have unusually short 5’ UTRs. Expression of SAC genes is additionally influenced by the coding sequence. This is partly through a high fraction of “non-optimal” codons, which lowers the steady-state mRNA concentration. As in budding yeast (*S. cerevisiae*), this requires the RNA helicase Ste13 (S.c. Dhh1), suggesting that the pathway linking codon optimality to mRNA stability is conserved between budding and fission yeast. Overall, our work extends the so far largely protein-centric view of SAC function to the underlying gene expression control.

P1977/B220

ATP Availability Limits Mitotic Duration and Impacts Cell Fate Determination.

C. Ferrás[1], J. Oliveira[1], J. Monteiro[1], A. Santos[1], K. Bezstarosti[2], J. Demmers[2]; [1]IBMC/I3S, Porto, PORTUGAL, [2]Erasmus University Medical Center, Rotterdam, NETHERLANDS.

Little is known regarding the impact of energy metabolism on a prolonged mitosis and it remains unclear which processes are energy dependent under conditions that prevent SAC satisfaction (e.g. unattached kinetochores and/or in the presence of anti-mitotic chemotherapy drugs). Our data, from live cell imaging, shows that in different human cell lines mitotic energy content is a critical factor for the cell fate decision following a prolonged mitosis. We demonstrate that decreasing mitotic ATP levels, accompanied by increasing AMPK activation, leads to a switch in cell fate from mitotic cell death to slippage, thereby enhancing cell survival frequency. This increase in mitotic slippage results from a weakened SAC response, since cells treated with ATP synthesis inhibitors show a faster degradation of the mitotic substrate Cyclin B1. In agreement, inhibition of the anaphase-promoting complex/cyclosome (APC/C), the major regulator of Cyclin B1 levels during mitosis, rescues this phenotype, switching cell fate from mitotic slippage to death. We found that kinetochore localization of Mad1, CENP-E and Spindly was not significantly compromised, which suggests that the weakened SAC response was independent of kinetochore SAC signaling. Conversely, we found that *de novo* protein synthesis was decreased in energy deficient cells, and this was independent of AMPK signaling pathway. Importantly, CDC20 levels were significantly decreased which compromised mitotic checkpoint complex (MCC) production, thereby causing a premature activation of the APC/C and consequent mitotic slippage. In agreement with this, mitotic arrested cells treated with the global protein synthesis inhibitor cycloheximide phenocopy energy deficient conditions. Additionally, we found by mass spectrometry analysis and western blot analysis a global dephosphorylation of APC/C subunits 1 and 3 in energy deficient cells, suggesting a lower CDK1 activity. Critically, we demonstrated that APC3 requires continuous CDK1 dependent mitotic phosphorylation, which might contribute to strengthen SAC signaling. Overall, our data suggests that *de novo* ATP synthesis during a prolonged mitosis is required for continuous protein translation and CDK1 kinase activity. Our findings bring awareness to the limitations of using ATP deprivation as a therapeutic option in anti-tumoral strategies.

P1978/B221

Branching Microtubule Nucleation Is the Main Source of Microtubules Generated at Chromosomes in Meiotic *Xenopus* Egg Extracts.

S. U. Setru, J. W. Shaevitz, S. Petry; Princeton University, Princeton, NJ.

Microtubules are made in several places in the dividing eukaryotic cell to form the spindle. Though centrosomes are the most visually prominent hubs of microtubule nucleation in most cell types, microtubules also form at chromosomes during cell division. Indeed, chromosomal microtubules are necessary for assembling the entire spindle in cells that lack centrosomes, such as egg cells. Alongside centrosomes and chromosomes, microtubules themselves act as sites for generating new microtubules, a process referred to as branching microtubule nucleation. Chromosomal and branched microtubules are crucial for the proper alignment and segregation of chromosomes, and both rely on the GTPase RanGTP. RanGTP exists as a gradient centered around chromosomes and spurs the release of spindle assembly factors (SAFs). One of these SAFs is the protein TPX2, which stimulates branching microtubule nucleation together with the protein complex augmin and the γ-tubulin ring complex. It is currently not

understood how microtubule nucleation around chromosomes is related to branching microtubule nucleation. In this study, we investigated the relationship between chromosomal and branching microtubule nucleation. To do so, we developed an assay to watch microtubule nucleation and growth at chromosomes *ex vivo*. We attached chromosomes purified from mitotic cells to the coverslip of a microscope flow chamber and then introduced *Xenopus* egg extract. Using TIRF microscopy, we visualized that chromosomes generate branched microtubule networks. This can even occur from a single microtubule whose lattice directly overlaps or touches chromatin. These experiments define the distances and times at which branching microtubule nucleation is stimulated around chromosomes. Notably, we saw that a single microtubule captured at the kinetochores can also serve as the mother microtubule upon which daughter microtubules will nucleate. This finding helps explain how a kinetochore fiber can be made efficiently. Finally, by depleting TPX2 and augmin from the extract, we demonstrated that branched microtubules are the chief source of the microtubules that grow from chromosomes. Taken together, our experiments show that branching microtubule nucleation mediated by TPX2 and augmin is the main source of microtubules generated at chromosomes and kinetochores in *Xenopus* egg extracts. We propose that branching microtubule nucleation is the main pathway initiated at chromosomes to assemble spindles and capture kinetochores.

Cellular Limits on the an aphase Spindle Elongation Rate Ensure That Chromosomes Are Dynamically Disentangled during Cell Division.

S. Mukherjee[1], D. Tank[1], E. Davidson[2], M. McClellan[1], T. Davis[2], M. K. Gardner[1]; [1]University of Minnesota, Minneapolis, MN, [2]University of Washington, Seattle, WA.

At anaphase, elongation of the mitotic spindle facilitates the segregation of duplicated sister chromatids into future daughter cells. This elongation is driven by forces derived from the combined action of motor proteins and microtubule polymerization at the spindle midzone. In all known eukaryotes, a regulatory switch linked to the metaphase to anaphase transition greatly reduces the magnitude of force that is produced at the spindle midzone, thereby limiting the maximum speed at which the spindle elongates in anaphase. While the molecular correlates of this regulatory switch have been described in detail, the cellular consequences of exceeding this speed limit is unknown. In this study, we dramatically increased the speed of anaphase spindle elongation in budding yeast by introducing four point mutations into *Cik1*, a binding partner of the kinesin 14 motor protein Kar3. These mutations abrogate the interaction of the Kar3-Cik1 complex with the plus end microtubule tracking protein Bim1. Loss of this interaction leads to a ~3-fold increase in anaphase spindle elongation rate, without causing spindle collapse. We found that cells with these rapid anaphase spindle elongation rates were unable to properly disentangle separating chromosomes, leading to increased persistence, and more frequent breakage, of ultrafine DNA bridges. As a result, cells with rapid anaphase spindle elongation rates had increased incidence of DNA damage at anaphase, as well as delays in cytokinesis, ultimately leading to a ~6-fold increase in cells that were stalled in G2 with improper chromosomal content. Taken together, these findings describe a novel and critical protective function of the speed limit that cells impose upon the anaphase spindle elongation rate: the timing that is set by a tightly regulated anaphase spindle elongation speed is required to ensure that chromosomes are dynamically disentangled during anaphase chromosome segregation.

Mechanisms of Acentrosomal Spindle Assembly and Maintenance in *C. Elegans* Oocytes.

I. D. Wolff, S. M. Wignall; Northwestern University, Evanston, IL.

In female germ cells, or oocytes, the meiotic divisions are mediated by a microtubule-based spindle that is built and stabilized in the absence of centrosomes. While much is known about the proteins and forces underlying centrosome-based spindle assembly in mitotically-dividing cells, the molecular basis of force generation in acentrosomal spindle assembly and maintenance is far less understood. We are using *C. elegans* as an in *vivo* model to investigate these mechanisms. We previously characterized the stages of acentrosomal spindle assembly in *C. elegans* oocytes and found that KLP-18, a kinesin-12 family microtubule motor, and MESP-1, a rapidly evolving adaptor protein, are essential for outward force generation during this process. However, the biochemical mechanism of how these proteins generate force was unknown. We have now employed a combination of in *vitro and* in *vivo* approaches to gain insight into this important problem. First, we purified recombinant truncations of the KLP-18 coiled-coil stalk domain along with full length MESP-1 to use in microtubule binding experiments in *vitro.* We identified a novel non-motor microtubule binding site at the C-terminus of the KLP-18 stalk and found that this microtubule binding site is activated through MESP-1 interaction with an adjacent region of the stalk. Therefore, MESP-1 binding to KLP-18 may allow the motor to crosslink two microtubules using its motor and C-terminal microtubule binding domains, thereby generating force. To interrogate this model, we tested the importance of the KLP-18 C-terminal microtubule binding site in *vivo* using a temperature sensitive mutant strain containing two amino acid substitutions in the mapped domain. Prolonged incubation at the restrictive temperature caused spindle assembly defects that are identical to those observed following depletion of KLP-18 by RNAi; monopolar instead of bipolar spindles formed. In addition, we found that short incubation of this mutant at the restrictive temperature caused the collapse of already formed bipolar spindles into monopoles. In both cases, KLP-18 still localized to the aberrant spindles, indicating that the protein is present but non-functional. These results demonstrate that the C-terminal microtubule binding site that we identified in *vitro* is required for both spindle assembly and for the maintenance of spindle bipolarity in *vivo*. This work sets the basis for further investigation into how microtubule-associated proteins govern spindle assembly and maintenance, specifically in a system lacking centrosomes.

P1981/B224

Small Ovary Is Required for Genome Stability and Viability in Early*Drosophila*Embryos.

E. A. Castro[1], P. V. Ryder[1], L. Benner[2], B. Oliver[2], **D. A. Lerit**[1]; [1]Emory University, atlanta, GA, [2]National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, MD.

Heterochromatin contributes to the regional inactivation of gene expression required for normal cell function and viability. We recently identified *Drosophila small ovary* (*sov*) as a novel player in heterochromatin stabilization. While null animals are inviable, partial loss-of-function mutations lead to female sterility associated with degenerate oogenesis. Germline-specific depletion of *sov* permits oogenesis, yet results in embryonic lethality, indicating a maternal contribution of *sov* is required. We examined the requirements for *sov in* embryo development. While *sov* mRNA is enriched at centrosomes, Sov protein localizes within the nucleus in a cell cycle-dependent manner, where it colocalizes with the essential heterochromatin factor, HP1a. Depletion of *sov* by germline-specific RNAi or through germline mutant clonal analysis results in mitotic asynchrony and DNA damage, indicating

Sov is necessary for genome stability. Live imaging reveals *sov* knockdown results in prolonged prophase, delayed chromosome congression, and errant chromosome segregation. Further, we demonstrate Sov is required for efficient microtubule organization, as loss of *sov* causes a range of spindle defects. Ultimately, these defects result in impaired cellularization and embryonic lethality. These findings suggest Sov is required for the fidelity of cell division during early embryogenesis.

P1982/B225

Dynein and ZYG-9 are required for acentriolar pole stability and maintenance in *C. elegans* oocytes.

G. Cavin, T. J. Mullen, S. M. Wignall; Molecular Biosciences, Northwestern University, Evanston, IL.

During cell division, a bipolar microtubule-based spindle is required to ensure faithful chromosome congression and segregation. While centrosomes function as microtubule organizing centers (MTOCs) to aid spindle assembly in most cell types, oocyte meiotic spindles of many species are acentriolar; how spindle poles form and are maintained in the absence of centrosomes is poorly understood. Some microtubule-associated proteins (MAPs) that localize to acentriolar poles have been previously identified; we are studying these proteins in *C. elegans* oocytes to determine if they have a role in meiotic spindle assembly and maintenance. First, we assessed DHC-1, a *C. elegans* homolog of the heavy chain of dynein, and found that long-term depletion of this motor using an auxin-inducible degron (AID) system resulted in splaying of microtubules at the poles and an increased number of disorganized spindles, suggesting a role in pole formation during spindle assembly. We also used *emb*-30 RNAi to induce metaphase arrest and then acutely depleted DHC-1 from pre-formed bipolar spindles. This resulted in similar phenotypes, suggesting that dynein is also required to maintain the integrity of poles after they form. We obtained similar results when we used the AID system to deplete another pole protein, ZYG-9, the *C. elegans* homolog of XMAP215. Following long-term depletion of ZYG-9, oocyte spindles did not stably achieve bipolarity, and poles went through a process of splitting and coming back together. Moreover, acute ZYG-9 depletion from metaphase-arrested spindles resulted in pole fragmentation, demonstrating a role for ZYG-9 in acentriolar pole stability and maintenance. Finally, we used the same AID approach to deplete DHC-1 and ZYG-9 from monopolar spindles (generated by *klp-18* RNAi), as another assay for pole integrity. Interestingly, in this context DHC-1 and ZYG-9 depletion had markedly different phenotypes. While depletion of ZYG-9 did not dramatically affect monopolar spindle morphology, DHC-1 depletion led to disintegration of the monopole, releasing chromosomes and associated microtubule bundles into the cytoplasm. Taken together, our data suggest that dynein and ZYG-9 are both required for acentriolar pole stability and maintenance during oocyte meiosis, but likely perform distinct functions. Further investigation of how these proteins stabilize acentriolar poles will help elucidate how mechanisms in meiotic spindles compare and contrast to those with centrosomes.

P1983/B226

Endoplasmic Reticulum (ER) Membranes Impose a Physical Constraint on the Mitotic Spindle.

M. M. Araújo, D. V. Vieira, I. A. Telley, R. A. Oliveira; Instituto Gulbenkian De Ciência, Oeiras, Lisboa, PORTUGAL.

Chromosome capture, alignment and segregation all depend on the microtubule-based mitotic spindle, the major force generator inside cells. However, whether spindle function and checkpoint control are mechanically decoupled from the cytosol and cell cortex is still uncertain. In *Drosophila melanogaster* syncytial embryos, the ER is excluded from the spindle and forms an envelope with seemingly elastic

properties. The ER envelope surrounds the spindle throughout mitosis, but whether it is involved in the mechanics of chromosome segregation is not known. Conventional inactivation approaches are difficult to interpret owing to the importance of the ER for various cellular processes. To circumvent this experimental limitation, we disrupted this membranous organelle specifically, in a highly acute manner, using microinjection techniques for *D. melanogaster* syncytial embryos. We show that acute ER membrane fragmentation by ectopic addition of Reticulon-like protein 1 (Rtnl1) changes the surrounding environment and shortens spindle length over time in metaphase-arrested embryos. To probe for spindle function upon ER fragmentation we released the cohesive forces that hold chromosomes together and tested if the mitotic spindle can pull sister chromatids apart. Under these conditions spindle function is perturbed in multiple ways. Although chromosomes are pulled apart when the ER barrier is absent, chromosome movement occurs concomitantly with spindle elongation beyond the length under control condition. The oscillatory motions typically seen during alignment and under premature loss of cohesion are not observed. When the ER fragmentation is induced during interphase, one of the mitotic checkpoint proteins, Mad2, accumulates both along the spindle midzone and at the poles, leading to an apparent arrest of the cycle at metaphase. While this localization of Mad2 suggests that the checkpoint silencing mechanism is active, its mechanical framework is altered. Thus, our results reveal that the ER imposes a physical constraint on the mitotic spindle. Furthermore, they suggest that the ER mechanically feeds back to the mitotic checkpoint control. Ongoing experiments are now aiming to dissect the principles behind this action.

P1984/B227

3d Reconstruction of Meiotic Spindles in Mouse and Humans.

S. Redemann, H. Yazdkhasti; University of Virginia, Charlottesville, VA.

Hindered by the limits of light microscopy we can neither resolve individual microtubules connecting to the chromosomes, nor their interaction with other components of the spindle. 3D Electron tomography provides the 'ultimate' resolution to the lack of structural information.We study the structure of individual chromosomes and their interactions with microtubules by 3D tomography, providing single microtubule resolution, and state-of-the-art light microscopy. Subsequently, computational analysis and simulations will be used to develop a mechanical model of how shape and structure of individual chromosomes affect their faithful segregation. Our methodology allows us to detect differences between individual chromosomes and their interactions with microtubules on a microscale level. We will present our preliminary results on the reconstruction of mouse meiotic spindles in Metaphase II.

P1985/B228

Probing the Dynamic Mitotic Proteome to Understand the Biological Clock Underlying the Mitotic Surveillance Pathway.

C. R. Gliech[1], F. Cisneros-Soberanis[2], W. Earnshaw[2], A. J. Holland[1]; [1]Johns Hopkins University, Baltimore, MD, [2]University of Edinburgh, Edinburgh, UNITED KINGDOM.

Faithful replication and segregation of genetic information is essential for successful cell division. Indeed, numerous safeguards have evolved to prevent errors in these processes. Delays in cell division lead to an increased frequency of mitotic errors and DNA damage. Consequently, the Mitotic Surveillance Pathway (MSP) measures mitotic duration and triggers an arrest in cells that exceed a specific mitotic temporal threshold (*Sluder 2010*). Despite the important role of the MSP in protecting

genomic integrity, how cells determine mitotic duration remains unknown. We hypothesize that the shifting abundances of pro- and anti-arrest proteins over the course of normal mitotic progression is the mechanism for such a timer, but as of yet, no such proteins have been robustly linked to the failsafe pathway. Here, mass spectrometry analysis of highly synchronous mitotic lysates reveals the dramatic depletion of a subset of the mitotic proteome, generating a candidates list for drivers of the MSP timer and potentially identifying novel APC/C substrates. These proteins were further scrutinized for their possible role in the MSP as well as their mechanism of degradation. Finally, MSP proteins 53BP1, USP28, and p53, previously identified through genome wide CRISPR knockout screens, were used as a platform for further mechanistic understanding of the pathway.

Kinetochore Assembly and Functions 2

***In Vitro* Reconstitution Unveils the Phospho-regulated Ska-Ndc80 Macro-complex.**

Q. Zhang[1], L. Hu[2], Y. Chen[1], H. Liu[1]; [1]TULANE UNIVERSITY, New orleans, LA, [2]Huazhong University of Science and Technology, Wuhan, CHINA.

Faithful chromosome segregation requires proper kinetochore-microtubule interactions during mitosis. The human Ska (spindle and kinetochore associated) complex is essential for mediating kinetochore-microtubule attachments and its loading onto the kinetochore complex Ndc80 (Ndc80C) plays a critical role in its function. However, the key determinant that docks Ska onto Ndc80C still remains elusive. Here, we address this question using biochemical reconstitution followed by functional analysis. We identified six Cdk1 sites in Ska3 distributed in three conserved regions, including the previously identified T358 and T360. In vitro, Cdk1 phosphorylation on the Ska complex enhanced WT, not phospho-deficient 6A, binding to Ndc80C. Strikingly, the phospho-mimetic Ska 6D complex formed a stable macro-complex with Ndc80C, but Ska WT failed to do so, suggesting that Cdk1 phosphorylation is necessary and sufficient for the formation of the Ska-Ndc80 macro-complex. In cells, Ska 6A completely lost its localization to kinetochores and its functions in chromosome segregation; whereas Ska3 6D partially restored them. Quadruple mutations that excluded T358 and T360 barely affected Ska3 localization at kinetochores and its functions; whereas, quadruple mutations that included these two sites significantly compromised Ska3 kinetochore recruitment as well as its functions. Altogether, our findings not only reveal the key phospho-regulated Ska-Ndc80 macro-complex essential for faithful chromosome segregation, but also pave the way for mechanistic analyses of kinetochore-microtubule interactions.

P1987/B230

Inter-kinetochore Tension Promotes Microtubule Release and Inhibits Depolymerization in Response to Aurora B Activity.

G. Chen[1], H. Zhang[1,2], A. Gokden[1], D. Wu[3], D. M. Chenoweth[3], M. A. Lampson[1]; [1]Department of Biology, University of Pennsylvania, Philadelphia, PA, [2]Current: Department of Biological Sciences, Carnegie Mellon University, Pittsburgh, PA, [3]Department of Chemistry, University of Pennsylvania, Philadelphia, PA.

Error-free chromosome segregation requires Aurora B kinase regulating the interaction between kinetochores and associated microtubules. Two mechanisms by which Aurora B resets incorrect

chromosome configurations have been proposed: inducing kinetochore-microtubule unbinding or inducing microtubule depolymerization while maintaining kinetochore attachment. To distinguish between these models, we acutely recruited Aurora B to kinetochores using a photo-activatable chemical dimerizer. Because kinetochore-microtubule unbinding relaxes inter-kinetochore tension whereas microtubule depolymerization generates tension, the contrasting mechanisms would cause opposite directions of chromosome movement. For a monopolar spindle, we find that Aurora B recruitment drives kinetochore poleward movement, consistent with Aurora B promoting microtubule depolymerization under low resisting loads. In contrast, Aurora B recruitment to a single kinetochore of a bioriented sister kinetochore pair can trigger movement of the targeted kinetochore away from its attached pole, indicating kinetochore-microtubule unbinding under high tension. Furthermore, increasing inter-kinetochore distance increases the likelihood of unbinding rather than microtubule depolymerization. Thus, the kinetochore response to Aurora B activity depends on the cellular context: depolymerization at low tension and unbinding at higher tension. These findings suggest distinct mechanisms to correct different microtubule attachment errors, under the control of a single kinase.

Kinetochores Attached to Microtubule-ends Are Stabilised by Astrin Bound PP1 to Ensure Proper Chromosome Segregation.

D. Conti[1,2], P. Gul[1], R. Rose[1], J. M. Martin-Duran[1], V. M. Draviam[1,2]; [1]Queen Mary University of London, London, UNITED KINGDOM, [2]University of Cambridge, Cambridge, UNITED KINGDOM.

Microtubules segregate chromosomes by attaching to macromolecular kinetochores. Only microtubule-end attached kinetochores can be pulled apart; how these end-on attachments are selectively recognised and stabilised is not clear. Using the kinetochore and microtubule-associated protein, Astrin, as a molecular probe, we show that end-on attachments are rapidly stabilised by spatially-restricted delivery of PP1 near the C-terminus of Ndc80, a core kinetochore-microtubule linker. PP1 is delivered by the evolutionarily conserved tail of Astrin, which promotes Astrin's own enrichment creating a highly-responsive positive feedback loop, independent of biorientation or Aurora-B, a classical regulator of attachment stability. Abrogating Astrin:PP1-delivery disrupts attachment stability and anaphase onset; these can be reversed by artificially tethering PP1 near the C-terminus of Ndc80. Premature constitutive Astrin:PP1-delivery disrupts chromosome congression and segregation, revealing a dynamic safety-lock mechanism that stabilises attachments. Thus, Astrin:PP1 selectively and rapidly stabilises end-on attachments, independent of biorientation, to ensure normal chromosome segregation.

Modeling Chromosome Attachment, Oscillation and Faithful Segregation during Fission Yeast Mitosis.

Y. Gachet[1], s. Theis[1], Y. Le cunff[2], H. Mary[1], C. Reyes[1], s. Tournier[1], J. Pecreaux[2]; [1]LBCMCP (CBI) CNRS, TOULOUSE, FRANCE, [2]CNRS, Univ Rennes, IGDR – UMR 6290, RENNES, FRANCE.

We previously described a minimal mathematical model of fission yeast chromosome segregation based on the stochastic attachment and detachment of kinetochore microtubules. This force-balance model accurately reproduced chromosome alignment, bi-orientation and segregation and predicts chromosome attachment defects such as merotelic attachment when an " aurora B-like " activity is perturbed (*1*, *2*, *3*). We recently implemented microtubule dynamics-dependent features, such as chromosome capture and oscillations to our model. Indeed, during metaphase, the attached sister

chromatids oscillate along the spindle axis. The precise mechanics of this conserved process is poorly understood although it can reveal the dynamics of microtubule-kinetochore attachment. Ndc80p, with its long coiled-coil domain, was previously suggested to connect the microtubules with the kinetochores. Modelling with a minimum number of actors suggests that alternating microtubule poly- and depolymerization without kinetochore detachment, together with an asymmetric generated pulling/pushing force or load-dependent switch between these two states, account for the oscillations. In particular, directed movements of the paired kinetochores toward one pole appear because the states of microtubules coordinate (one side growing and the other shrinking), thanks to the force dependence of the state switching rate. Finally, porting this model to the agent-based cytoskeleton simulator Cytosim paved the way for investigating how these oscillations interplay with other aspects of spindle mechanics. 1. G. Gay, T. P1990/B233

Multiple Kinetochore Maps Coordinate for Robust End-on Kinetochore-Microtubule Attachments during Mitotic Metaphase.

D. Varma[1], S. Agarwal[1], S. Agarwal[1], S. Seshadrinathan[1], A. Rahi[1], T. C. Bidone[2], R. J. McKenney[3]; [1]Cell and Developmental Biology, Northwestern University, Chicago, IL, [2]Department of Bioengineering, University of Utah, Salt Lake City, UT, [3]Molecular and Cellular Biology, University of California Davis, Davis, CA.

Cdt1, a DNA replication licensing protein, is recruited to kinetochores during mitosis via the loop domain of the Ndc80 complex (*Varma et al., Nat Cell Biol., 2012*). Our recent study had demonstrated a direct binding of Cdt1 to microtubules (MTs) and a role for Aurora B kinase phosphorylation in modulating the strength of this interaction (*Agarwal et al., J Cell Biol., 2018*). Besides Cdt1, the Ndc80 loop domain has been shown to recruit another important microtubule-associated protein (MAP), the Ska complex to kinetochores. In this study, we demonstrate an interaction between these two loop-localized MAPs, i.e. Cdt1 and the Ska complex, using multiple biochemical approaches. This interaction was also mapped in mitotic cellular extracts and was found to be essential for proper recruitment of Cdt1 to kinetochores. Total internal reflection fluorescence microscopy (TIR-FM) experiments demonstrated that Ska strikingly augments MT-binding of Cdt1. These findings were substantiated by studies in HeLa cells, where Ska facilitated enhanced localization of Cdt1 on spindle MTs, indicating a synergy between the two MAPs for MT-binding. Consistently, depletion of Ska resulted in reduced binding of Cdt1 to spindle MTs. TIR-FM experiments also show that Cdt1 synergizes with the Ndc80 complex for binding to MTs as proposed by our previous studies (*Varma et al., Nat Cell Biol., 2012*). Our data points to a model where the Ska complex binds to Cdt1 and facilitates its docking on to the Ndc80 loop domain producing a trimolecular complex. We further used computational modelling to understand the interplay between Ndc80, Ska and Cdt1 for the formation of end-on kMT attachments in metaphase. These simulations suggest that the displacement of a possible complex formed by Ndc80-Ska-Cdt1 is significantly higher than that formed by Ndc80 alone or Ndc80-Ska. Further, we find that the rupture force and time of attachment of the kMT interface in metaphase formed by the Ndc80 complex increases in the presence of Ska and/or Cdt1. We postulate that the trimolecular complex formation between Ndc80, Ska and Cdt1 may be necessary to generate robust end-on kMT attachments in *vivo* to cope with the dynamic flux of spindle

MT growth and shrinkage, and contributing to persistent coupling of kinetochores to dynamic MT ends during metaphase and anaphase.

P1991/B234

Quantitative Measurement of Phosphorylation Occupancy Reveals That Both Graded and Switch-like Mechanisms Regulate Kinetochore Functions during Mitosis.

T. J. Kucharski[1], R. Hards[1], S. A. Gerber[1,2,3], D. A. Compton[1,2]; [1]Department of Biochemistry and Cell Biology, Geisel School of Medicine at Dartmouth, Hanover, NH, [2]Norris Cotton Cancer Center, Geisel School of Medicine at Dartmouth, Lebanon, NH, [3]Department of Molecular and Systems Biology, Geisel School of Medicine at Dartmouth, Hanover, NH.

Faithful chromosome segregation during mitosis requires the formation of bi-oriented attachments between microtubules and kinetochores. The affinity of kinetochores for microtubules is tightly regulated by phosphorylation. Current evidence indicates roles for multiple kinases (Cdk, Aurora, Plk1, etc) and phosphatases (PP1, PP2A, etc) in tuning kinetochore phosphorylation at each stage of mitosis to generate appropriate kinetochore-microtubule (K-Mt) attachment stability to ensure both robust error correction and efficient satisfaction of the SAC. This view assumes that phosphorylation at any particular site is graded through tight coordination between kinases and phosphatases to properly tune K-Mt stability, yet the extent to which kinetochore proteins are phosphorylated (i.e. Absolute phosphorylation occupancy) is unknown. Here, we develop methods using mass spectrometry to measure the absolute phosphorylation occupancy of the Hec1 subunit of the NDC80 complex derived from mitotic cells under different conditions. Multiple Aurora B kinase-dependent phosphorylation sites display variable occupancy ranging from 20%-30% (low nocodazole treatment) to 40%-50% (high nocodazole or STLC treatment). Inhibition of phosphatase activity significantly increases the extent of phosphorylation of these sites indicating a continuous antagonism between kinase and phosphatase activity to establish the absolute occupancy level. In contrast, we identify a new Cdk-dependent phosphorylation site in the same region of Hec1 that switches phospho-occupancy from <20% (high nocodazole treatment) to >90% (low nocodazole or STLC treatment). These data demonstrate that both switch-like and graded mechanisms of phosphorylation regulate an essential protein at the kinetochore-microtubule binding interface to ensure faithful chromosome segregation. We propose a model whereby Cdk1 acts as a switch to convert kinetochores from an “attachment-favorable” state to an “error correction” state which allows Aurora B to act in a graded fashion to finely tune the attachments to achieve proper bi-orientation.

P1992/B235

Measuring Load-bearing Interactions between the Dam1 Complex and Its Multiple Binding Sites in the Ndc80 Complex.

R. Flores, Z. Peterson, C. Asbury, T. Davis; University of Washington, Seattle, WA.

In mitosis, accurate chromosome segregation requires the kinetochore to stably attach to the dynamic tip of spindle microtubules. The Ndc80 complex is the main microtubule-binding component of the outer kinetochore. Heterodecameric protein complex known as Dam1 enhances the ability for Ndc80 complex to bear load. We previously identified three interaction sites between the Ndc80 and Dam1 complexes. Electron micrographs of Dam1 and Ndc80 complexes binding to microtubules showed that the Ndc80 complex bridges two Dam1 rings in *vitro*. Mutations in any of these three sites disrupt the

ability of the Ndc80 complex to bridge two rings in *vitro and* disrupt proper Dam1 complex localization to the rest of the kinetochore in *vivo*. However, which interaction sites between the Ndc80 and Dam1 complexes play a role in load bearing is still unknown. Ipl1 phosphorylates the Dam1 complex at six different sites: Dam1p S20, S257, S265, S292; Ask1p S200; Spc34p T199. Phosphorylation at Dam1p S20 disrupts oligomerization of the Dam1 complex. Phosphorylation at the other five sites disrupts interaction with the Ndc80 complex. Therefore, I have phosphorylated regions A^{Dam1p}, B^{Ask1p}, or C^{Spc34p} in the Dam1 complex. I utilized the optical trap to measure the strength of the Ndc80 complex attachment to microtubules in the presence of phosphorylated Dam1 complex. Phosphorylation at sites A^{Dam1p} and B^{Ask1p} resulted in partial defects in the ability of the Ndc80 complex to bear load in the presence of the Dam1 complex. Therefore, regions A^{Dam1p} and B^{Ask1p} play a role in establishing load-bearing interactions with the Ndc80 complex on growing microtubule tips, while region C^{Spc34p} does not. To test whether the same regions in the Ndc80 complex play a role in establishing load-bearing interaction with the Dam1 complex, I have generated two lethal insertion mutations along the Ndc80 protein (B^{Ndc80p} and C^{Ndc80p}). The addition of an insertion mutation to either regions B^{Ndc80p} or C^{Ndc80p} did not affect the ability of the Ndc80 complex itself to bind to dynamic microtubules or to bear load. However, region B^{Ndc80p} showed a partial defect in the ability of the Ndc80 complex to bear load in the presence of the Dam1 complex, while region C^{Ndc80p} did not show any defect. In conclusion, two regions (A and B) are required for load-bearing and the function of the third region is being explored.

P1993/B236

Force and Phosphorylation Tune the Performance of the Kinetochore-Microtubule Interface Reconstituted *in Vitro*.

V. A. Volkov[1], P. J. Huis in 't Veld[2], A. Musacchio[2], M. Dogterom[1]; [1]Delft University of Technology, Delft, NETHERLANDS, [2]Max Planck Institute of Molecular Physiology, Dortmund, GERMANY.

The dynamic molecular interface between the microtubule (MT) ends and the kinetochore is tightly regulated to ensure proper segregation of mitotic chromosomes to the daughter cells. This regulation is based on phosphorylation of MT-binding domains in the outer kinetochore, as well as the MT-generated force being translated into a biochemical signal by yet unidentified tension sensors. To deconstruct this regulation, we reconstituted the kinetochore-MT interface in *vitro* from purified components. Using Ndc80 and Ska complexes, the two principal MT-binding components of the human kinetochore, we systematically analyzed the contributions of their multivalency, as well as phosphorylation state and presence of the unstructured regions in these complexes, to the coupling efficiency between the reconstituted kinetochore and dynamic MTs. We found that oligomerized Ndc80 complex binds different features of the MTs through different interfaces: the globular calponin homology domain interacts with the stable lattice of the MT, while the unstructured N-terminal tail is required for interaction with the shortening MT end. This was especially important under MT-generated force: force-dependent MT rescue required the presence of dephosphorylated Ndc80 tail, which frequently caused stalls lasting for a second or more. The tailless Ndc80 oligomers, or the full-length Ndc80 oligomers treated with Aurora B stalled MT shortening for a shorter time and failed to rescue MT shortening. Finally, we reconstituted in *vitro* the direct binding between full length Ska and Ndc80 complexes and found that the joint complex was stable towards the active Aurora B kinase and required Cdk1-phosphorylated Ska3 T358/360 and Ndc80 coiled coil. Under the MT-generated force, the presence of Ska increased the duration of Ndc80-dependent stalls whether the Ndc80 tail was absent, present, or phosphorylated, thus promoting MT rescue and opposing the destabilizing effect of Aurora B

phosphorylation. In summary, we conclude that the ability of oligomeric Ndc80 to stall and rescue MT shortening depends on the Ndc80 N-terminal tail and is regulated by Aurora B kinase, while Ska provides an orthogonal pathway to stabilize NDC80-microtubule attachment independently of Ndc80's N-terminus.

P1994/B237

Asymmetric Microtubule Binding-pausing Behavior of Yeast Ring-forming Dam1 Complex Revealed by Ultrafast Force-clamp.

S. Wu[1], V. Demidov[1], F. I. Ataullakhanov[2], E. L. Grishchuk[1]; [1]University of Pennsylvania, Philadelphia, PA, [2]Center for Theoretical Problems of Physicochemical Pharmacology, Moscow, RUSSIAN FEDERATION.

In dividing yeast cells, spindle microtubules attach to kinetochores with the help of the heterodecameric Dam1 complex, which assembles into the microtubule-encircling rings. When a kinetochore-bound microtubule shortens, it pulls the ring-coupled kinetochore toward the associated spindle pole, whereas the Dam1 ring coupled to its sister kinetochore is dragged toward the microtubule plus-end. How Dam1 complex translocates under pulling force in different microtubule directions has never been examined. To bridge this gap we applied a highly sensitive ultrafast force-clamp to the Dam1 heterodecamers immobilized on the surface of the bead and interacting with the wall of taxol-stabilized microtubule. In this assay, microtubule-wall gliding of Dam1 complex is examined under controlled forces ranging from 3 to 8 pN, imitating the forces and motions experienced by Dam1 when it couples chromosomes to dynamic microtubule ends. Surprisingly, single Dam1 heterodecamers exhibited brief stationary bindings to the microtubule. The frequency and duration of these bindings were increased when Dam1 was translocating toward the microtubule plus-end. Moreover, this asymmetry increased with increasing pulling force, implying a catch-bond-associated translocation mechanism. These results suggest that conformation of the Dam1 ring changes when the ring slides toward or away from the spindle pole. The increased molecular friction of the ring dragged toward the microtubule plus-end could help to explain how chromosome stays attached to the microtubule end while moving under load.

P1995/B238

Individual Mammalian Kinetochores Count Attached Microtubules in a Switch-like, Highly Sensitive Manner to Control Cell Cycle Progression.

J. Kuhn[1,2], S. Dumont[2]; [1]Johns Hopkins University, Baltimore, MD, [2]University of California, San Francisco, San Francisco, CA.

The Spindle Assembly Checkpoint (SAC) prevents anaphase until all kinetochores attach to the spindle. Each mammalian kinetochore binds many microtubules, but how many attached microtubules are required to turn off the checkpoint, and how the kinetochore monitors microtubule numbers, are not known - and central to understanding SAC mechanisms and function. To address these questions, here we systematically tune and fix the fraction of Hec1 molecules capable of microtubule binding. We show that Hec1 molecules independently bind microtubules within single kinetochores, but that the kinetochore does not independently process attachment information from different molecules. Few attached microtubules (20% occupancy) can trigger complete Mad1 loss, and Mad1 loss is slower in this case. Finally, we show using laser ablation that individual kinetochores detect changes in microtubule binding, not in spindle forces that accompany attachment. Thus, the mammalian kinetochore responds specifically to the binding of each microtubule, and counts microtubules as a single unit in a sensitive

and switch-like manner. This may allow kinetochores to rapidly react to early attachments and maintain a robust SAC response despite dynamic microtubule numbers.

P1996/B239

Stress Testing the Kinetochore: Determining the Minimum Number of Ndc80 Molecules for Force Generation and Checkpoint Silencing.

A. A. Kukreja, A. P. Joglekar; University of Michigan, an n Arbor, MI.

During mitosis, the kinetochore binds the dynamic plus-ends of up to ~24 spindle microtubules to produce the force needed to move chromosomes and to silence the spindle assembly checkpoint (SAC). The heterotetrameric Ndc80 complex (Ndc80C) plays crucial roles in both these functions. To simultaneously interact with multiple microtubules, the human kinetochore uses ~250 copies of Ndc80C distributed over its ~200 nm diameter disk-like surface. Interestingly, the number of Ndc80C molecules actively engaged with a microtubule continuously fluctuates over the course of mitosis, correlating with changes in the number of kinetochore-bound microtubules (between 12 to 24). Furthermore, recent studies show that kinetochores can segregate the chromosomes accurately when the number of microtubules that they interact with is depressed artificially to 12-14. This observation raises two questions: (1) what is the minimum number of Ndc80C molecules required for proper chromosome segregation and, (2) how does the Ndc80C number affect force generation and SAC silencing? We address these questions by titrating HeLa kinetochores with microtubule-binding mutants of Ndc80C. Specifically, we express fluorophore-tagged Hec1 (a subunit of Ndc80C) with mutations either in its basic N-terminal tail (whose microtubule-binding affinity is biologically modulated by a kinase) or within its calponin homology domain (which has no known regulation on its microtubule-binding affinity). We allow the mutant Hec1 to compete with unlabeled, wild-type Hec1 for kinetochore binding, and then correlate the amount of mutant protein per kinetochore with phenotypes of chromosome segregation. Our initial experiments reveal that the SAC becomes constitutively activated when ≥30 - 40% of the kinetochore is occupied by Hec1 mutants defective in microtubule-binding and silenced when the kinetochore is occupied by ≥60% of a Hec1 mutant with high microtubule affinity. Additionally, we find that chromosome mis-segregation consistently occurs when the kinetochore incorporates ≥20% of high microtubule affinity Hec1 mutant whose attachment strength cannot be modulated. These observations suggest that: 1) SAC silencing occurs when only 60% of the total number of Ndc80C molecules is bound to microtubules and, 2) that proper chromosome segregation relies on the kinetochore's ability to dynamically tune Ndc80C microtubule affinity, failing when as low as 20% of the Ndc80C is in a constitutively high affinity state. Overall, our investigations suggest that the human kinetochore incorporates an excess of Ndc80C and allow us to delineate the limits on this number for proper force generation, SAC signaling, and ultimately, accurate chromosome segregation.

P1997/B240

Proteomic Dissection of the Spindle Assembly Checkpoint.

Y. A. Garcia, E. Velasquez, L. Gao, J. Whitelegge, J. Torres; University of California, Los an geles, Los an geles, CA.

Eukaryotic cell division promotes the correct transmission of genetic material from one mother cell to two newly formed daughter cells. To ensure the fidelity of this process, the Spindle Assembly Checkpoint (SAC), a group of proteins that includes Mad1, Mad2, Bub1, BubR1, and Bub3, works in unison to

rigorously verify microtubule-kinetochore attachment and tension in a time-dependent manner. If the SAC senses any errors it halts cell division at the metaphase to anaphase transition until errors are repaired. To gain insight into the associations that are critical for the spatial-temporal regulation of the SAC, we employed a label-free proximity-based association mapping approach. We generated BioID2-tagged inducible stable cell lines for core SAC components (Mad1, Mad2, Bub1, BubR1, and Bub 3) and a control BioID2-tag only cell line. We utilized these BioID2-SAC protein cell lines to perform proximity-based biotin labeling reactions, purified the biotinylated proteins, and analyzed the identity of these proteins by liquid chromatography tandem mass spectrometry. We further developed a statistical proteomic data analysis pipeline called CANVS in R that 1) is user friendly 2) can be used analyze data with an input control and can generate statistically significant results 3) uses the existing CRAPome database 4) generates visual protein association maps from the identified proteins using Reactome. Using these proteomic and computational approaches, we identified known and novel associations for the core SAC proteins, which will allow us to gain insight into the establishment and regulation of the SAC. Interestingly, we found associations between some core SAC proteins and the Astrin/Kinastrin complex. Additionally, we were able to recapitulate the Mad1-Mad2, Mis12-centromere, mitotic checkpoint, and Bub1-Bub3 complexes. Our current and future work is focused on better understanding the significance of these identified associations by analyzing their importance for SAC function.

P1998/B241

Polo Regulates the RZZ-Spindly Module to Ensure Kinetochore-microtubule Attachment Fidelity.

J. Barbosa[1,2,3], T. Bange[4], L. Tao[5], C. Conde[1,2], C. Sunkel[1,2,3]; [1]I3s - Institute for Research and Innovation in Health Sciences, Porto, PORTUGAL, [2]IBMC - Institute for Molecular and Cell Biology, University of Porto, Porto, PORTUGAL, [3]ICBAS - Instituto de Ciências Biomédicas Abel Salazar, University of Porto, Porto, PORTUGAL, [4]MPI für Molekulare Physiologie, Dortmund, GERMANY, [5]Department of Biology, University of Hawaii, Hilo, HI.

Accuracy of chromosome segregation relies on the formation and stabilization of correct attachments between kinetochores and microtubules. Ultimately, amphitelic attachments, in which sister chromatids bind to microtubules from opposite spindle poles, must be preserved. Multiple roles have been attributed to Polo kinase in the regulation of kinetochore-microtubule (KT-MT) interactions, promoting either stabilization or destabilization of attachments. However, a more detailed analysis that helps to integrate these functions is still missing. Here, resorting to an RNAi-screen in *Drosophila* to suppress a constitutively active Polo mutant, we identified a genetic interaction between Polo and the Rod-ZW10-Zwilch (RZZ) complex. Expression of constitutively active Polo both in *Drosophila* S2 cells and larval neuroblasts results in delayed formation of stable KT-MT attachments. Importantly, depletion of Rod rescues this delay, confirming a recently reported function for the RZZ complex in the regulation of KT-MT interactions. Mechanistically, Polo phosphorylates Spindly, a kinetochore adaptor for cytoplasmic dynein, impairing its binding to Zwilch. This prevents premature stripping of the RZZ complex from kinetochores and minimizes the stabilization of erroneous attachments that form during early mitotic stages. In agreement with this, expression of different phosphomutant Spindly constructs that affect RZZ kinetochore accumulation results in increased formation of KT-MT attachment defects. We propose a model in which Polo kinase-mediated regulation of the RZZ-Spindly-dynein module during mitosis contributes to ensure the fidelity of KT-MT attachments and chromosome segregation.

P1999/B242

Bub1 Activates the Mad1-mad2 Complex at Unattached Kinetochores to Kick-start Spindle Checkpoint Signaling.

P. Lara-Gonzalez, T. Kim, K. Oegema, A. Desai; Ludwig Inst Cancer Research, La Jolla, CA.

The spindle checkpoint senses the attachment status of kinetochores, the structures that mediate the interaction between mitotic chromosomes and spindle microtubules, to promote accurate chromosome segregation. When kinetochores are unattached, they recruit the Mad1-Mad2 complex that in turn catalyzes the formation of an anaphase onset inhibitor. How Mad1-Mad2 localization to unattached kinetochores triggers spindle checkpoint signaling is currently unclear. In yeast and human cells, Mad1-Mad2 localization involves a conserved motif (CM) in the Bub1 kinetochore scaffold, which when phosphorylated by mitotic kinases, interacts with the Mad1 C-terminus. However, we found that in *C. elegans*, the Bub1 CM and the Mad1 C-terminus are dispensable for Mad1-Mad2 kinetochore localization, consistent with our previous finding that in this species a different region of Bub1 interacts with Mad1 (Moyle et al. J Cell Biol 204(5):647-57). Nonetheless, we observed that both the Bub1 CM and the Mad1 C-terminus were essential for checkpoint signaling in *C. elegans*, indicating that the interaction between them is critical for activating signaling beyond kinetochore localization; a similar conclusion was derived in yeast and human cell studies using artificial kinetochore tethering of Mad1-Mad2 (Heinrich et al. EMBO Rep 15(3):291-8; Kruse et al., EMBO Rep 15(3):282-90; Ballister et al. J Cell Biol 204(6):901-8). To address how the Bub1 CM interaction with the Mad1 C-terminus activates checkpoint signaling, we focused on the key initiating event of the signaling mechanism: recruitment by kinetochore-localized Mad1-Mad2 of a dynamic, free pool of Mad2 through Mad2-Mad2 dimerization. Employing a fluorescent version of *C. elegans* Mad2 that exclusively localized to kinetochores through dimerization with endogenous Mad2, we found that the Bub1 CM and the Mad1 C-terminus are essential to recruit the dynamic pool of Mad2 to unattached kinetochores. We further show that both the folded RWD domain and putative C-terminal phosphorylation sites in Mad1 are important for this function. These findings lead us to propose that the conserved interaction between phosphorylated Bub1 CM and the Mad1 C-terminus activates the Mad1-Mad2 complex to recruit the dynamic pool of Mad2, thereby triggering checkpoint signaling. Such a mechanism explains coupling of the activation of spindle checkpoint signaling to kinetochore localization of Mad1-Mad2, irrespective of the precise molecular basis for Mad1-Mad2 kinetochore localization. Our current work is testing different models for the activation mechanism, facilitated by the natural dispensability in *C. elegans* of the Bub1 CM and Mad1 C-terminus for Mad1-Mad2 kinetochore localization.

***Drosophila* KNL1 Regulates the Spindle Assembly Checkpoint through Tension Sensing.**

M. R. Audett[1], E. Johnson[1], D. McSweeney[1], N. D. Derr[2], T. J. Maresca[1]; [1]University of Massachusetts Amherst, Amherst, MA, [2]Smith College, Northampton, MA.

The kinetochore protein KNL1 is a large intrinsically disordered protein (IDP) that recruits spindle assembly checkpoint (SAC) proteins and is required for SAC signaling in a conserved manner. Chromosome biorientation satisfies the SAC and while it has been proposed that SAC satisfaction may require the establishment of stable kinetochore-MT (KT-MT) attachments and tension generation, the question of whether tension directly regulates SAC signaling is unresolved and controversial. Here we present data in support of KNL1 as a tension-sensing IDP that directly regulates checkpoint protein localization and signaling independent of the establishment of stable KT-MT attachments. The N-

terminus of *Drosophila melanogaster (Dm)* KNL1 utilizes two basic patches to bind directly to MTs via electrostatic interactions. Pull-down experiments with purified components demonstrated that the checkpoint protein Bub3 binds to the central disordered region of *Dm*KNL1 in the absence of phospho-regulation due to the presence of divergent, “phospho-mimetic” Bub3-interacting motifs in *Dm*KNL1. Deletion of the N-terminal MT binding region (KNL1ΔN) resulted in a 104 +/- 15 minute delay in metaphase compared to an 8.7 +/- 0.8 minute metaphase duration in control cells. KNL1ΔN-expressing cells retained ~2-fold higher levels of Bub3 at bioriented KTs that were hyper-stretched relative to controls. KNL1ΔN-expressing cells established KT-MT attachments that were more stable, as measured by PA-GFP-α-tubulin turnover, than KT-MT attachments in control cells. The delay was fully rescued upon introduction of both the MT-binding protein Tau and a protein phosphatase 1 (PP1) binding motif to the N-terminus of KNL1ΔN. Insertion of a FRET-based tension sensor (TSMod) into its central disordered region revealed that *Dm*KNL1 is a force-transducing KT protein. Single molecule experiments are ongoing to determine if physiological force application to *Dm*KNL1 reduces its affinity for Bub3. We propose that KNL1 acts as a tension sensor to directly regulate SAC signaling independent of KT-MT attachment stability. More specifically, we posit that the central IDP domain of *Dm*KNL1 binds SAC proteins under low tension, and when its N-terminus associates with dynamic MTs, tension-generation reduces its affinity for checkpoint proteins. We see no reason why this mechanical mechanism would not be conserved beyond *Drosophila* in systems where the focus has been exclusively on the phospho-regulation of KNL1.

P2001/B244

The Number and Effectiveness of the Melt Motifs in Spc105 Represents a Compromise for Potent Mitotic Checkpoint Signaling and Its Effective Silencing.

B. Roy; University of Michigan, an n Arbor, MI.

Maintenance of genome stability and timely cell division are both essential for cell viability and proliferation. To achieve these objectives, a dividing cell must implement a strong mitotic checkpoint that prevents cell division from proceeding in the presence of one or more unattached chromosomes, and but also a responsive one that allows chromosome segregation to occur soon after the last chromosome achieves bipolar attachment with the spindle apparatus. Here we show that the tuning of both the number and the Bub3-Bub1 binding affinity of the ‘MELT’ motifs in the kinetochore protein Spc105 is necessary to implement a potent mitotic checkpoint that can be effectively silenced. Many, high affinity MELT motifs per Spc105 molecule are desirable to prevent chromosome missegregation especially under dynamic signaling conditions wherein the number of unattached chromosomes is small and changing (e.g. In media containing low doses of the microtubule poison benomyl). However, too many high affinity MELT motifs per Spc105 become problematic for checkpoint silencing, and they can result a prolonged cell cycle. Furthermore, high affinity MELT motifs require the binding of Protein Phosphatase 1 to Spc105 for SAC silencing. By recruiting of PP1 via Spc105 specifically for SAC silencing budding yeast cells incur an inherent cost in the form of the harmful cross-talk between SAC silencing and error correction. Therefore, the cumulative action of a combination of high and low affinity MELT motifs represents a compromised solution that achieves a strong and responsive checkpoint. Our findings reveal a potential driver behind the evolutionary trend of the amplification of MELT motif number per Spc105, but the absence of a strong positive selection for their amino acid sequence. We use these insights to engineer an optimal variant of Spc105 that exhibits robust SAC signaling under dynamic signaling conditions, rapid SAC silencing, and improved chromosome biorientation.

PP1 and PP2A-B56 Remove Kinetochore-localised PLK1 Activity to Silence the Spindle Assembly Checkpoint.

M. H. Cordeiro, R. J. Smith, A. T. Saurin; University of Dundee, Dundee, UNITED KINGDOM.

The phosphatases PP1 and PP2A-B56 localise to the outer kinetochore to silence the spindle assembly checkpoint (SAC) signal. This is thought to occur through dephosphorylation of MELT repeats on the SAC scaffold KNL1, which are otherwise phosphorylated by MPS1 to recruit the SAC machinery to kinetochores. We show here that, surprisingly, these phosphatases are not required to dephosphorylate the MELT repeats directly. Instead, they remove PLK1 from the BUB complex, which can otherwise maintain MELT phosphorylation in the absence of MPS1 activity. This occurs due to regulation of two phospho-binding epitopes on the BUB complex (BUB1-T609 and BUBR1-T620), which are phosphorylated by CDK1 to recruit PLK1. Removing either phosphatase increases phosphorylation at these sites and enhances kinetochore PLK1 levels in wild-type, but not BUB1-T609A/BUBR1-T620A mutant cells. This localised PLK1 prevents MELT dephosphorylation upon MPS1 inhibition because co-inhibition of PLK1, or mutation of its binding epitopes on the BUB complex, can fully restore MELT dephosphorylation and SAC silencing in the absence of either phosphatase. In fact, if PLK1 is inhibited we can find no requirement for PP1 or PP2A in SAC silencing at all, because MELT dephosphorylation kinetics are identical even after strong inhibition of both phosphatases. In summary, this study clarifies how MPS1 collaborates with PLK1 to activate the SAC: MPS1 initiates MELT phosphorylation to recruit the BUB complex and this primes local PLK1 activity to maintain MELT phosphorylation. Kinetochore phosphatases must then ultimately co-operate to remove this co-localised PLK1 and silence the checkpoint.

Defining the Mechanism by Which Aurora B Contributes to Mitotic Checkpoint Signaling.

A. Joglekar, B. Roy, A. Fontan, S. Han; University of Michigan, an n Arbor, MI.

The mitotic checkpoint, also known as the Spindle Assembly Checkpoint (SAC), ensures genomic stability by preventing chromosome missegregation during cell division. It is activated by a conserved mitotic kinase known as Mps1. Mps1 phosphorylates conserved motifs known as ‘MELT motifs’ in the kinetochore protein Spc105/KNL1 specifically within unattached kinetochores. This enables Spc105/KNL1 to recruit SAC signaling proteins, and ultimately results in the production of the Mitotic Checkpoint Complex (MCC) to inhibit anaphase onset. It has long been known that the Aurora B kinase, which is responsible for the correction of erroneous kinetochore-microtubule attachments, also contributes to SAC signaling. However, the underlying molecular mechanism has remained poorly understood. Using an ectopic SAC activation system, we show while Aurora B by itself cannot activate the SAC signaling cascade by phosphorylating the MELT motifs. However, it contributes to MCC production by phosphorylating SAC signaling proteins that the MELT motifs recruit. We also find that unlike Mps1, this contribution of Aurora B to SAC signaling is dependent on the SAC signaling protein Bub1. Finally, the Bub1-dependent Aurora B activity is conserved in both budding yeast and human cells. In summary, Mps1 activates the SAC by phosphorylating the MELT motifs as well as the SAC signaling proteins that they recruit. Aurora B then acts downstream from Mps1 on a subset of the SAC signaling proteins to positively and directly contribute to MCC generation. These findings explain prior

observations regarding the cooperation between Aurora B and Bub1 in SAC signaling. They also suggest an integrative model for the role of kinetochore-microtubule attachment and centromeric tension in activating the mitotic checkpoint.

P2004/B247

Phosphorylation Cascade Regulates Kinetochore Localization of Spindle Assembly Checkpoint Proteins during an aphase.

D. Sherwin, M. Bokros, Y. Wang; Florida State University, Tallahassee, FL.

The spindle assembly checkpoint (SAC) prevents anaphase onset in response to chromosome attachment defects, and must be silenced for anaphase progression. Following anaphase onset, activated Cdc14 phosphatase dephosphorylates CDK substrates to further facilitate correct chromosome segregation. In budding yeast, Cdc14 dephosphorylates Fin1, a regulatory subunit of protein phosphatase 1 (PP1), to enable kinetochore localization of Fin1-PP1. We previously showed that kinetochore-localized Fin1-PP1 inhibits kinetochore association of SAC protein Bub1. We report here that Fin1-PP1 inhibits this localization by reversing Ipl1 kinase-dependent phosphorylation of the kinetochore protein Ndc80. Therefore, Ndc80 dephosphorylation promotes kinetochore dis-association of SAC protein Bub1 during anaphase. Additionally, phospho-deficient *ndc80* mutants exhibit compromised checkpoint activity in response to tensionless attachments. These results suggest that the removal of SAC protein Bub1 from the kinetochore is regulated by increasing phosphatase activity during anaphase.

P2005/B248

Regulation of Protein Kinase a (pka) Activity to Mediate Chromosome Segregation in Saccharomyces Cerevisiae.

H. Alsufyani, S. B. Shah, J. Choy; the Catholic University of America, Washington, DC.

Chromosome segregation results in the partitioning of sister chromosomes into two new cells with an equal number of chromosomes. This process occurs during mitosis and meiosis and errors can lead to aneuploidy, a karyotypic state in which cells carry the incorrect number of chromosomes. Most of the intrinsic factors that regulate the chromosome segregation process such as the multi-subunit kinetochore complex that connects chromosomes to the mitotic spindle are highly studied and virtually all of the protein subunits have been identified in yeast, flies, worms, and humans. However, much less is known about how extrinsic factors, which include nutrients, temperature, and pH might act on the intrinsic chromosome segregation machinery. Recently, the major glucose signaling pathway (Ras/Protein Kinase A) was shown by our lab to phosphorylate the outer kinetochore subunit, Dam1, and contributes to chromosome segregation fidelity in the budding yeast, *S. cerevisiae*. While this is the first description of a molecular pathway connecting glucose to chromosome segregation many questions remain. In particular, what is the mechanism regulating PKA-mediated phosphorylation of the kinetochore. Is the known Ras/PKA pathway that responds to glucose also directing PKA toward the kinetochore or are there additional signaling components that are specific to PKA's role in kinetochore phosphorylation. As a first step toward determining the mechanism of PKA regulation, we measured the expression and activity of PKA at different cell cycle stages. Our initial results show that PKA activity increases through the cell cycle although protein levels remain constant. Associated with the increase in PKA activity we also observe increasing levels of Dam1 phosphorylated at the PKA site. Our next step is

to determine if the known Ras/PKA pathway components are required for the cell cycle regulation of PKA activity and Dam1 phosphorylation. These studies will bring new insights into how extrinsic factors such as glucose can directly modulate kinetochore function and chromosome segregation fidelity.

P2006/B249

Investigating the Role of KIF18A in Satisfying the Spindle Assembly Checkpoint.

H. Kim[1], **K. A. Queen**[2], C. L. Fonseca[2], J. K. Stumpff[2]; [1]University of Washington School of Medicine, Seattle, WA, [2]University of Vermont, Burlington, VT.

Progression from metaphase to anaphase during mitosis requires end-on attachments between spindle microtubules and kinetochores. These attachments mature as chromosomes are aligned at the metaphase plate. However, the mechanisms that couple chromosome alignment and attachment are not fully understood. The kinesin family protein, KIF18A, suppresses kinetochore microtubule dynamics to promote chromosome alignment. Interestingly, KIF18A is also necessary, in certain cell types, to satisfy the spindle-assembly checkpoint (SAC). Two general models have been proposed to explain KIF18A's role in satisfying the SAC. In one model KIF18A promotes kinetochore microtubule attachments through an unknown mechanism, and in the other KIF18A is necessary to produce inter-kinetochore tension, which may satisfy the SAC. Our work aims to determine how KIF18A contributes to satisfaction of the SAC. In agreement with previous work, we find that loss of KIF18A results in increased localization of the SAC protein MAD1 to a subset of kinetochores. We used live cell imaging to analyze the behavior of MAD1-positive kinetochores during metaphase and found that these kinetochores exhibit "tumbling" motions rather than oscillations, consistent with an attachment defect. As cells progress from prometaphase to metaphase and kinetochore-microtubule attachments mature during mitosis, phosphorylation of Ser44 and Ser55 of Hec1 decrease. Our data indicate that loss of KIF18A increases phosphorylated Hec1 in metaphase-arrested cells to levels normally seen in prometaphase. These results support a model in which KIF18A coordinates chromosome alignment with attachment and SAC satisfaction during metaphase. Current studies are focused on determining how KIF18A promotes HEC1 dephosphorylation and kinetochore-microtubule attachment.

P2007/B250

Exploring the Link between Centromere Stiffness and Mitotic Dynamics.

E. Garcia, X. Li, L. Peyton, A. Hayes, J. Chen, D. Cimini; Virginia Tech, Blacksburg, VA.

Mitosis involves a number of dynamic processes, such as mitotic spindle formation and chromosome congression during prometaphase, maintenance of spindle position and size in metaphase, and chromosome segregation in anaphase. These dynamic processes are orchestrated by a delicate balance of forces produced by various structural components (microtubules, motors, chromosomes, etc.) of the mitotic apparatus, which can produce forces actively and/or can respond to and transmit forces due to their intrinsic mechanical properties. Recent studies have shown that the centromere and the kinetochore display viscoelastic behavior and that this behavior is conserved in distantly related eukaryotes. In the present study, we aimed to investigate whether changes in centromere stiffness, by changing the transduction of forces through the kinetochore to the microtubules of the mitotic spindle, affect the dynamics of specific mitotic events. To this end, we are using small molecule inhibitors that perturb chromosome compaction and we infer changes in centromere stiffness by measuring inter-kinetochore distance in metaphase cells, with an increase in such distance being interpreted as a

decrease in stiffness and a decrease in the distance as reflective of increased stiffness. Our results so far indicate that the time required to achieve bipolar spindle assembly and chromosome alignment to the metaphase plate changes in response to changes in centromere stiffness. Moreover, we find that altering centromere stiffness suppresses chromosome oscillations in metaphase, regardless of how centromere stiffness is altered. This suggests that centromere stiffness may have been fine-tuned over evolutionary times to facilitate timely and faithful mitotic progression.

P2008/B251

Spatial Positioning and Dynamic Behavior of the Spindle and Kinetochore Associated (SKA) Complex.

T. E. Germanova, A. V. Inchingolo, N. J. Burroughs, A. D. McAinsh; University of Warwick, Coventry, UNITED KINGDOM.

Prior to the segregation of sister chromatids in anaphase, all chromosomes are first maneuvered to the spindle equator in a process termed congression. Bi-orientated sister chromatids achieve this through microtubule depolymerisation-coupled pulling from the leading sister kinetochore. During this process, there is evidence of progressive microtubule recruitment and accumulation of the Spindle and Kinetochore associated (Ska) complex. We proposed that this maturation is part of a mechanical microtubule attachment self-check: if the kinetochore does not recruit sufficient Ska complex, or microtubule recruitment is too rapid, the kinetochore will detach. We have now used CRISPR/Cas9 gene editing to add a fluorescent protein tag to the endogenous Ska1 and investigate how Ska binding/unbinding relates to kinetochore mechanics. GFP-Ska1 appears to be largely absent from the spindle with a dominant kinetochore signal. Moreover, we have deployed our recently developed three-color subpixel co-localization (fGPS) methods to map the position and orientation of the Ska complex within kinetochores as they cycle between attached and unattached states. Finally, we have reconstituted Ska complex behavior on dynamic microtubules in vitro and have evidence for different modes of tracking growing and shrinking tips. Here we will present an updated model for Ska function at human kinetochores.

P2009/B252

Investigating the Link between BubR1 and Hec1 Tail Domain Phosphorylation in Human Cells.

H. K. Shirnekhi, J. G. DeLuca; Colorado State University, Fort Collins, CO.

BubR1 is a kinetochore-associated protein with important roles in both spindle assembly checkpoint signaling and kinetochore-microtubule attachment regulation. It has been previously shown that BubR1 becomes essential for the formation of proper kinetochore-microtubule attachments in a subset of glioblastoma cancer cells, while non-transformed cells do not require this function of BubR1 (Ding et al., 2013. Cancer Discov 3, 198-211). As a component of the Mitotic Checkpoint Complex (MCC), which is required to bind and inhibit the an aphase Promoting Complex/Cyclosome (APC/C) in the presence of unattached kinetochores, BubR1's role in the checkpoint is essential in both cancer and non-cancer cells. In a separate function, BubR1 is responsible for the recruitment of the PP2A-B56 phosphatase complex to kinetochores. This complex works to antagonize the kinase Aurora B, which acts to destabilize kinetochore-microtubule attachments early in mitosis by phosphorylating key substrates at the kinetochore. Why this kinetochore-microtubule attachment function of BubR1 appears to be critical in only transformed cells is unknown. In this study, we are working to understand the specific substrates and sites that the BubR1-recruited pool of PP2A-B56 is responsible for dephosphorylating. We have

tested three phosphorylation sites in the Hec1 tail domain, a known Aurora B kinase substrate. We find that depletion of BubR1 results in increased phosphorylation at all three sites in cells in early mitosis. Additionally, we quantified kinetochore-microtubule attachment stability in BubR1-depleted cancer cells and find that the defects in forming stable attachments are rescued by over-expression of a non-phosphorylatable Hec1 mutant. We are currently working to compare kinase and phosphatase activities in transformed and non-transformed cells to determine if an imbalance of these two components involved in kinetochore-microtubule attachment regulation might explain why cancer cells have an added dependency for the BubR1-recruited pool of PP2A-B56.

P2010/B253

Systematic Phosphorylation an alysis of Bubr1 Kinase Signaling in Mitosis.

S. Muthusamy; Morehouse School of Medicine, Atlanta, GA.

Orchestration of mitotic chromosome segregation depends on a large number of protein machines that regulate the major structural, physiochemical and physiological transitions necessary for equal distribution of parent genomes. Recent studies show that mitotic processes are regulated by acetylation-phosphorylation cascades (Bao et al., 2018. *J. Mol Cell Biol.* 10, 18-32; Yang & Yu. 2018. *J Mol Cell Biol.* 10, 89-90). Although many mitotic phosphorylation events have been identified in proteome-scale mass spectrometry studies, information on how these phosphorylation sites are distributed within mitotic protein complexes and which kinases generate these phosphorylation sites is largely lacking. Give the recent identification of BubR1 chemical inhibitor bubristatin (Huang et al., *Cell Res*. 29, 562-578; Limzerwala & van Deursen. 2019. Cell Res. 29, 605-606), we compared phosphorylation sites in mitotic HeLa cells that were or were not treated with the bubristatin, by phosphopeptide enrichment via immobilized metal affinity chromatography. An alysis by quantitative mass spectrometry identified 313 unique mitotic phosphorylation sites on 163 proteins. Of these, 69 proteins contained one or multiple phosphorylation sites whose abundance was decreased by BubR1 inhibition. These include proteins implicated in BubR1-regulated processes such as senescence, spindle assembly checkpoint signaling, and chromosome segregation, but also numerous proteins that were not suspected to be regulated by BubR1 (Song et al., 2018. *J. Mol Cell Biol.*10, 559-572; Li et al., 2018. *J. Mol Cell Biol.*10, 2-17). An alysis of amino acid sequence motifs among phosphorylation sites down-regulated under BubR1 inhibition in this data set identified the BubR1 consensus phosphorylation motif.

P2011/B254

Investigating the Role of Kinetochore Dynein-dynactin in Spindle Assembly Checkpoint Function.

A. Hodges, J. G. DeLuca, S. M. Markus; Colorado State University, Fort Collins, CO.

The kinetochore is a large proteinaceous structure that assembles upon centromeric chromatin during cell division. This complex structure is involved in linking mitotic chromosomes to spindle microtubules, as well as identifying and correcting erroneous kinetochore-microtubule attachments to ensure accurate chromosome segregation. Monitoring of kinetochore-microtubule attachments is carried out by the spindle assembly checkpoint (SAC), a surveillance system that generates a “wait anaphase” signal at unattached kinetochores. During metazoan mitosis, the minus end-directed motor protein cytoplasmic dynein-1 localizes to a domain at the outer kinetochore called the fibrous corona. Upon stable kinetochore-microtubule attachment, it is thought that kinetochore-localized dynein strips SAC components away from the kinetochore, thus silencing the checkpoint and allowing for anaphase

progression. The three-subunit Rod-Zwilch-ZW10 (RZZ) complex recruits the dynein cargo adaptor Spindly to kinetochores; Spindly, in turn, is responsible for recruiting dynein to the kinetochore. It remains unknown how kinetochore dynein is activated to evict checkpoint proteins away from the kinetochore upon stable microtubule attachment. Here, we investigate the role of dynein at the kinetochore, as well as potential regulatory mechanisms governing Spindly, RZZ, and dynein-dynactin activity. By using a cell culture system that prevents dynein recruitment to kinetochores, we have identified a subset of SAC effectors as bona fide dynein cargoes. Additionally, we have demonstrated that the fibrous corona, a meshwork of proteins at the kinetochore that is supported by RZZS (RZZ + Spindly) and disassembled by dynein, likely has a role in amplification of the SAC signal at unattached kinetochores. Our current work is focused on purification of these kinetochore proteins for use in reconstituted motility assays to further elucidate the nature of their function and interaction.

Nuclear Receptor Coactivator SRC-1 Promotes Colorectal Cancer Progression through Enhancing Gli2-mediated Hedgehog Signaling.

P. Guo, P. Mo, J. Jin, C. Yu, Y. Zhang; Xiamen University, Xiamen, CHINA.

Background and Aims:A growing body of evidence has demonstrated that nuclear coactivators NCOAs (SRCs) are associated with the progression of various cancers and addressing of underlying mechanism represents a promising opportunity to improve cancer therapy. The Hedgehog (Hh) pathway, which is also often aberrantly activated and associated with various tumorigenesis as well. However, the significance of SRC-1 in colorectal cancer (CRC) and the contribution of SRC-1 toward Hh activity have not been characterized yet. **Methods**: SRC-1 knockout CRC cell lines or mouse model was generated to evaluate the role of SRC-1 during CRC tumorigenesis. The SRC-1/GLI2 looping axis was identified through the GSEA analysis of TCGA CRC RNA-seq data and confirmed through RNA and protein expression analysis of clinical CRC samples. The regulation of GLI2 targeted genes by SRC-1 was confirmed through luciferase reporter, Co-IP, and ChIP assays. The cell and xenograft model was used to evaluate genetically or chemically suppression of SRC-1/GLI2 for CRC therapy. **Results**: the ablation of SRC-1 in-vivo significantly suppresses the AOM/DSS induced mouse model of CRC tumorigenesis. Consistently, the mechanistic investigations show that SRC-1 activates the transcription of GLI2, a major downstream transcription factor of Hh pathway and then SRC-1 functions as a coactivator of GLI2 to enhance the expression of multiple GLI2 targeted oncogenes, including GLI2, BCL-2, CCND1, SLUG, and VIM. Furthermore, blockage of SRC-1 and Hh signaling via small molecular inhibitor also largely retard the CRC progression both in human CRC cells and mouse CRC models. **Conclusions**: Together, the present studies uncover an SRC-1/GLI2 regulated Hh signaling looping axis that promotes CRC tumorigenesis, offering an attractive therapeutic strategy for CRC.

P2013/B257

CD82 Regulation of C-met and CD151 in Metastatic Prostate PC3 Cell Lines.

I. Simo, D. Adams, S. Sridhar; University of South Florida, St Petersburg, St. Petersburg, FL.

CD82 regulation of c-Met and CD151 in metastatic prostate PC3 cell lines CD82 (KAI), is a metastasis tumor suppressor protein that is under-expressed in the prostate as well as in several other types of

metastatic cancers. It inhibits cancer metastasis, but the mechanism through which the regulation happens still remains unclear. Various pathways are being explored in our lab, including regulation of c-Met, a growth factor receptor observed from our previous studies that was observed to be regulated by CD82. CD82 and c-Met do not co-localize and recent literature indicates an association exists between c-Met and another tetraspanin, CD151. CD151 does the opposite of what CD82 does ie., it promotes tumor formation. We are currently exploring the link between CD151, CD82, and c-Met. Once we identify what the association of c-Met is with CD151 in the presence and absence of CD82 then it would disclose how exactly the tumor suppressor regulates c-Met and inhibits metastasis. These findings could further help us identify proteins that are regulated by CD82 that could serve as biomarkers or potential drug targets.

P2014/B258

Investigation of PKHD1L1 as a Potential Tumor Suppressor Gene.

K. Lindsay, L. Yoo PhD; Denison University, Granville, OH.

Polycystic Kidney and Hepatic Disease 1-Like 1 (PKHD1L1) was identified in several genome wide association studies as a gene of interest because it is implicated to have a role in cancer development, however little research has been performed to elucidate its function. The Cancer Genome Atlas database search was conducted and missense mutations and variants of PKHD1L1 were found at very high rates across several cancers including skin melanoma, breast and bladder cancer. In addition, these data showed suppressed expression of PKHD1L1 in bladder urothelial carcinoma (Grossman et al., 2016). These clinical data lead us to believe PKHD1L1 could potentially function as a tumor suppressor gene. Besides its association to cancer, PKHD1L1 has been linked to diabetic retinopathy via glucose metabolism experimentation in which hyperglycemic conditions lead to gene suppression (Ung et al., 2017). Immunofluorescent staining revealed that PKHD1L1 appears to be localized to the cytoplasm and nucleus, including nuclear bodies. To characterize PKHD1L1 function, we generated stable knockout lines using CRISPR/Cas9 and observed a frameshift mutation in the targeted exon 2 of PKHD1L1 via TIDE assay. We saw no difference between the parental and knockout cell lines in either wound healing or colony formation assay. However, we observed a modest decrease in proliferation of the PKHD1L1 knockout via MTS assay in reduced glucose culture conditions. These data suggest that PKHD1L1 might trigger a compensatory mechanism in response to reduced glucose levels. Though initial data provide some insight, we require further investigation to help us understand PKHD1L1's role and function.

P2015/B259

Inhibition of Kinase Ikkbeta Suppresses Cellular Abnormalities Induced by the Human Papillomavirus Oncoprotein HPV18E6.

M. Padash Barmchi[1], M. Thomas[2], J. Thatte[2], B. Zhang[3], R. Cagan[4], L. Banks[2]; [1]University of Oklahoma, Norman, OK, [2]International Centre for Genetic Engineering and Biotechnology, Trieste, ITALY, [3]University of Missouri, Columbia, MO, [4]Icahn School of Medicine at Mount Sinai, New York, NY.

Human Papillomavirus (HPV) is the leading cause of cervical cancer and has been implicated in several other cancer types including head-and-neck, vaginal, vulvar, penile and oropharyngeal cancers. Despite the recent availability of a vaccine, there are still over 270,000 deaths each year worldwide. Current treatments for HPV-mediated cancers show limited efficacy, and would benefit from improved understanding of disease mechanisms. Recently, we developed a *Drosophila* 'HPV 18 E6' model that

displayed loss of cellular morphology and polarity, junctional disorganization, and degradation of the major E6 target Magi; we further provided evidence that mechanisms underlying HPV E6-induced cellular abnormalities are conserved between humans and flies. Here, we report a functional genetic screen of the *Drosophila* kinome that identified IKK*β*—a regulator of NF-κB—as an enhancer of E6-induced cellular defects. We demonstrate that inhibition of IKK*β* reduces Magi degradation and that this effect correlates with hyperphosphorylation of E6. Further, the reduction in IKK*β* suppressed the cellular transformation caused by the cooperative action of HPVE6 and the oncogenic Ras. Finally, we demonstrate that the interaction between IKK*β* and E6 is conserved in human cells: inhibition of IKK*β* blocked the growth of cervical cancer cells, suggesting that IKK*β* may serve as a novel therapeutic target for HPV-mediated cancers.

P2016/B260

PA28γ Expression Does Not Determine ERα Expression in Mammary Cancer Cells.

J. L. Hoffman, B. A. McMillen, L. F. Barton; Austin College, Sherman, TX.

The proteasome activator PA28γ shows increased expression in cancer cells and is positively correlated with cancer severity. Through its role as a proteasome activator, PA28γ has been associated with protein stability and gene expression affecting cancer growth. One possible mechanism in which PA28γ has been connected to breast cancer growth is through regulating levels of the estrogen receptor, ERα. ERα expression can be correlated with the growth and severity of human breast cancers. Many human breast cancers are ERα positive and show estrogen dependent growth. The purpose of this research was to further evaluate whether PA28γ and ERα are correlated across multiple mammary cancer cell types. Furthermore, the gene activity of ERα can be measured by evaluating the transcription rates of ERα gene targets. Cathepsin D, the gene target being measured in these experiments, is a lysosomal protease whose transcription is promoted by ERα. Western blot data showed that cells with increased concentration of PA28γ protein were not significantly correlated to protein concentration of ERα as expected. RT-qPCR data showed that there was no universal correlation between PA28γ concentration and ERα gene expression, which was consistent with the western blot results. Additionally, RT-qPCR demonstrated that Cathepsin D gene expression is not tightly correlated with ERα gene expression. Therefore, alterations in PA28γ expression do not affect ERα expression or activity in mammary cancer cell lines.

P2017/B261

Identification and Functional Characterization of Prooncogenic Regulators and Effectors of the Ser Thr Kinase Map4k4 in Medulloblastoma.

J. Migliavacca, B. Seckin, M. Baumgartner; University Children's Hospital Zürich, Children's Research Center, Pediatric Neuro-oncology Research group, Balgrist Campus, Zurich, SWITZERLAND.

Migration and invasion of Medulloblastoma (MB) tumor cells cause metastatic disease that is associated with poor prognosis and high morbidity. Blocking tumor cell migration and local infiltration could restrict tumor progression and metastasis in MB and other pediatric malignant CNS tumors. However, molecular mechanisms leading to aberrant migration and tissue invasion in pediatric brain tumors are poorly understood and no targeted anti-metastatic therapies exist till date. We found that the Ser/Thr protein kinase MAP4K4 is upregulated in primary pediatric brain tumors compared to normal cerebellum and demonstrated that it is required for growth factor-induced migration and tissue invasion in MB. MAP4K4

modulates cortical F-actin cytoskeleton and membrane dynamics, which promote invasive cell protrusions at the leading edge of MB tumor cells. However, the molecular mechanisms of MAP4K4 control of cell invasion are still insufficiently understood for the design of novel targeting strategies to prevent MAP4K4-driven tissue invasion. Our objectives are to determine how MAP4K4 controls invasive protrusions and tissue infiltration and to design means to target the underlying molecular mechanisms. To identify interactors of MAP4K4 in MB, we employed a proximity-dependent biotinylation (BioID) approach using MAP4K4 N- or C-terminally fused with a biotin ligase. Streptavidin pull-down followed by mass-spectrometry analysis identified a number of novel putative MAP4K4 effector proteins with known functions in the regulation of cell adhesion and migration and validated their direct or complex-dependent interaction with MAP4K4 through immuno-precipitation. We combined this comprehensive interactor screen with a loss of function phospho-antibody-array analysis, which allowed us to detect activity changes in key signaling pathways that are the result of altered MAP4K4 expression. This approach not only confirmed MAP4K4 implication in pathways controlling cytoskeleton and membrane dynamics but also revealed a previously unknown possible role of MAP4K4 in anti-apoptotic signaling in MB cells. Our data indicate that MAP4K4 contribution to pro-invasive tumor cell functions in MB depends on its presence in supramolecular protein complexes controlling cytoskeleton dynamics and phospho-pathway regulation. We will discuss the potential significance of the proteins identified in the context of invasion control and MB tumor progression.

P2018/B262

Uncovering the Role of a Myosin Phosphatase Regulator in Pancreatic Tumor Cell Mechanics and Behavior.

S. M. An gstadt; Johns Hopkins University Sch Med, Baltimore, MD.

Pancreatic ductal adenocarcinoma (PDAC) remains one of the deadliest cancers due to its 5-year survival rate of about 8.5%. A majority of patients present with symptoms post metastatic spread, which contributes to its overall lethality as the 3rd leading cause of cancer-related deaths. There is a critical need for better understanding the molecular mechanisms underlying PDAC formation and progression, which will allow the development of new PDAC-specific targets. To this end, we are investigating the role of the myosin phosphatase targeting subunit 1 (MYPT1) in PDAC as a potential biomarker and lead into the targetability of pancreatic cancer cell mechanics. MYPT1 was originally identified through its being targeted by the immune system in a clinical trial for a cytokine-secreting whole tumor cell vaccine. An antibody response against MYPT1 in patients treated with the tumor cell vaccine correlated to a positive treatment outcome of greater than 3-years of disease-free survival. In addition to MYPT1's elicited antibody response, its expression is highly upregulated in PDAC cells as observed by immunohistological staining of surgically resected patient samples and in established PDAC cell lines. MYPT1 was discovered as an interaction platform between the PP1β/δ catalytic phosphatase subunit and the phosphorylated regulatory light chain (RLC) of non-muscle myosin II (NMII), allowing for RLC dephosphorylation and NMII inactivation. As a major regulator of NMII, MYPT1 has implications in cancer cell shape control, especially during cell growth, division, adhesion, invasion, and metastasis. To elucidate MYPT1's function in PDAC, I am using genetic engineering to generate PDAC cells with varied MYPT1 expression, mimicking the wide range of MYPT1 expression observed in healthy to cancerous states. I am assessing MYPT1's effect on cell mechanics (*e.g*. cortical tension), if MYPT1 responds to applied mechanical stresses, and how MYPT1 affects each of the NMII paralogs' ability to respond to these stresses. I am also characterizing MYPT1's impact on cell oncogenic behavior, including cell

growth, survival, migratory, and invasive phenotypes. Finally, I will characterize MYPT1's effect on tumor formation and progression in *vivo*. Overall, this research will provide insight into MYPT1's biomechanical role in cancer cell behavior and response to its surrounding environment. We aim to provide insight for investigations into MYPT1's targetability and the effect of biomechanical properties on cell oncogenic behavior, which may facilitate its use as a biomarker for precision medicine, leading to a decline in PDAC morbidities.

P2019/B263

Keratin 19 Regulates Cell Cycle Pathway to Promote Proliferation of Breast Cancer Cells.

P. Sharma[1], S. Alsharif[1], K. Bursch[1], S. Parvathaneni[2], A. Fallatah[1], M. Hafner[3], S. Sharma[2], B. Chung[1]; [1]The Catholic University of America, Washington, DC, [2]Howard University, Washington, DC, [3]National Institute of Arthritis and Musculoskeletal and Skin Diseases, Bethesda, MD.

Keratin 19 (K19) is overexpressed in select human carcinomas, where it is utilized as a diagnostic and prognostic marker. Despite the positive correlation between higher expression of K19 in tumor and worse patient survival, the role of K19 in breast cancer remains unclear. Therefore, we ablated K19 expression in MCF7 breast cancer cells and found that K19 was required for proper cell cycle progression. Specifically, K19 regulated D-type cyclins (Cyclin D1 and Cyclin D3) expression. We found that K19 interacts with cyclin D3, and a loss of K19 resulted in decreased protein stability of cyclin D3. Since cyclic AMP (cAMP) regulates cell cycle and cyclin D3 degradation, we tested the involvement of K19 in cAMP-mediated cyclin D3 degradation. Elevation of intracellular cAMP through forskolin increased cyclin D3 turnover in the absence of K19. Using this system, we are in the process of characterizing specifics of K19-dependent regulation of cyclin D3 stability. We aim to provide evidences for a novel mechanism by which a cytoskeletal protein stabilizes a cell cycle regulator and promotes proper cell cycle progression.

The Centrosome Linker Protein, Cep68, Localizes to the Nucleus and Relates to Cell-cell Contact Inhibition.

H. Hung, C. Blackstone; National Institute of Neurological Disorders and Stroke, NIH, Bethesda, MD.

CEP68 is an essential structural protein of the centrosome linker, connecting the two centrioles at proximal ends during interphase. When cells enter mitosis, CEP68 is degraded in prometaphase which allows bipolar spindle formation and cell cycle progression. Besides its primary localization and roles at the centrosome, CEP68 can be detected in cell nuclei by immunofluorescence staining. Exogenous expressed N-terminus fragment of CEP68 shows a strong nuclear localization while the full-length protein primarily localizes at the centrosome. Taken together, we hypothesize that the nuclear localization of CEP68 presents a cellular function and is tightly regulated. Interestingly, we discover the nuclear localization of CEP68 is cell density-dependent. CEP68 localizes to the nucleus at low cell density, and exits the nucleus when cultures reach confluence. To elucidate the control of CEP68 localizations, truncated fragments are expressed in cells and examine their localization at different cell density. N-terminus fragments display nuclear localization depending on cell density, while localizations of fragments deleted of this region are not affected by the density of cells. The cell density-dependent nuclear localization of CEP68 is similar to the Yes-associated protein (YAP) of the Hippo/YAP pathway, which regulates the contact inhibition growth. YAP is a transcriptional co-activator and binds to TEAD

transcription factors to promote cell growth. While cells reach confluence, the Hippo kinases (Mst1/2 and Lst1/2) phosphorylate YAP and stimulate its cytosol retention and or degradation. Overexpression of CEP68 causes nuclear retention of YAP as cells reach confluence and affects its phosphorylation state. In addition, CEP68 interacts with upstream Hippo pathway components, Lats and AMOT. Taken together, our results demonstrate that CEP68, an essential structural protein of the centrosome, localizes to the nucleus in response to cell density and is a novel modulator for cell-cell contact inhibition through interacting with the Hippo/YAP pathway.

***SETD2* Loss Drives Genomic Instability by Increasing CENP-A Levels and Generation of Dicentric Chromosomes.**

F. M. Mason[1], E. S. Kounlavong[1], I. Park[2], C. L. Walker[2], W. K. Rathmell[1]; [1]Vanderbilt University Medical Center, Nashville, TN, [2]Baylor College of Medicine, Houston, TX.

Epigenetic regulation is critical for genome maintenance and identity of the centromere, the site of kinetochore assembly and microtubule attachment during mitosis. Alterations to the “epigenetic code” at the centromere can disrupt the organization and function of the histone H3 variant that specifies the centromere, CENP-A. Changes in CENP-A levels or localization lead to errors in kinetochore assembly and chromosome segregation in mitosis causing aneuploidy, a hallmark of cancer. However, genetic perturbations in epigenetic regulators that function as tumor suppressors or oncogenes have not yet been strongly linked to changes in centromere identity or CENP-A function/localization. Previously, we have identified that loss or mutation of the tumor suppressor and H3 methyltransferase *SETD2* causes errors in chromosome segregation and aneuploidy. Yet, it is unclear how loss of SETD2-dependent histone methylation (H3K36 tri-methylation, H3K36me3) directly leads to chromosome mis-segregation. Here, we demonstrate that loss of *SETD2* increases total CENP-A protein levels and CENP-A levels at the centromere. This increase in CENP-A is accompanied by an increase in expression of the DAXX/ATRX histone chaperone complex, which has been previously demonstrated to regulate ectopic, non-centromeric CENP-A localization. Importantly, loss of *SETD2* leads to the generation of chromosomes with two CENP-A containing centromeres (dicentric chromosomes), which are due in part to the formation of neocentromeres (centromeres forming at non-centromeric locations). Staining of metaphase spreads from *SETD2* mutant cells demonstrates that many dicentric chromosomes contain the kinetochore protein Hec1/Ndc80 at both centromeres, suggesting that both centromeres are active and may contribute to chromosome segregation errors. We propose that *SETD2*-dependent H3K36me3 regulates centromeric identity and acts as a tumor suppressor by inhibiting ectopic CENP-A deposition and dicentric chromosome formation, thereby promoting genome stability.

Myt1 Upregulation Protects Cells from Centromere Fragmentation in the Presence of Adavosertib.

C. Lewis, T5H 0S2, E. Xiao, W. Choi, J. Smith, A. Bukhari, J. Mackey, A. Gamper, S. Campbell, G. Chan; University of Alberta, Edmonton, AB, CANADA.

During interphase, Wee1 and Myt1 kinases negatively regulate Cdk1 through phosphorylation. Ectopic activation of Cdk1 can induce mitosis with damaged or under-replicated DNA, which results in cell death by mitotic catastrophe. Adavosertib is a potent small molecule inhibitor of Wee1 that has single agent clinical activity in multiple solid tumours, including sarcoma, glioma, head and neck cancer, and ovarian

cancer. In HeLa and a subset of breast cancer cell lines, Adavosertib treatment forces S-phase cells into mitosis with under-replicated chromosomes resulting in chromosome breaks at the centromere (centromere fragmentation) and mitotic cell death. However, not all cancer cells respond to Adavosertib and the reason for the lack of response is unclear.We find that cells exhibiting intrinsic resistance to Adavosertib have higher Myt1 protein levels relative to those with lower Myt1 levels. Furthermore, cancer cells (HeLa and MDA-MB-231) that are selected for Adavosertib resistance have 2 to 3 times more Myt1 relative to parental cells. Additionally, tumour cells within xenografts that survival Adavosertib treatment also have higher Myt1 protein levels relative to non-treated xenografts from control mice. siRNA knockdown of Myt1 restores cell sensitivity to the Wee1 inhibitor in resistance cells whereas transient overexpression of Myt1 induces Adavosertib resistance in otherwise sensitive cell lines. We confirmed that Adavosertib resistant cells are less prone to undergoing premature mitosis and centromere fragmentation in the presence of the Wee1 inhibitor. Consistent with this finding, we find that cells with high levels of Myt1 (including cells selected for Adavosertib resistance) have low in vitro Cdk1 activity.We compared patient breast tumour tissue and observed that Myt1 is overexpressed relative to normal breast tissue. Furthermore, higher Myt1 levels strongly correlate with a worse overall survival and an increase in disease relapse. Given the correlation between high Myt1 levels and Adavosertib resistance in pre-clinical models, assaying Myt1 levels in future clinical trials may be useful in identifying resistant tumours. Our data also highlight a rationale for developing small molecule Myt1 inhibitors for clinical use.

P2023/B267

Restoring Chemosensitivity in Multiple-Drug Resistant Breast Cancer through Activation of the an aphase Promoting Complex.

C. VanGenderen, G. Davies, A. Khawaja, T. Harkness, T. Arnason; University of Saskatchewan, Saskatoon, SK, CANADA.

Common malignancies of the breast, colon, and blood are notable for exhibiting high rates of inherent, or more frequently, acquired resistance to therapy. This transformation into multiple drug resistant (MDR) cancer is associated with poorer patient outcomes as this recurrence is both more aggressive and difficult to treat. One mechanism of developing MDR is the aberrant chromosomal segregation occurring during an abnormal mitotic cycle, inducing chromosomal damage. Accumulation of chromosomal damage may result in subpopulations of cancerous cells developing MDR characteristics. The an aphase Promoting Complex (APC) is a multi-subunit E3 ubiquitin ligase which drives regulated chromosomal segregation during mitosis, and whose proper function is necessary to prevent chromosomal damage. The APC functions by polyubiquitination followed by proteasomal degradation of multiple protein targets including securin, whose degradation permits release and segregation of sister chromatids. The APC is highly evolutionarily conserved both structurally and functionally; from yeast to humans. There is substantial evidence for APC dysfunction during tumor development, and our previous work has associated impaired APC activity with MDR cell populations. We hypothesize that restoring APC activity in MDR breast cancer will result in the enhancement of chemosensitivity. A yeast 2-hybrid system identified multiple novel peptides that physically bind and activate the yeast APC, and through evolutionary conservation, are predicted to similarly activate human APC. Multiple peptides were cloned into mammalian expression vector pcDNA3.1 and stably transfected into a triple-negative breast cancer cell line (innately chemoresistant). Peptide-expressing cells revealed increased APC activity, as several APC protein targets had significantly reduced abundance, presumably due to augmented E3 ligase

activity. These same cells had significantly elevated chemosensitivity to doxorubicin, a common breast cancer chemotherapeutic drug. Furthermore, analysis of the marker for DNA damage H2A.X revealed a reduction in protein quantity. This indicates that cancer cells which have enhanced APC activity correlate with reduced rates of chromosomal damage. Whether this is because heavily damaged cells are removed through apoptosis (or other measures) or there is enhanced DNA repair is yet to be determined. This supports our hypothesis that restoring APC activity in MDR cancer results in enhanced chemosensitivity.

P2024/B268

Role of Jumonji-C Histone Demethylase in the Development of Hepatocellular Carcinoma.

D. Jeong, Y. Chun; Seoul National University College of Medicine, Seoul, KOREA, REPUBLIC OF.

Reprogramming in lipid metabolism has received increasing recognition as a hallmark of cancer cells. In cancer cells, large demands of lipids were required to meet excessive synthesis of membranes, energy production and activation of intracellular signaling pathways during cell proliferation and division. To meet these demands, cancer cells express increased levels of lipogenic enzymes responsible for FAs synthesis, which is a target of crucial transcriptional regulator, sterol regulatory element binding protein 1c (SREBP1c). SREBP1c is a well-known master transcription factor for de novo lipogenesis and is found frequently increased in many human cancers. However, the molecular mechanisms involved in the regulation of SREBP1c remain incompletely understood. In this study, we uncover the role of jumonji-C histone demethylase (JHDM) as a repressor of SREBP1c, thereby preventing lipogenesis and proliferation of hepatocellular carcinoma (HCC) cells. JHDM directly interacts with SREBP1c at basic helix-loop-helix domain of SREBP1c and plant homeodomain of JHDM, promoting proteasomal degradation of SREBP1c protein. In addition, knockdown of JHDM stimulates mRNA levels of lipogenic enzymes and induces lipogenesis in HCC cells. However, JHDM-loss-induced lipogenesis is recovered by SREBP1c knockdown, implying that SREBP1c is crucial for the effects of JHDM toward lipogenesis. In contrast, ectopic expression of JHDM shows protective effects on oleic acid-induced lipid accumulation in HCC cells. We also found that JHDM knockdown using si-RNAs promotes mRNA expressions of cell cycle regulators, accompanied with enhanced cell growth, colony formation and spheroid formation. However, the effects of JHDM knockdown which promote HCC proliferation are reversed by knockdown of SREBP1c. In accordance with these data, JHDM overexpression represses cell growth in HCC cells, indicating that JHDM acts as a tumor suppressor by inhibiting SREBP1c-mediated lipogenesis and cell cycle regulation. Overall, our findings suggest that JHDM serves as a molecular bridge between lipid metabolism and cancer development through regulation of SREBP1c and thus JHDM could be a therapeutic target in defense against HCC.

Induction of Fabp by Fatty Acid Is Crucial for Switching on Hif-driven Lipid Accumulation and Cell Growth in Hepatocellular Carcinoma.

J. Seo, Y. Chun; College of Medicine, Seoul National University, Seoul, KOREA, REPUBLIC OF.

As a hallmark of cancer malignancy, reprogramming of lipid metabolism is currently rising since lipid metabolic abnormalities in cancer are distinguished from normal cells. Increasing demands for rapid growth even under harsh cancer microenvironment, cancer cell alters increasing uptake of exogenous fatty acid and accumulation of lipid droplets, and decreasing beta-oxidation. Previous researches

focused on metabolic changes mediated by Hypoxia Inducible Factor-1 (HIF-1) have been discussed intensively, however, its precise mechanism in reprogramming of lipid metabolism is to be fully clarified. Here, we report that a novel HIF-1 binding partner, Fatty acid binding protein (FABP), is required for switching on reprogramming of lipid metabolism through reinforcing HIF-1 function. Mechanistically, we demonstrate that FABP binds to N-terminal of HIF-1 and enhances HIF-1 activity. Furthermore, treatment of fatty acid triggers FABP gene expression and sequentially activates HIF-1 function in hepatocellular carcinoma (HCC) cell. Up-regulated FABP under fatty acid enriched condition results in HIF-1-mediated shift toward lipid storage and accelerates HCC cell growth. We utilize bioinformatics analysis and clinical data to confirm FABP and HIF-1 expression in the liver of HCC tissues, and both expressions are up-regulated in HCC patients and positively correlated. Finally, we demonstrate that Fatty acid/FABP/HIF-1 axis facilitates HCC proliferation using colony formation and three-dimensional culture. Our findings suggest important roles of fatty acid induced FABP/HIF-1 signaling pathway on lipid accumulation and proliferation in HCC, and this axis might be a potential therapeutic target for metabolism related development of hepatocellular carcinoma.

P2026/B270

Heat Shock Factor 1 Is a Direct an tagonist of AMP-activated Protein Kinase to Promote Tumor Growth.

K. Su[1], S. Dai[2], Z. Tang[1], M. Xu[1], C. Dai[1]; [1]National Cancer Institute, Frederick, MD, [2]University of Massachusetts Medical School, Worcester, MA.

Rationale: AMP-activated protein kinase (AMPK), a key cellular metabolic sensor and downstream effector of the tumor suppressor LKB1, activates catabolic pathways but suppresses anabolic pathways, including fatty acid and cholesterol biosynthesis, thereby maintaining energy homeostasis. Heat shock factor 1 (HSF1) is the master transcriptional regulator of the evolutionarily conserved proteotoxic stress response, thereby preserving proteomic stability upon environmental insults. HSF1 is also a potent pro-oncogenic factor, suggesting that proteomic stability enables oncogenesis. We previously showed that upon activation by metabolic stressors, AMPK interacts with and phosphorylates HSF1 to inactivate it and cause proteomic instability, leading to tumor suppression. Intriguingly, we also discovered that HSF1 suppresses AMPK and controls body fat mass. **Objective:** to investigate the mechanisms by which HSF1 suppresses AMPK and the roles of this suppression in lipid metabolism and tumorigenesis. **Results:** by utilizing recombinant proteins, HSF1 peptide libraries and transcription-deficient HSF1 mutants, our in *vitro* studies reveal that through physical interactions HSF1 imposes multilayer regulations on AMPK, including blocking AMP binding to γ subunits, impairing LKB1-mediated Thr172 phosphorylation, promoting Thr172 de-phosphorylation by PP2A, and impeding ATP binding to catalytic α subunits. Circular dichroism spectroscopy reveals that HSF1 induces global AMPK conformational changes. Biologically, *Hsf1* deficiency suppresses lipogenesis and decreases lipid content via AMPK activation. Moreover, *Hsf1*-deficient cells and mice display reduced cholesterol levels. Interestingly, this defect leads to impaired cholesteroylation of sonic hedgehog (SHH). Consequently, the oncogenic SHH signaling is impaired in *HSF1*-deficient cells. In *vivo*, *Hsf1* deficiency reduces body fat mass in mice, which can be markedly rescued by either pharmacological or genetic inhibition of AMPK. Importantly, the transcription-deficient HSF1 mutant, through AMPK suppression, enhances the lipid content and SHH cholesteroylation, and promotes the in *vivo* growth of xenografted human melanomas. **Conclusions:** HSF1 is a direct AMPK antagonist. This transcription-independent interaction of HSF1 with AMPK

epitomizes a reciprocal kinase-substrate regulation whereby lipid metabolism and proteomic stability intertwine and promotes cancer anabolism and oncogenesis.

Increased NAD(H) Pool Promotes Colon Cancer Progression by Suppressing Ros Level.

S. Hong, 16499; Ajou University School of Medicine, Suwon, KOREA, REPUBLIC OF.

Nicotinamide adenine dinucleotide (NAD), a coenzyme with crucial roles in various cellular processes, exists in an oxidized form (NAD^+) and reduced form (NADH). While cancer cells require high rate of NAD^+ turnover than normal cells, it remains unclear whether the NAD(H) pool could be used as biomarker for cancer progression. Here, we showed that NAD(H) pool size (NAD^+ and NADH) and NAD^+/NADH ratio both were increased during colorectal cancer (CRC) progression. The NADH fluorescence intensity measured by two-photon excitation fluorescence (TPEF) microscopy was consistently increased in CRC cell lines, azoxymethane/dextran sodium sulfate (AOM/DSS)-induced CRC tissues and tumor tissues from CRC patients. We also confirmed that the increase of NAD(H) pool was due to the activation of NAD^+ salvage pathway mediated by nicotinamide phosphoribosyltransferase (NAMPT). The NAMPT expression was upregulated in adenoma and adenocarcinoma tissues from CRC patients. The increases in the NAD(H) pool inhibited the accumulation of excessive ROS levels induced by inflammation. FK866 treatment decreased the CRC nodule size by increasing ROS levels in the AOM/DSS mice. Collectively, our results suggest that NAMPT-mediated upregulation of the NAD(H) pool protects cancer cells against detrimental inflammation-induced ROS and detection of NADH fluorescence by TPEF microscopy could be a potential non-invasive method for monitoring CRC progression.

Ror1 Is a Key Regulator of Chemoresistance in Breast Cancer Via Modulation of the Drug Efflux Pump Abcb1 in a P53/mapk-dependent Manner.

N. Fultang, A. Illendula, Z. Klase, B. Peethambaran; University of the Sciences, Philadelphia, Philadelphia, PA.

ROR1 Is a Key Regulator of Chemoresistance in Breast Cancer Via Modulation of the Drug Efflux Pump ABCB1 in a P53/mapk-dependent Manner Resistance to chemotherapy is one of the leading causes of mortality in most human cancers. In most instances, these tumorous masses exhibiting resistance to chemotherapy require higher treatment doses with toxic side effects for patients. In breast cancer especially, subsets of chemoresistant cells often contribute to dismal survival rates. Understanding the molecules and pathways underlying chemoresistance is critical in order to combat these malignancies. To this aim, our work identifies and characterizes one such clinically targetable regulator of chemoresistance. Our focus is the Receptor Orphan tyrosine-kinase-like Receptor 1 (ROR1), an oncofetal receptor highly expressed during development but absent or minimally expressed in normal adult tissue. It is however, highly expressed in chemoresistant cancerous tissue. We previously isolated and characterized a novel ROR1 inhibitor which represses basal-chemoresistant breast cancer survival and motility. Our results also suggest that chemoresistant breast cancer cells and patient tissue express high levels of ROR1. siRNA knockdown and inhibition of ROR1 increased sensitivity to Cisplatin and Doxorubicin, two widely used chemo drugs. We also observed downregulation of ABCB1 expression after ROR1 knockdown and inhibition in these cells. ABCB1 is a drug efflux pump, highly expressed in chemoresistant malignancies, which pumps out chemo drugs from cells. Mechanistically, after ROR1

knockdown and inhibition, we observed downregulation of MAPK/ERK signaling, a pathway known to prevent proteasomal degradation of ABCB1 via RSK1. On the transcriptional level, when p53 is increased at the ABCB1 promoter, ABCB1 transcription is repressed. SMARCB1 was similarly shown to repress ABCB1 transcription. ChIP analysis suggests ROR1 knockdown and inhibition increases p53 and SMARCB1 at the ABCB1 promoter, which correlated with decreased ABCB1 mRNA levels. We also observed a global increase in p53 activity and nuclear localization in both conditions. Overall our findings suggest ROR1 inhibition with drugs like Cirmtuzmab® and strictinin might represent a viable therapeutic strategy for chemoresistant malignancies.

Tumor Invasion and Metastasis 2

P2029/B273

Metabolic Stress Induced Aggression in Non-invasion Breast Tumor Model.

S. Gayan, A. Nair, A. Teli, T. Dey; Institute of Bioinformatics and Biotechnology, Savitribai Phule Pune University, Pune, INDIA.

An actively growing tumor face various alternation in microenvironment during its life cycle. Changes such as hypoxia, scarcity of nutrients and mechanical confinement most often influence the tumor behavior. The metabolic crosstalk between the tumor and the microenvironment might help in shaping the tumor pathophysiology. We hypothesize the tumor as a smart enterprise, which can revise their internal wiring to survive such stress conditions. The main objective of this study is to understand the impact of extrinsic stress conditions on tumor growth and migration. Non-invasive multicellular spheroids (MCF7) are fabricated and subjected to individual or combined starvation of glucose, protein, and oxygen, to create chronic and acute stress conditions. It is observed that combined stress conditions alter the physical appearance of the tumor, while chronic combine stress deters the in *vitro* spheroid formation thus mimicking the invasive one. This is further strengthened by the reduced level of mRNA expression of cell adhesion specific proteins such as E-cad and EpCAM. Migration of the spheroids is analyzed under different conditions. Continually stressed spheroids exhibit dormant behavior and do not migrate while, in rescued condition, spheroids from acute stress showed epithelial migration. Interestingly rescued spheroids from extreme nutritional stress show single-cell migration. Chronically stressed spheroids exhibit epithelial migration too after the rescue. In the acute combined stressed spheroids, both single and collective mode of migration is observed. To analyze the nature of single-cell migration inhibitors of mesenchymal and amoeboid migration have been used. Inhibitors such as ML7 Hydrochloride restrict the single-cell migration, whereas Bisindolylmaleimide-I and Marimastat cannot. Several cellular events such as the formation of apoptotic bodies, cell-in-cell structures, the formation of cytoplasmic extensions are also observed which need further probing to prove their importance in the process of metastasis. In conclusion, we can assume that nutritional and hypoxic stress conditions synergistically influence the metastatic potential of cancer cells and can inculcate a quasi-invasive nature to a non-invasive cell line. This study highlights the potential of such metabolic stress conditions on metastasis which need more attention in the future.

P2030/B274

Metabolic Control of Tumor Cell Invasion by Lipid Droplet Storage and Metabolism.

C. Rozeveld, R. J. Schulze, G. L. Razidlo; Mayo Clinic, Rochester, MN.

Metastatic invasion is a particularly energy-intensive cellular process, and how tumor cells fuel the energetic demands of metastasis remains poorly defined. Obesity is a risk factor for multiple cancer types, including pancreatic cancer (PDAC), and correlates with increased metastasis. Excess lipids, present due to obesity or increased fatty acid synthesis, could provide a fuel source for cancer progression and metastasis. We hypothesized that tumor cells can store and metabolize excess lipid to drive metastatic invasion. Indeed, introduction of excess exogenous fatty acids augments lipid accumulation and storage in lipid droplets (LDs) in PDAC cells, and leads to enhanced PDAC cell motility and invasion in *vitro*. LDs are metabolized by the concerted action of lipases. Importantly, we have found that treatment of tumor cells with lipase inhibitors blocks tumor cell invasion, indicating that utilization of stored lipids via lipase-mediated LD breakdown is required for invasive migration. Hormone sensitive lipase (HSL) is a lipolytic enzyme, best characterized in adipose tissue, that is critical to the breakdown and utilization of LDs in *vitro* and in *vivo*. We have made the surprising observation that oncogenic KRas downregulates expression of HSL in pancreatic cancer cells, which shifts the cells towards lipid storage. In PDAC, mutational activation of the oncogene KRas occurs in 95% of tumors and contributes to metabolic rewiring of tumor cells. Our data suggest that the metabolic shift induced by mutant KRas includes increased lipid storage in LDs via downregulation of HSL. Indeed, re-expression of HSL shifts tumor cell metabolism from glycolysis towards elevated oxidative phosphorylation. Importantly, KRas-mutant cells still require the catalytic activity of HSL for tumor cell invasion, even though HSL expression is downregulated. Using redox ratio imaging, we have found that migratory cells upregulate oxidative phosphorylation during the process of migration to metabolize stored lipid droplets and fuel invasive migration. Finally, depletion of LD stores via overexpression of HSL blocks tumor cell invasion in *vitro* and metastasis in mice, even in the context of oncogenic KRas. These data indicate that regulation of HSL is important for both lipid storage and maintaining cancer cell invasiveness. Therefore, we propose a novel mechanism by which oncogenic KRas mediates HSL activity in a tunable manner, thereby transiently altering the metabolism of PDAC cells and enabling increased metastatic ability.

P2031/B275

Elovl2 Promotes Breast Cancer Malignancy by Regulating Fatty Acid Biosynthesis.

Y. Ha, H. Noh, H. Park, M. Kim, Y. Lee, Y. Kim; Ajou University, Suwon, KOREA, REPUBLIC OF.

<META NAME="author" CONTENT="하유진"> ELOVL2 promotes breast cancer malignancy by regulating fatty acid biosynthesis *Yu-Jin Ha, Hyun-Jin Noh, Han-Hee Park, Min-Kyoung Kim, Yu-Sang Lee and You-Sun Kim Department of Biochemistry, Ajou University School of Medicine & Department of Biomedical Sciences, Graduate School, Ajou University, Suwon, KOREA* Metabolic rewiring has been recognized as an important feature to the progression of cancer. However, the essential components and functions of lipid metabolic networks in breast cancer progression are not fully understood. In this study, we investigated the roles of altered lipid metabolism in the malignant phenotype of breast cancer. Using a spheroid-induced epithelial-mesenchymal transition (EMT) model, we conducted multi-layered lipidomic and transcriptomic analysis to comprehensively describe the rewiring of the breast cancer lipidome during the malignant transformation. A tremendous homeostatic disturbance of various complex lipid species including ceramide, sphingomyelin, ether-linked phosphatidylcholines, and ether-linked

phosphatidylethanolamine was found in the mesenchymal state of cancer cells. Noticeably, polyunsaturated fatty acids composition in spheroid cells was significantly decreased, accordingly with the gene expression patterns observed in the transcriptomic analysis of associated regulators. For instance, the up-regulation of SCD, ACOX3, and FADS1 and the down-regulation of PTPLB, PECR, and ELOVL2 were found among other lipid metabolic regulators. Significantly, the ratio of C22:6n3 (docosahexaenoic acid, DHA) to C22:5n3 was dramatically reduced in spheroid cells analogously to the down-regulation of ELOVL2. Following mechanistic study confirmed the up-regulation of SCD and down-regulation of PTPLB, PECR, ELOVL2, and ELOVL3 in the spheroid cells. Furthermore, the depletion of ELOVL2 induced metastatic characteristics in breast cancer cells via the SREBPs axis. A subsequent large-scale analysis using 51 breast cancer cell lines demonstrated the reduced expression of ELOVL2 in basal-like phenotypes. Breast cancer patients with low ELOVL2 expression exhibited poor prognoses (HR = 0.76, CI = 0.67–0.86). Collectively, ELOVL2 expression is associated with the malignant phenotypes and appear to be a novel prognostic biomarker in breast cancer. In conclusion, the present study demonstrates that there is a global alteration of the lipid composition during EMT and suggests the down-regulation of ELOVL2 induces lipid metabolism reprogramming in breast cancer and contributes to their malignant phenotypes.

The Creatine Phosphagen System in Mechanoresponsive in Pancreatic Ductal Adenocarcinoma Cells and Fuels Invasive Behaviour.

V. Papalazarou[1], T. Zhang[2], N. Paul[1], M. Cantini[3], O. Maddocks[2], M. Salmeron-Sanchez[3], L. Machesky[1]; [1]CRUK Beatson Institute, Glasgow, UNITED KINGDOM, [2]Institute of Cancer Sciences, University of Glasgow, Glasgow, UNITED KINGDOM, [3]Centre for the Cellular Microenvironment, University of Glasgow, Glasgow, UNITED KINGDOM.

Unbalanced cues from the extracellular matrix (ECM) govern pancreatic tumorigenesis and dissemination. Stiff fibrotic stroma and cancer cell mechanosensing regulate cell proliferation, migration and invasion. Such key processes are highly dependent on energy availability and need to be fueled by metabolic adaptations to tumorigenic microenvironments. However, it is still unknown how ECM mechanics influence cellular energetics and metabolism as well as how cells meet their ATP requirements during invasion and metastasis. We found that pancreatic cancer cells tune their metabolic networks to favour ATP production on stiff ECM. This process appeared dependent on mitochondrial fusion and polarization on stiff substrata as well as in pseudopods formed during ECM invasion. In addition, this was accompanied by a mechano-dependent regulation of ATP recycling through the creatine phosphagen system. The cytoplasmic creatine kinase CKB was expressed on stiff substrata in a YAP-dependent manner providing a critical advantage to the invasion capacity of pancreatic cancer cells. Collectively our results indicate that ECM mechanics can positively regulate tumour invasion by favouring ATP production and sharpening the gradient of ATP vs ADP through CKB activity. Our study highlights the importance of this ATP recycling circuit as a mechanism generating an efficient energy balance within the cytoplasm boosting invasion. Interestingly, targeting creatine phosphorylation hindered migration and invasion in 2D and 3D, revealing CKB as a potentially druggable target against the spread of pancreatic cancer.

P2033/B277

Mitochondrial Localization and Plasticity within MDA-MB-231 Cell Migration in Vitro.

J. Lawrence, S. Lundin-Schiller; Austin Peay State University, Clarksville, TN.

Triple negative breast cancer cells, MDA-MB-231, employ the Warburg effect during growth. During cellular migration the Warburg effect may not be the main ATP source. To test the hypothesis that mitochondrial ATP is an important source of energy for leading edge dynamics in migrating MDA-MB-231 cells, relative locations and morphology of mitochondria (Mito) were quantified during migration in a scratch wound assay. Confluent cell monolayers were grown in glass bottom dishes, a scratch was made through monolayer, and cells were stained with Mitotracker Green FM and Hoescht 33342 for one hour at 37°C. Cells were treated with increasing concentrations of EGF (epidermal growth factor) [0 (n=97), 10 (n=67), 100ng/ml (n=65)] one hour post staining and imaged using scanning laser confocal microscopy. Max Intensity Projections of Z stack images were analyzed to observe Mito through entirety of cell thickness. Thresholding DAPI and FITC channels identified nuclei and Mito. Determining nuclei centroids and direction of migration, cells were split into anterior and posterior regions of interest (ROI). Mitochondrial Localization Index (MLI) was determined by comparing sum mitochondrial fluorescence in anterior ROI to reciprocal posterior ROI; and MLI's were defined as posterior (0-0.35), peri-nuclear (0.35-0.7) or anterior (0.70-1.0). In the absence of EGF (0ng/ml, n=38) cells migrating into scratch wound had significantly more Mito in the anterior region than non-migratory cells (n=59) ($p=0.004$). Increasing concentrations of EGF however decreased the number of Mito localized in anterior regions significantly (ANOVA, $p=0.049$). This was unexpected as EGF increases rates of migration in scratch wound assays. Lamellipodia localized Mito morphology was compared across EGF treatments. Mito were characterized as fused tubular networks or fissioned. Fissioned Mito predominated in lamellipodia of migrating control and EGF treated cells [0ng/ml= 60.5%, 10ng/ml = 64.18%, 100ng/ml = 61.5%] (Logistic Regression $p<0.0001$). In conclusion, Mito localize in the anterior region during migration. EGF results in a decrease in total anterior Mito, but an increase in relative numbers of fissioned Mito in lamellipodia. These data support the hypothesis that Mito are necessary for leading edge dynamics but does not support EGF inducing anterior localization of Mito.

P2034/B278

Aquaporin-7 Is a Metabolic Sensor That Regulates Response to Cellular Stress in Breast Cancer.

C. Dai, V. Charlestin, M. Wang, N. Dovichi, J. Li, **L. Littlepage, 46556**; University of Notre Dame, Notre Dame, IN.

Misregulation of nutrient signaling contributes to cancer growth and treatment response. Using GC-MS, LC-MS/MS, and capillary zone electrophoresis (CZE)-MS platforms, we quantified and compared the levels of 374 metabolites in breast tumor tissue from normal tissue and transgenic mouse breast cancer models overexpressing a panel of oncogenes (PyMT, PyMT-DB, Wnt1, Neu, and C3-TAg). We then effectively integrated metabolomics and gene expression data from breast cancer mouse models through a novel unbiased correlation-based network analysis and have identified 35 metabolite and 34 gene hubs with the most network correlations. These hubs have prognostic value and are likely integral to tumor metabolism and breast cancer. We focused on the gene hub Aquaporin-7 (AQP7), a water and glycerol channel, as a novel regulator of breast cancer. AQP7 is prognostic of overall survival in breast cancer patients. In mouse breast cancer models, reduced Aqp7 expression caused reduced primary tumor burden and lung metastasis. Metabolomics and complex lipid profiling of cells and tumors with

reduced Aqp7 revealed dramatically altered lipid metabolism, glutathione metabolism, and urea/arginine metabolism compared to controls. These data identify Aqp7 as a critical regulator of the metabolic and signaling responses to environmental cellular stresses in breast cancer, highlighting AQP7 as a potential cancer-specific therapeutic vulnerability. Because breast cancer cells with Aqp7 deficiency are sensitive to these perturbations, Aqp7 is an attractive therapeutic target.

Confined Cancer Cell Migration Causes DNA Damage by Increasing Replication Stress.

P. Shah[1], C. W. McGuigan[1], S. Cheng[1], C. M. Hobson[2], M. J. Colville[3], K. Wolf[4], M. J. Paszek[3], R. Superfine[2], J. Lammerding[5]; [1]Weill Institute of Cell and Molecular Biology, Cornell University, Ithaca, NY, [2]Dept. Of Physics and Astronomy, University of North Carolina, Chapel Hill, NC, [3]Smith School of Chemical and Biomolecular Engineering, Cornell University, Ithaca, NY, [4]Dept. Of Cell Biology, Radboud University Medical Center, Nijmegen, NETHERLANDS, [5]Meinig School of Biomedical Engineering, Weill Institute of Cell and Molecular Biology, Cornell University, Ithaca, NY.

Cancer metastasis i.e., the spreading of cancer cells from primary tumors to distant sites in the body, is responsible for over 80% of cancer related deaths. During this process, cancer cells often migrate through very small interstitial spaces about 1-2 µm in size, i.e., much smaller than the cell diameter. Deformation of the nucleus, which is the largest and stiffest organelle in the cell, can form a rate-limiting step during such confined 3D migration. As cancer cells squeeze through confined spaces, they incur extensive nuclear deformation, and frequently exhibit nuclear envelope rupture and DNA damage. Here, we investigated the molecular mechanism responsible for the migration-induced DNA damage. We used a panel of different cancer cell lines, custom-built microfluidic devices that mimic the interstitial spaces encountered by cells in *vivo*, and fluorescent reporters to detect nuclear envelope rupture, DNA damage, and cell cycle phase. We found that in some cancer cell lines, DNA damage associated with nuclear envelope rupture occurred in all cell cycle stages, suggesting that influx of cytoplasmic nuclear may be responsible. Intriguingly, in other cell lines, nuclear deformation was sufficient to induce DNA damage, even in the absence of nuclear envelope rupture. Furthermore, DNA damage associated with nuclear deformation occurred predominantly in the S/G2 phase of cell cycle, suggesting that the damage might be associated with replication stress. Supporting this hypothesis, the DNA damage was frequently localized at stalled replication forks inside the confined spaces. Physical compression of cells was sufficient to reproduce the confinement-induced DNA damage, confirming that nuclear deformation can induce replication stress. This study, thus introduces a novel concept wherein physical confinement of the nucleus can lead to increased replication stress and replication fork stalling, providing new insights on possible causes of DNA damage during cancer cell migration.

Confined Migration Induces Heterochromatin Formation in Cancer Cells.

C. Hsia[1,2], O. Hasan[2], C. Chang[2,3], J. Lammerding[1,2,3]; [1]Department of Molecular Biology and Genetics, Cornell University, Ithaca, NY, [2]Weill Institute for Cell and Molecular Biology, Cornell University, Ithaca, NY, [3]Nancy E. An d Peter C. Meinig School of Biomedical Engineering, Cornell University, Ithaca, NY.

During cancer metastasis, cancer cells migrate through confined interstitial spaces, requiring extensive deformation of the cell body and nucleus. The severe physical stress on the nucleus during this frequently results in rupture of the nuclear envelope (NE) and nuclear fragmentation. Previous studies

found that mechanical force application on cells can induce mechanosensitive gene expression and chromatin rearrangement. However, it remains unclear whether physical stress on the nucleus during confined migration can induce histone modification and gene expression changes. Here, we performed live-cell and immunofluorescence imaging of HT1080 fibrosarcoma and MDA-MB-231 breast cancer cells migrating through collagen gel matrices and custom-made microfluidic migration devices that mimic interstitial spaces *in vivo*. Cell migration in confined 3D environments resulted in increased H3K9me3 and H3K27me3 heterochromatin marks and DNA methylation compared to unconfined conditions. The heterochromatin enrichment was particularly prominent in cells with visible nuclear deformation and in chromatin protrusions that formed inside nuclear blebs. In addition, we observed GFP-labeled HP1α enrichment within nuclear blebs in HT1080 and MDA-MB-231 cells during confined migration. By using a fluorescence recovery after photobleaching (FRAP) assay, we verified those GFP-HP1α enrichments to be heterochromatin. Treating cells with a pan histone methyltransferase inhibitor 3-Deazaneplanocin a (DZnep) significantly reduced the extent of heterochromatin formation after confined migration, suggesting an active enzymatic process underlying the increased heterochromatin formation. In particular, enriched phosphorylated (pSer424) HDAC3 nuclear staining suggested activation of HDAC3, potentially due to the mechanical force cells encountered during confined migration. Consistent with this idea, chemical inhibition of HDAC3 significantly reduced heterochromatin formation during confined migration. Interestingly, cells treated with DZnep showed significantly slower migration when compared to control treatment, suggesting the importance of chromatin condensation for efficient migration in 3D environment. Taken together, our research indicates that migration of cancer cells through confined spaces can induce heterochromatin formation, which is expected to both alter the physical properties of the nucleus and to modulate gene expression. These modifications could promote further metastatic cancer progression. Targeting the ability of chromatin condensation upon confined migration may potentially serve as a novel approach in treating metastatic cancers.

P2037/B281

Examining the Role of Chromatin Remodeler-*Skp-1*(snw1) during Cellular Invasion.

N. Parsan[1,2], J. J. Smith[1], D. Q. Matus[1]; [1]Stony Brook University, Stony Brook, NY, [2]Clements High School, Sugar Land, TX.

Cellular invasion - the specialized transgression of a basement membrane - is crucial for normal development and a fundamental feature of cancer metastasis. We utilize a unique in *vivo* model, studying the process of anchor cell (AC) invasion into the vulval epithelium during *C. elegans* development as a model for cellular invasion. Previous studies have identified the conserved nuclear hormone receptor transcription factor NHR-67 as crucial to maintaining the AC in G0/G1 cell cycle arrest and have demonstrated the necessity of a histone deacetylase, HDA-1, for the expression of pro-invasive genes. These findings suggest invasion is a differentiated cell behavior requiring genome modification and arrest. To identify additional chromatin modifiers that mediate invasion, we are conducting a tissue-specific RNAi screen using a commercially available ORF library. Thus far, we have screened 70 genes annotated as chromatin regulators and have implicated 6 genes in AC invasion. We have further investigated the gene *skp-1*, of which the mammalian homolog, SNW1, has been studied in the context of oncogenesis. To characterize the function of *skp-1* in AC invasion, we have utilized a cell cycle biosensor providing a visual readout of cell cycle state live based on the ratio of localization of a GFP-tagged fragment of DNA Helicase B in the cytoplasm to nucleus based on CDK2 activity. Our findings demonstrate that RNAi mediated depletion of *skp-1* results in cycling, non-invasive ACs. In addition, we

created an improved RNAi vector, which has increased the penetrance of invasion defects, using available cDNA sequences. We are currently examining the interactions of *skp-1* with the previously identified set of four conserved pro-invasive transcription factors, *fos-1a, egl-43*, *hlh-2*, and *nhr-67* to understand the influence *skp-1* has on the gene regulatory network promoting AC invasion.

P2038/B282

Mechanistic Insights into Cell Motility Under High Hydraulic Resistance.

D. Maity, Y. Li, S. Sun; Johns Hopkins University, Baltimore, MD.

Cells in *vivo* encounter a diverse chemo-mechanical micro-environment which influences various cellular processes such as growth, development, disease and motility. This is especially true for a tumor microenvironment where a plethora of cells, extracellular matrix secreted by the cells, macromolecules and interstitial fluid crowd the landscape. These essentially augment the local hydraulic resistance of the microenvironment. It has been previously reported that enhanced extracellular fluidic viscosity (resulting in enhanced hydraulic resistance) leads to augmentation of cell motility. Here we examine the underlying mechanistic insights which play a critical role in augmenting cell motility under high hydraulic resistance. We add a thickening agent to the cell culture medium, resulting in an effective viscosity of 1Pa.s (x 1000 viscosity of water). We found, via pharmacological inhibitions, that the key players of motility under high hydraulic resistance are ion-channels/ pumps, namely, NKCC1 (sodium potassium chloride co-transporter 1), NHE1 (sodium/ hydrogen exchanger 1) and NaK (sodium potassium pump) which influence water permeation. Disruption of cell polarization (via Latrunculin A), which also causes a disruption of polarization of these ion-channels/ pumps, resulted in a significant speed reduction. Interestingly, there is no change in F-Actin expression levels under the influence of high viscous media compared to normal media. We also observed a reduction in actin retrograde flow speed and no change in traction stress in high viscous media compared to the case of normal media. We also investigated calcium dynamics, and found that higher frequencies of calcium oscillations dominate immediately when cells come in contact with high viscous media. These findings have significant implications in shedding light on mechanical aspects of tumor microenvironment, cell motility under significant hydraulic resistance such as in an airway or gastric mucus and cancer cell metastasis.

P2039/B283

Label-free Quantitative Phase Imaging: Applications for Cancer Cell Mechanobiology Studies.

J. Gumulec[1], M. Raudenska[1], J. Balvan[1], T. Vicar[2], M. Masarik[1]; [1]Masaryk University, Brno, CZECH REPUBLIC, [2]Brno University of Technology, Brno, CZECH REPUBLIC.

Mechanical properties of cells are associated with cellular physiological functions by modulating migration, polarization and deformability, and subcellular trafficking. Accordingly, these properties are important for development of cancer. Here we investigated mechanobiological properties on multiple cancer models: head and tumors (primocultures and cell lines) and prostate tumors. Characterization was performed by means of atomic force microscopy, non-coherent quantitative phase imaging, refractive index tomography and confocal microscopy. Cells were further exposed to tubulin-modulating docetaxel. Atomic force microscopy revealed that Young Modulus was increasing with higher invasiveness of cells (determined by engraftment rate in mice, migration speed, scratch and colony-forming assays), more demonstrated on head and neck and prostate cancer cell line model, contrary to a concept that more aggressive cells are of higher compliance. This trend was followed by quantitative

phase imaging - the cell dry mass was increasing with invasiveness pointing out to relation between cell mass density, cytoskeletal composition and cell stiffness. Based on immunofluorescence it was observed that upon docetaxel treatment either actin and tubulin changed from organized to perinuclear shell-like structure in all tested lines followed by dramatic increase of cell stiffness, which again correlated with cell dry mass. Data suggest that cytoskeleton changes affecting mechanobiological properties of cells can be estimated by means of quantitative phase imaging. This work was supported by the Czech Science Foundation GA18-03978S.

P2040/B284

FishATLAS: a Pipeline into Statistical Characterization of Cancer Metastasis in Ewing Sarcoma Zebrafish Xenografts.

D. Saucier[1], J. Amatruda[2], G. Danuser[1]; [1]Department of Bioinformatics, University of Texas Southwestern Medical Center, Dallas, TX, [2]Children's Hospital of Los an geles and Keck School of Medicine, University of Southern California, Los an geles, CA.

Survival rates of children with various forms of pediatric cancers have seen great improvement in the last 20 years, but unfortunately these gains have not occurred for patient with metastastic cancer. The poor prognosis of metastatic disease urgently calls for research tools that can unravel the complex underpinnings of the metastatic cascade in *vivo,* especially the microenvironmental conditions permissive to induction and growth of metastatic tumors remote from the primary tumor environment. This applies in particular to Ewing sarcoma, a malignant cancer of bone and soft tissue occurring in children, adolescents, and young adults characterized by an oncogenic fusion translocation: *EWS-FLI1*. One-in-three patients with Ewing sarcoma will have metastatic disease at diagnosis, with essentially no avenue to cure. To address this problem we have developed a system in which human Ewing sarcoma cells are xenografted into zebrafish embryos. FishATLAS extracts image data from a large cohort (N>100) of xenografts under different molecular conditions such as basal or knockdown expression levels of the EWS-FLI gene itself or one of its targets. Each fish image is registered by a diffeomorphic transform to a template fish to serve as a coordinate reference frame where FishATLAS determines two crucial pieces of information: 1) Distribution of metastatic spread in conserved, physiologically-relevant microenvironments in *vivo*, and 2) Metastatic microenvironments conserved across different genes and experimental conditions. *EWS-FLI1*'s thousands of genetic targets require a precise map of conserved gene contributions in order to elucidate the complex underpinnings of metastatic disease. Preliminary FishATLAS interrogation of TC32 Ewing sarcoma cell line with or without EWS/FLI1 knockdown shows distinct distributions of cell metastases and primary tumor location. We are expanding this model to patient derived xenografts (PDXs) as a more realistic representation of a human Ewing sarcoma tumor in the FishATLAS pipeline. We are currently in the process of adapting our protocols for this more complex PDX cell injection which includes both cancer and non-cancerous cells.

P2041/B285

Preventive Effect of Proinsulin C-peptide on Pulmonary Vascular Leakage and Metastasis of Melanoma Cells in Diabetic Mice.

H. Jeon[1], Y. Lee[1], J. Lee[1], Y. Kim[1], K. Ha[1,2]; [1]Department of Molecular and Cellular Biochemistry, Kangwon National University of medicine, Chuncheon, Kangwon-do, KOREA, REPUBLIC OF, [2]Scripps Korea antibody Institute, Chuncheon, KOREA, REPUBLIC OF.

Recently, C-peptide has emerged as a potential candidate for treating various diabetic complications; however, its function against hyperglycemia-induced metastasis is unknown. We hypothesized that hyperglycemia induces metastasis and C-peptide inhibits pulmonary vascular leakage and metastasis in the diabetic mice. VEGF, which is elevated in the lungs of diabetic mice, activated transglutaminase 2 (TGase2) in human pulmonary microvascular endothelial cells (HPMVECs) by sequential elevation of intracellular $Ca2^{+}$ and reactive oxygen species (ROS) levels. VEGF also induced vascular endothelial (VE)-cadherin disruption and increased the permeability of endothelial cells, both of which were prevented by the TGase inhibitors monodansylcadaverine and cystamine or TGM2-specific small interfering RNA. C-peptide prevented VEGF-induced VE-cadherin disruption and endothelial cell permeability through inhibiting ROS-mediated activation of TGase2. C-peptide supplementation inhibited hyperglycemia-induced ROS generation and TGase2 activation and prevented vascular leakage and metastasis in the lungs of diabetic mice. The role of TGase2 in hyperglycemia-induced pulmonary vascular leakage and metastasis was further demonstrated in diabetic $Tgm2^{-/-}$ mice. These findings demonstrate that hyperglycemia induces metastasis, and C-peptide prevents the hyperglycemia-induced metastasis in the lungs of diabetic mice by inhibiting VEGF-induced TGase2 activation and subsequent vascular leakage.

P2042/B286

Invadopodia Facilitate the Cooperative Invasion of Breast Cancer Cells.

L. Perrin[1], B. Gligorijevic[1,2]; [1]Temple University, Philadelphia, PA, [2]Fox Chase Cancer Center, Philadelphia, PA.

Invasive breast cancer is, in most cases, an uncurable disease while localized tumors are clinically manageable. We and others have shown that to negotiate the structural barrier imposed by the surrounding extracellular matrix (ECM) in the healthy tissue, invasive cancer cells utilize dynamic protrusions enriched in matrix metalloproteinases to remodel collagen fibers. While it is accepted that these protrusions, called invadopodia, contribute to the invasion of E-cadherin (-) cells, invading individually, whether and which cell assemble invadopodia during cohesive multicellular invasion of E-cadherin (+) remains unknown. So far, in an effort to limit cancer cell invasion and metastasis, most of the attention has been drawn to inherently invasive cells, frequently disregarding non-invasive cancer cells. However, tumors are highly heterogeneous, and contain cancer cell subpopulations with varying degrees of invasion potentials. Recently, it was observed that in 3D spheroid invasion assay, invasive cells create paths inside the ECM, into which non-invasive cells may subsequently migrate, a phenomenon termed “cooperative invasion”. Moreover, the possibility that cooperation among heterogeneous cancer cells might contribute to the dissemination of non-invasive cells in tumors is yet to be tested. Using the 3D spheroid invasion assay, our preliminary results in both human and mouse cell lines demonstrate that invadopodia are primarily assembled by cells located at the tip of invasive strands. This was observed in all types of strands, including both E-cadherin (-) strands and E-cadherin (+), cohesive strands. Furthermore, we found that coculture of non-invasive cells, together with invasive

cells that assemble invadopodia, enables the cooperative invasion of these two cell types. Hence, invadopodia are necessary only for path creation, but not for path following. To test if migration and lung colonization of non-invasive cells can be mediated by invadopodia during cooperative invasion, we are using preclinical mouse models of human and mouse mammary carcinoma. We propose that cooperative invasion is a new mechanism by which heterogeneous breast cancer cell populations can disseminate. In conclusion, targeting invadopodia may be a potent strategy to inhibit dissemination of both individually, as well as collectively migrating cells.

P2043/B287

Understanding the Coordination of Invadopodia with Cell Cycle Progression.

B. Bayarmagnai, L. Perrin, K. Esmaeili Pourfarhangi, E. Tüzel, X. Graña, B. Gligorijevic; Temple University, Philadelphia, PA.

Tumor cell invasion comprises cell migration and assembly of invadopodia, which are protrusions capable of degrading the extracellular matrix (ECM). The effect of cell cycle progression on invadopodia has not been elucidated. In this study, using invadopodia- and cell cycle- fluorescent markers, we show in 2D and 3D cultures, as well as in *vivo*, that breast carcinoma cells assemble invadopodia and invade into the surrounding ECM preferentially during the G1 phase. Interestingly, during strand invasion in 3D spheroids, the leader cells are enriched in G1 and upon transitioning to the S and G2 phases, they are replaced by another cell in G1 phase. Furthermore, cells synchronized in G1 phase exhibit significantly higher ECM degradation compared to the cells synchronized in S phase. Consistent with this, the expression (MT1-MMP, cortactin) and localization (Tks5) of invadopodia components are elevated in G1. The cyclin-dependent kinase inhibitor (CKI) $p27^{kip1}$ localizes to the sites of invadopodia assembly. Over-expression and stable knockdown of $p27^{kip1}$ affect invadopodia turnover and ECM degradation. Taken together, these findings suggest that expression of invadopodia components, as well as invadopodia function, are linked to cell cycle progression and that invadopodia is controlled by cell cycle regulators. Our results caution that this coordination between invasion and cell cycle must be considered when designing effective chemotherapies.

P2044/B288

Cells in Intermediate States during EMT Are Characterized by Specific Geometrical and Mechanical Intra-cellular Architectures.

Y. Margaron[1], L. Guyon[2], L. Kurzawa[3], A. Morel[4], A. Pinhiero[5], L. Blanchoin[3], F. Reyal[5], A. Puisieux[4], **M. Thery**[6]; [1]CytoMorpho Lab, IRIG, Paris, FRANCE, [2]Interdisciplinary Research Institute of Grenoble (IRIG), Grenoble, FRANCE, [3]CytoMorpho Lab, IRIG, Grenoble, FRANCE, [4]Cancer Research Center of Lyon, Lyon, FRANCE, [5]RT2Lab, PSL Research University, Paris, FRANCE, [6]CytoMorpho Lab, Hopital Saint Louis, Paris, FRANCE.

The epithelial to mesenchymal transition (EMT) allows mammary breast cancer cells to dissociate from the primary tumour and form metastases. Recent works have revealed that the *dangerous* cells that have acquired augmented capacity to migrate and transdifferentiate into several cell types are in an intermediate stage between the epithelial and the mesenchymal state. It is now required to unravel the molecular and cellular mechanisms responsible for the acquisition of these properties and to identify early and specific structural markers characterizing these stages. Here we induced the expression of ZEB1, a transcription factor responsible for EMT initiation, to generate intermediate stages of EMT in

human mamary epithelial cells and stimulation with TGFβ to push further the transition to the mesenchymal state. We measured and compared the architecture, internal organisation and mechanical properties of each state. We found that the lack of inter-cellular cohesiveness in intermediate and later stages of EMT can be detected early by microtubule destabilisation and the repositioning of the centrosome from the cell junction to the cell center. Consistent with their high migration velocities, we found that cells in intermediate state of EMT were in a low tensional state compared to epithelial and mesenchymal cells. The high contractility of mesenchymal cells powered a retrograde flow pushing the nucleus away from cell adhesion to the extra-cellular matrix. These measures revealed how defined structural and mechanical rearrangement in intermediate stages of EMT confered them specific dissociation and migration properties that distinguish them from epithelial and mesenchymal states.

P2045/B289

E-cadherin Is an Invasion Suppressor, Survival Factor, and Metastasis Promoter in Multiple Models of Breast Cancer.

V. Padmanaban[1], I. Krol[2], Y. Suhail[1], B. Szczerba[1], N. Aceto[2], J. Bader[1], A. Ewald[1]; [1]Johns Hopkins University School of Medicine, Baltimore, MD, [2]University of Basel, Basel, SWITZERLAND.

The loss of E-cadherin (E-cad) has been linked to increased invasion of cancer cell lines and has been inferred to promote metastasis, leading to its classification as a tumor, invasion, and metastasis suppressor. However, about 90% of breast cancers retain E-cad expression in both the primary tumor and distant metastases. In this study, we test the requirement of E-cad for metastasis using mouse models of luminal and basal breast cancers that allow for an inducible deletion of E-cad. Loss of E-cad increases tumor invasion and dissemination in both 3D organotypic *ex vivo* assays and in *vivo* assays. In contrast, E-cad loss strongly inhibits metastasis. Careful analysis of intermediate stages of metastasis revealed that despite an increase in local invasion, E-cad loss is associated with a decrease in migratory persistence, decrease in circulating tumor cell counts, decrease in tumor seeding potential, and decrease in metastatic outgrowth, collectively causing a strong decrease in metastasis. Mechanistically, we found a TGFβ-dependent enrichment of reactive oxygen species specifically within the disseminated E-cad- cancer cells, frequently leading to their apoptosis. Significantly, colony formation of E-cad-negative cells was rescued by treatment with a TGFβ-receptor inhibitor, an anti-oxidant, or an apoptosis inhibitor. These results suggest that E-cad acts as a survival factor during the detachment, systemic dissemination, and seeding phases of metastasis in these models of breast cancer.

P2046/B290

E-cadherin Promotes Cell Proliferation in Breast Cancer.

G. Russo, M. Karl, M. Lee, D. Wirtz; Johns Hopkins University, Baltimore, MD.

E-cadherin promotes cell proliferation in breast cancer Gabriella Russo, Michelle Karl, Meng-Horng Lee, Denis Wirtz Currently classified as a tumor suppressor gene, E-cadherin (Ecad) is a widely studied protein for its association with the epithelial to mesenchymal transition (EMT). Functioning as a cell-cell adhesion molecule, the loss of Ecad is a marker of cells undergoing a transition from a more epithelial phenotype to a more migratory and invasive one, resulting in the early dissemination of cancer cells from the primary tumor. However, recent clinical data for breast cancer suggest that Ecad may function as an oncogene in certain subtypes. This apparent contradiction may be due in part to the 2D *in vitro* systems widely used to study EMT processes. As the effect of Ecad loss on cell behavior can vary greatly

depending on the model used, we studied the role of Ecad in cancer cell proliferation and invasion/migration using a more physiologically relevant in *vitro* system developed in our lab. This novel two-compartment 3D organoid model contains both a basement membrane and stromal collagen I matrix allowing us to study the first step in the metastatic cascade. This 3D in *vitro* model suggests that Ecad induces hyper-proliferation in breast cancer cells through activation of the ERK signaling pathway. This result was validated in multiple in *vivo* mouse models. Depletion of Ecad and pharmacological inhibition of ERK in Ecad-expressing cells both depress tumor growth in preclinical models of breast cancer.

P2047/B291

Ovarian Carcinosarcoma with Epithelial-mesenchymal Transition.

N. Wali MD PhD[1], A. Arakawa MD PhD[2], R. Lu PhD[3], Y. Maimaitiaili PhD[4], H. Onagi MD PhD[5], S. Takeuchi MD PhD[6], K. Kajino MD PhD[7], A. Arakawa MD PhD[5]; [1]The Pathology Department in Juntendo University, tokyo, JAPAN, [2]The Pathology Department of Saku Hospital, Nagano, JAPAN, [3]Department of Human Pathology in Juntendo University, tokyo, JAPAN, [4]Department of Human pathology of Juntendo University, tokyo, JAPAN, [5]Department of Human pathology in Juntendo University, tokyo, JAPAN, [6]Juntendo University, tokyo, JAPAN, [7]Department of Pathology in Juntendo University, tokyo, JAPAN.

Ovarian cancer is one of the most common cancers in females. In 2018, nearly 300,000 new cases were reported [(1)]. Specifically, a portion of these incidences are attributed to malignant mixed mesodermal tumors such as ovarian carcinosarcoma, that is a rare and aggressive cancer of the ovary, characterized by biphasic histology, with both carcinomatous and sarcomatous elements. Early detection and therapeutic approaches have been unsuccessful as the origin and pathological process of this specific cancer is poorly understood[(3)]. Epithelial-mesenchymal transition (EMT) is a physiological process observed during embryogenesis also involved in cancer cell invasion and metastasis[(2)]. Five patients were identified with advanced-stage ovarian carcinosarcoma in our hospital from 2000 to 2018. Age ranged from the 50s to 70s with common clinical symptom was abdominal pain. The size of the tumor was 10 to 20 cm. The cancer component was mostly endometrioid carcinoma. The sarcoma component was osteosarcoma in 3 cases and homologous sarcomatous in 2 cases. Regarding staining, E-cadherin was partially negative, and N-cadherin was positive. Ideally, snail should be positive, but the result showed negative. Our result did not support the EMT transition hypothesis in carcinosarcomas genesis.

P2048/B292

Evaluation of EMT Markers in Cadmium-treated Mammary Epithelial Cells.

M. Zuniga-Eulogio[1], M. Olea-Flores[1], J. Hernandez-Moreno[1], L. Herrera-Zuniga[2], J. Bello-Martinez[1], M. Moreno-Godinez[1], N. Navarro-Tito[1]; [1]Facultad de Ciencias Quimico Biologicas, Universidad Autonoma de Guerrero, Chilpancingo de los Bravo, MEXICO, [2]Tecnológico de Estudios Superiores del Oriente del Estado de México, Los Reyes Acaquilpan, MEXICO.

The epithelial-mesenchymal transition (EMT) is a transdifferentiation process from an epithelial to a mesenchymal phenotype. During EMT occurs changes in expression and/or activation of adhesion proteins, kinases, transcription factors and hydrolases. Breast cancer is the most frequent neoplasia and the leading cause of death in women worldwide. In addition to the well-known classical and genetic risk factors for development and poor prognosis of breast cancer, exposure to environmental pollutants such as cadmium (Cd) are currently been investigated. In this context, we aimed to evaluate the effects

of chronic cadmium exposure in mammary epithelial cells, the expression of the canonical EMT markers such as morphological changes, E-cadherin and vimentin levels, kinases activity and cell migration. MCF10A cell line cultures were maintained through 28 days with different Cd concentrations (0.5, 1.5, 2.5, 5 and 10 µM). We visualized cell morphology using rhodamine-phalloidin in an epifluorescence microscope. Expression levels of E-cadherin and vimentin were evaluated by Western blot. Finally, wound-healing assays were performed to assess cell migration. Our data showed that after prolonged cadmium treatment, morphological changes and stress fibers formation depends on the Cd doses. We also observed a decrease in E-cadherin levels, increased vimentin expression, and gain of cell migration in MCF10A cell line. Together, our data suggest that chronic exposure to different cadmium concentrations promotes EMT features and enhanced migratory properties related to breast cancer progression in MCF10A epithelial breast cells.

P2049/B293

G1p3-induced Mtros Elicits Retrograde Signaling Alters Nuclear Gene Expression of Cav1 and Scn-1 to Promote Breast Cancer Cell Migration.

A. Davenport[1], M. Morris[2], D. Hynds Ph.D[1], V. Cheriyath Ph.D[2]; [1]Texas Woman's University, Denton, TX, [2]Texas A&M-Commerce, Commerce, TX.

Metastasis is the leading cause of deaths in > 90% of breast cancer patients. Recently, we reported that G1P3 (IFI6/ISG6-16), an interferon-stimulated gene, promotes breast cancer metastasis. Although G1P3 was suggested as a mitochondrial protein with a role in elevating mitochondrial reactive oxygen species (mtROS), its submitochondrial localization was inconclusive. Therefore, pure mitochondria were isolated using anti-TOM22 microbeads (Miltenyi Biotec) and sub-fractionated by differential centrifugation. Western blot analysis identified localization of G1P3 in the inner mitochondrial membrane (IMM) fractions. Additionally, sodium carbonate flotation assay that releases peripheral membrane proteins failed to extract G1P3 and intact mitochondria protected G1P3 from trypsin digestion, confirming its IMM localization. Based upon these results and G1P3's ability to promote cancer cell migration by mtROS levels, we hypothesized that retrograde signaling elicited by G1P3-induced mtROS alter nuclear gene expression to confer migratory potential in breast cancer cells. This hypothesis was tested by comparative gene expression and pathway analysis of G1P3-expressing (MCF-7^{G1P3}) and nonexpressing cells ($MCF7^{Vector}$). In agreement with its effects on actin remodeling to promote migratory structures, genes involved in regulation of wound healing, epithelial to mesenchymal transition (EMT), cytoskeleton organization, and oxidative response pathways were enriched in $MCF7^{G1P3}$ cells. In quantitative RT-PCR analysis, in $MCF7^{G1P3}$ cells, Scinderin1 that sever F-actin was downregulated by 5-fold and Caveolin 1, a regulator of endocytosis was upregulated in by 4-fold ($p \leq 0.05$). Moreover, MitoTEMPO, a mitochondrial specific ROS scavenger, reversed the expression of Caveolin 1 and Scinderin in MCF-7^{G1P3} cells. The direct role of G1P3 in regulating Cav1 expression was assessed using a specific siRNA. In immunoblot analyses, Cav1 protein was 3-fold higher in MCF-7^{G1P3} cells that was abrogated by siG1P3 or by mitoTEMPO with a concurrent abrogation of mtROS levels. Taken together, our results demonstrate a role for G1P3-induced mtROS in eliciting retrograde signaling to alter nuclear gene expression of Cav1 and Scn 1 to promote breast cancer cell migration.

P2050/B294

FAK and Src: Regulators of EMT-related Transcription Factors in Mammary Epithelial Cells Stimulated with Leptin.

M. Olea-Flores[1], M. Zúñiga-Eulogio[1], E. Acosta[1], C. Ortuño-Pineda[1], E. Castañeda-Saucedo[1], M. Ordoñez[2], M. Mendoza-Catalán[1], N. Navarro-Tito[1]; [1]Autonomous University of Guerrero, Chilpancingo, MEXICO, [2]Autonomous University of State of Morelos, Cuernavaca, MEXICO.

The Epithelial-Mesenchymal Transition (EMT) is a reversible cellular trans-differentiation program from epithelial to a mesenchymal phenotype, where specific transcription factors such as Snail, Slug, Zeb and Twist are activated. Leptin is a hormone secreted mainly by adipose tissue, and in a lesser extent by normal and tumorigenic mammary epithelial tissue, its main function is regulating the appetite, however, the overexpression of leptin and its receptor, ObR, has been associated with tumor progression in breast cancer. However, the molecular mechanism that underlies these events is not fully understood; nevertheless, the activation of different signaling pathways appears to be essential. The aim was to determine the role of Src and FAK in the expression of EMT-related transcription factors in MC10A and MCF7 mammary epithelial cell lines stimulated with leptin. Specific events occurring during EMT were also evaluated in the presence or absence of the kinases's chemical inhibitors PP2 and PF-573228. For instance, we tested the expression and subcellular localization of the EMT-related transcription factors Twist and β-catenin, by western blot and immunofluorescence. We also evaluated the secretion and activation of matrix metalloproteases (MMP-2 and MMP-9) by gelatin zymography. Invasiveness properties of leptin-stimulated cells were determined by invadopodia formation assays, and by the transwell chamber method. Our results showed that leptin promotes EMT through Src and FAK activation, which leads to the secretion and activation of MMP-2 and MMP-9, invadopodia formation and cell invasion in MCF10A cells. In conclusion, our data suggest that leptin promotes an increase in the expression levels of Twist and β-catenin, the secretion of MMP-2, MMP-9, the invadopodia formation and invasion in MCF10A cells in a Src and FAK-dependent manner.

P2051/B295

Inhibition of the Fractionated Ionizing Radiation-induced Epithelial to Mesenchymal Transition Signal by Socs1 through Ros Regulation.

C. Lee, S. Kim; SungKyunKwan University, Suwon, KOREA, REPUBLIC OF.

Fractionated ionizing irradiation (FIR) is widely employed for the treatment of diverse types of cancers. However, cancer cells often develop resistance to the FIR therapy given at multiple low doses. Epithelial to mesenchymal transition (EMT) is recognized as a process associated with the therapy-induced resistance of cancers. The present study was conducted to investigate the mechanism of FIR-induced EMT response and the associated signaling pathways to understand molecular basis of the FIR-mediated radioresistance. In HCT116 colorectal cancer cell lines, FIR induced intracellular reactive oxygen species (ROS) and changes indicative of EMT features such as down-regulation of E-cadherin along with up-regulation of Twist and Snail. Anti-oxidant pretreatment abrogated the FIR-induced ROS generation and significantly attenuated EMT response, indicating that FIR-induced EMT is mediated by ROS signal. Mechanistically, the FIR-induced ROS-mediated EMT process appeared to proceed through Akt --> Src -->Erk signaling pathways. As suppressor of cytokine signaling 1 (SOCS1) has been reported for the anti-ROS and anti-EMT action, the transduction of SOCS1 into HCT116 cells inhibited the FIR-induced changes for EMT with thioredoxin (Trx)1 up-regulation. Notably the shRNA-mediated Trx1 ablation in SOCS1-

transduced cells restored the FIR-induced ROS and EMT features. Together, the results of the present study indicate that ROS signal acts as a mediator of the FIR-induced EMT response, which suggest a potential anti-tumor function of SOCS1 in colon cancer cells through the regulation of ROS/Trx1 axis.

Tumor Microenvironment: Immune Microenvironment

P2052/B296

Contact-mediated Macrophage Mitochondrial Transfer in Breast Cancer Cell Metastasis.

C. U. Kidwell, J. S. Johnson, M. Roh-Johnson; University of Utah, Salt Lake City, UT.

The presence of macrophages in the tumor microenvironment has been correlated with poor prognosis and increased tumorigenicity in many cancer types. However, the macrophage-tumor cell interactions that contribute to this increased tumorigenicity remain unclear. Recently, we discovered that macrophages transfer cytoplasm to melanoma cells in *vivo and* the majority of the recipient melanoma cells disseminate from the primary transplantation site. These data suggest macrophages transfer a "package" of cytoplasm containing molecules that may influence the behavior of recipient cells. However, central questions that remain are: 1) what is identity of the transferred molecules? and 2) what is the mechanism underlying this transfer? Here, we report that mitochondria are transferred from macrophages to cancer cells and this occurs through a cell contact-dependent mechanism. Most examples of mitochondrial transfer in the literature show population-level phenotypes, thus it is still unclear what is happening in recipient cells on a cell-biological level and whether the observed phenotypes can be attributed to the receipt of functional mitochondria. By genetically labeling mitochondria in primary human macrophages and human breast cancer cells, we found that donated mitochondria do not incorporate into the host cancer cell mitochondrial network, but instead persist as a separate, intact population. Furthermore, we discovered that recipient cancer cells exhibit an increased proliferative index. Interestingly, our data suggests this phenotype may not be due to the receipt of functional mitochondria as these donated mitochondria have a reduced membrane potential yet they can be visualized in recipient cells several hours post-transfer suggesting they are not being degraded. Taken together, our results indicate the transfer of macrophage mitochondria elicits an increase in proliferation in recipient cancer cells. We aim to explore this further by investigating the following possibilities: 1) donated mitochondria are sufficient to trigger a biological response in the recipient cell or 2) additional cellular contents are co-transferred and have instructive capabilities. Towards these ends, we are directly testing the function of transferred mitochondria by exogenously injecting purified mitochondria into cancer cells. In addition, we are characterizing the function of transferred mitochondria using biosensors and in *vivo* models. Future work will address whether mitochondria or other transferred molecules provide essential cues that drive increased tumorigenesis. These studies will more clearly define how donated molecules can lead to functional changes in recipient cells and determine how macrophage and tumor cell interactions contribute to metastasis.

P2053/B297

Macrophage-dependent Mitochondrial Dynamics in Cancer.

J. R. Casalini, C. U. Kidwell, J. S. Johnson, **M. Roh-Johnson**; University of Utah, Salt Lake City, UT.

Metastasis is not a one-time event, but a progressive process in breast cancer, generally occurring multiple times over the course of a patient's life. Since metastasis is the main cause of cancer-related deaths, it is imperative to develop treatment strategies to prevent progression of the disease after initial diagnosis. In addition to genetic changes in tumor cells, a major determinant of tumor cell behavior stems from local interactions within the tumor microenvironment. With the initial successes of immunotherapies, a wealth of studies have defined roles for many of the tumor microenvironmental immune components in controlling tumor cell behavior. It has become clear that intercellular communication strongly underlies therapeutic resistance and tumor relapse. One immune cell type known to frequently communicate with tumor cells is tumor-associated macrophages, which can both promote and block tumorigenesis. This plasticity is due to the ability of macrophages to differentiate into distinct states in response to environmental cues. Recently, we discovered an unconventional form of cell-cell communication in which human macrophages transfer mitochondria to breast cancer cells. Cancer cells that receive macrophage mitochondria exhibit increased proliferation, a critical step in metastasis. To understand how mitochondrial transfer is regulated, we altered macrophage differentiation by inhibiting the Notch pathway. Inhibiting the Notch pathway resulted in macrophage differentiation to a pro-tumorigenic state and increased macrophage mitochondrial transfer to cancer cells. We are currently testing how the Notch pathway regulates mitochondrial intercellular dynamics in macrophages, and how altering intercellular dynamics affects mitochondrial transfer to cancer cells. These studies will reveal valuable insight into how cellular differentiation influences intracellular organelle dynamics. Furthermore, given that Notch inhibitors are currently under clinical pursuit, these studies will provide critical information on the efficient use of these inhibitors to treat cancer patients.

P2055/B299

Progesterone Receptor Promotes Degradation of Stat2 to Inhibit the Interferon Response in Breast Cancer.

K. Walter, C. Hagan; University of Kansas Medical Center, Kansas City, KS.

The progesterone receptor (PR) is a nuclear receptor that is activated in response to its ligand, progesterone. Traditionally, PR exerts its effects following ligand activation by translocating to the nucleus and binding to DNA where it affects the transcription of a variety of genes involved in growth, survival and proliferation. Our lab, using microarray data combined with Gene Set Enrichment an alysis, has identified a novel subset of genes that have altered expression following PR activation. These genes are primarily involved in interferon signaling—a pathway normally utilized in response to viral infection. Our data show that many genes that are normally activated in response to interferon signaling (interferon stimulated genes, ISGs) are repressed when PR is activated by its ligand. As much of the past research focus has been on PR's ability to promote transcription of its target genes during pregnancy/mammary gland development, little is known of PR's role as a transcriptional repressor. In attempting to elucidate a mechanism by which PR exerts this effect, we have investigated crosstalk of PR with canonical interferon signaling proteins and have found that PR interacts with these proteins and significantly reduces their ability to become activated. In particular, a new finding from our lab has found that PR promotes the ubiquitination and degradation of STAT2-an indispensable protein involved

in the interferon signaling cascade. Without STAT2, interferon signaling is effectively abrogated. Experiments are currently underway to identify precisely how PR activation results in turnover of the STAT2 protein, and how this translates to inhibition of the interferon response. Our lab is interested in identifying the consequences of this PR-dependent inhibition of efficient type I interferon signaling in the context of breast cancer. Evasion of the immune system is considered a Hallmark of Cancer and our preliminary data suggest a potential mechanism by which breast cancer is able to accomplish this. Activation of type I interferon signaling is an early step in marking tumors for immune clearance. By repressing ISG protein expression, it is possible that these tumors are able to avoid detection by host immune cells leading to tumor establishment and subsequent progression. This novel role of PR offers insight that could aid in improving upon established estrogen only-based therapies for prevention and treatment of hormone dependent breast cancers.

P2054/B298

Upregulation of the Nlrc4 Inflammasome Contributes to Poor Prognosis in Glioma Patients.

J. Lim[1], M. Kim[1], Y. Park[2], J. Ahn[2], J. Sim[2], J. Kim[2], S. Hwang[1], J. Moon[3], K. Cho[1], **K. Kwack**[2]; [1]Department of Neurosurgery, Bundang CHA Medical Center, CHA University, Seongnam-si, KOREA, REPUBLIC OF, [2]Institute Department of Biomedical Science, College of Life Science, CHA University, Seongnam-si, KOREA, REPUBLIC OF, [3]Soonchunhyang Institute of Medi-bio Science (SIMS), Soonchunhyang University, Cheonan-si, KOREA, REPUBLIC OF.

Inflammasomes which are majority complex of NLRs family with caspase-1 is strongly associated with various tumor development. However, among the NLRs family, role of NLRC4-mediated inflammasome to glioma is unclear. in this study, we identified that the NLRC4-mediated inflammasome is associated with poor prognosis of glioma patients from TCGA data. Immunohistochemistry was shown that NLRC4 and caspase-1 were co-expressed in astrocytoma cells in 11 tissue of glioma patients. in addition, several key proteins which are related with NLRC4-mediated inflammasome pathway were also associated with poor prognosis of glioma patients in TCGA dataset. Our results suggest that the upregulation of the NLRC4-mediated inflammasome contributes to a poor prognosis for gliomas and presents a potential therapeutic target and diagnostic marker.

P2056/B300

The CXCL5/CXCR2 Axis Is Sufficient to Promote Breast Cancer Colonization during Bone Metastasis.

R. Romero-Moreno, K. Curtis, G. Niebur, **L. Littlepage**; University of Notre Dame, Notre Dame, IN.

Bone is one of the most common sites for metastatic tumor growth across cancers, including breast cancer. Cancer cells that travel through the vasculature and invade a new tissue can remain in a quiescent, non-proliferative dormant state for years until the cancer cells are induced to colonize the metastatic site. This switch from dormancy to colonization is the rate-limiting step for bone metastasis. To model the cancer cells as they colonize, we developed an *ex vivo* co-culture system of mouse bones and cancer cells and identified culture conditions with high or low cancer cell proliferation and invasion using healthy bones or cancer primed bones. To identify the factors that promote cancer cell colonization, we profiled cytokines, chemokines, and growth factors from conditioned media and identified the chemokine CXCL5 as a candidate to induce metastatic colonization. Additional studies using CXCL5 recombinant protein further suggest that CXCL5 is sufficient to promote breast cancer cell

proliferation and colonization in bone, while inhibition of its receptor CXCR2 with an antagonist blocks proliferation of metastatic cancer cells. This study suggests that CXCL5 and CXCR2 inhibitors may have efficacy in treating metastatic bone tumors that are dependent on the CXCL5/CXCR2 axis.

P2057/B301

Mesenchymal Stromal Cell-derived CXCL16 Promotes Proliferation and Migration of Gastric Cancer Cells by Inducing STAT3-mediated Expression of Ror1.

T. Ikeda[1], M. Nishita[2], Y. Kakeji[1], Y. Minami[1]; [1]Kobe university graduate school of medicine, Kobe, JAPAN, [2]Fukushima Medical University School of Medicine, Fukushima, JAPAN.

Bone marrow-derived mesenchymal stem or stromal cells (MSCs) have been shown to be recruited to various types of tumor tissues, where they interact with tumor cells to promote their proliferation, invasion, and metastasis, depending on the types of the tumor cells. We have previously shown that Ror2 receptor tyrosine kinase and its ligand, Wnt5a, are expressed in MSCs, and activated Wnt5a-Ror2 signaling in MSCs induces expression of CXCL16, which in turn promotes proliferation of co-cultured MKN45 gastric cancer cells via CXCL16-CXCR6 axis. However, it remains unknown how CXCL16 regulates proliferation of MKN45 cells. Here, we show that siRNA -mediated knockdown of *CXCL16* in MSCs suppresses not only proliferation, but also migration of co-cultured MKN45 cells. We also show that MSC-derived CXCL16 or recombinant CXCL16 induces expression of Ror1 through activation of STAT3 in MKN45 cells and that up-regulated expression of Ror1 plays an important role in mediating proliferation and migration of MKN45 cells in *vitro*. Moreover, it was found that transplantation of MKN45 cells along with MSCs in nude mice promoted tumor formation in a manner dependent on expression of Ror1 in MKN45 cells, and that anti-CXCL16 neutralizing antibody suppressed tumor formation of MKN45 cells co-transplanted with MSCs. Collectively, these results indicate that CXCL16 derived from MSCs induces expression of Ror1 through activation of STAT3 pathway in MKN45 cells, eventually leading to promotion of tumor formation.

P2058/B302

Molecular Delineation of Ccl18-elicited Membrane Organelle Interactions during Breast Cancer Migration and Invasion.

N. Zohbi, M. Mullen, X. Yao; Morehouse School of Medicine, Atlanta, GA.

Mitochondria are dynamic organelles with context-dependent subcellular redistribution in response to extracellular cue changes, although the underlying mechanisms remain largely elusive. The ARF6 GTPase and its signaling pathway involving ACAP4 promote cell invasion via Grb2-adaptored integrin recycling (Yu et al., 2011. JBC). Our recent work demonstrated that ACAP4 acetylation elicited by CCL18 regulates dynamic membrane-membrane remodeling associated with breast cancer cell migration (Yuan et al., 2018. JMCB). Using functional proteomics screen, we identified a novel regulator of ACAP4 named Acapin. Our biochemical characterization showed that Acapin binds and inhibits the GAP activity of ACAP4. Interestingly, CCL18 stimulation elicited the recruitment of Acapin to thelamellipodium membrane in addition to mitochondria polarization toward the lamellipodium. We are currently carrying out spectral imaging analyses to visualize how ACAP4, ARF6 and Acapin interact and orchestrate dynamic organelle contacts during CCL18-elicited breast cancer cell migration and invasion.

P2059/B303

CCL18-elicited Segregation of Mitochondria Drives Breast Cancer Cell Migration and Invasion.

M. Mullen[1], N. Zohbi[1], F. Yang[2], S. Muthusamy[1], X. Liu[2], X. Yao[1]; [1]Morehouse School of Medicine, Atlanta, GA, [2]University of Science and Technology, Hefei, CHINA.

Tumor metastasis represents the main cause of cancer-related death. Our early study showed that chemokine CCL18, secreted from tumor-associated macrophages, regulates breast tumor metastasis. Our recent work demonstrated that ARF6 GTPase-activating protein ACAP4 regulates CCL18-elicited breast cancer cell migration via the acetyltransferase PCAF-mediated acetylation (Yuan et al., 2018, JMCB). Using triple negative breast cancer cells as a model, we show that mitochondria actively segregate toward leading edge lamellipodia in response to CCL18 stimulation, thereby increasing local mitochondrial mass and relative ATP concentration. Since the organization of membrane-bound organelles allow for the separation of incompatible biochemical processes, we are currently carrying out spectral imaging analyses to understand how CCL18-elicited organelle communication orchestrates directional cell migration. In addition, we combine live cell imaging with chemical probes to delineate the molecular mechanisms underlying CCL18-elicited organelle interactome during directional cell migration.

P2060/B304

The Role of PTPRJ in Neutrophil Polarization in the Tumor Microenvironment.

M. A. Giese[1], J. Rindy[1], E. E. Rosowski[2], A. Huttenlocher[1]; [1]University of Wisconsin Madison, Madison, WI, [2]Clemson University, Clemson, SC.

Neutrophils are highly infiltrative into many solid tumor types and a high neutrophil-to-lymphocyte ratio is an indicator of poor patient prognosis. However, increasing evidence indicates that neutrophils are highly plastic cells that can have either tumor promoting or inhibiting capabilities. This polarization can be influenced by the tumor microenvironment, but the intracellular signaling changes responsible for neutrophil pro- or anti-tumor polarization are not well understood. Therefore, we sought to identify a novel pathway that modifies neutrophil polarization in the tumor microenvironment. To identify putative transcriptional targets involved in neutrophil polarization in cancer, we have conducted Translating Ribosomal Affinity Purification Sequencing (TRAPseq) using the zebrafish model organism. Zebrafish are an ideal model for studying the role of neutrophils in early cancer initiation and progression due to their optical transparency and high fecundity. In accordance with human clinical data, our lab has previously shown that neutrophils are tumor promoting in these zebrafish models. Using TRAPseq in our established zebrafish HRas-transformed keratinocyte cancer model, we identified upregulation of targets specifically in the neutrophil population. PTPRJ, a transmembrane phosphatase, was found to have a 5-fold increase in expression in the cancer model over wild-type zebrafish. In mice, PTPRJ has previously been shown to modify neutrophil superoxide production and chemotaxis, processes that are both important to neutrophil function in the tumor microenvironment. Therefore, we have chosen to evaluate the role of human neutrophil PTPRJ in the context of cancer. As genetic manipulation of primary human neutrophils is not possible, we have generated PTPRJ knockout lines in the HL-60 neutrophil-like cell line using CRISPR/Cas9. Using these lines, we have shown that PTPRJ has an effect on neutrophil chemotaxis in an in *vitro* microfluidic device. Furthermore, we have identified a published PTPRJ agonist to evaluate phosphatase activity in primary human neutrophils, which has previously not been possible due to their short lifespan *ex vivo*. Finally, we have generated a PTPRJ-

knockout zebrafish line using CRISPR/Cas9 to evaluate neutrophil function in an in *vivo* tumor xenograft model. This study demonstrates the power of combining TRAPseq technology with the zebrafish model system to identify transcriptional targets that are altered in disease backgrounds.

P2061/B305
Characterizing the Inflammatory Consequences of Failed Mitoses.
P. J. Flynn, P. Koch, T. J. Mitchison; Harvard Medical School, Boston, MA.

Cytoplasmic self-DNA (cyDNA) accumulation has been proposed to play a causative role in multiple pathologies including autoimmune disorders, cancer and possibly aging by activating innate immune pathways. Specifically, the cGAS-STING-Interferon (IFN) pathway has been identified as playing a critical role in mediating cellular and tissue response to cyDNA. cyDNA is thought to accumulate through multiple routes, including mechanical rupture of micronuclei, nuclear budding and export of DNA fragments via nuclear pores. Anti-microtubule drugs, such as Vinca alkaloids and Taxanes, represent a cornerstone of cancer chemotherapy. They kill cancer cells in culture via perturbation of mitosis, and are often termed “anti-mitotics”. However, other drugs that target mitosis-specific proteins such as inhibitors of Eg5/Kif11, Aurora kinases a and B, and Polo-like kinase 1 have proven to be ineffective for cancer treatment. I hypothesized that anti-mitotic drugs might differ in their ability to trigger cGAS-STING signaling after a failed mitosis, and this might help to explain their observed differences in clinical efficacy. To test this I performed a pharmacological screen of a diverse set of anti-mitotics and systematically measured their ability to induce micronuclei, cyDNA and IFN. To measure IFN production in a physiologically relevant manner, I developed a high-throughput co-culture assay in which engineered immune cells report on the concentration of extracellular IFN secreted by drug treated cancer or stromal cells. I found that some anti-mitotic drugs generate more IFN than Taxanes, and others much less. My data point to a role for mitotic kinases in regulating cGAS activation following a failed mitosis. Manipulation of mitotic kinases also allowed me to distinguish alternative pathways by which DNA enters the cytoplasm in response to anti-mitotic vs. DNA-damaging drugs.

Cancer Therapy 3

P2062/B306
Identification of Genome-wide Molecular Characteristics in Ameloblastoma: Role of *Tlr2* in Ameloblastoma Cells.
S. Kondo, **A. Ota**, T. Ono, S. Karnan, M. Wahiduzzaman, T. Hyodo, M. L. Rahman, K. Ito, A. Furuhashi, T. Hayashi, H. Konishi, S. Tsuzuki, Y. Hosokawa, Y. Kazaoka; Aichi Medical University School of Medicine, Nagakute, JAPAN.

Ameloblastoma is a rare odontogenic benign tumor accounting for less than 1% of head and neck tumors. Despite the reports regarding whole genomic sequence information from patients with ameloblastoma, gene expression profiles in ameloblastoma are still obscure. The present study is the first to demonstrate novel genome-wide molecular characteristics in ameloblastoma, which is a rare neoplasm, yet also the most frequent in odontogenic tumors. Our high-resolution comparative genomic hybridization <aCGH> showed wide-range of minimal somatic copy number aberrations <CNAs> as well as distinct gene expression pattern in ameloblastoma, in which oncogenic gene signatures including Kras-responsive genes and EGFR-related genes are significantly activated. Of note, the altered gene

expression partly paralleled the CNAs detected. Interestingly, expression of toll-like receptor 2 <TLR2> is highly upregulated in ameloblastoma tumors and in the ameloblastoma cell line AMU-AM1. Importantly, TLR2 knockdown suppressed the activation of *KRAS*-responsive genes as well as inflammatory response genes. Furthermore, TLR2 knockdown significantly increased caspase-3 activity. In summary, our findings uncovered possible genome-wide molecular characteristics and showed the significant involvement of TLR2 in the cellular biological properties of ameloblastoma. Our data might be a help to further understand the molecular pathogenesis of ameloblastoma in future clinical biological studies.

P2063/B307

Understanding the Human Equilibrative Nucleoside Transporter (slc29a1): New Modalities of Regulation and Therapeutics.

B. Scuric, S. Appak Baskoy, Z. Tarmakova, M. Kolios, **I. R. Coe**; Ryerson University, Toronto, ON, CANADA.

The nucleoside transporter, hENT1 (SLC29A1), is responsible for the flux of endogenous nucleosides such as adenosine, across the plasma membrane and is therefore an important component of the cellular purinome (Dos Santos Rodrigues et al 2014). ENT1 is also a major route of entry for nucleoside analog drugs, such as gemcitabine, which are used widely in chemotherapy and anti-viral treatments. While we have made significant advances in understanding the complex regulation of ENT1 (Grane-Boladeras et al 2019) including identification of novel interactors (Guo et al. 2019), a deeper understanding of the cell biology of hENT1 is needed in order to develop more specific and effective nucleoside analog based chemotherapeutics. Moreover, drug-resistance is a significant clinical challenge and one way to address this challenge is by developing novel therapies that combine well-established pharmacology (nucleoside analog drugs) and innovative biophysical interventions, such as ultrasound microbubble (USMB) treatments. To this end, we are using the pancreatic tumour cell lines PANC1 & BXPC3 which express high levels of hENT1 and which are differentially sensitive to gemcitabine, a front-line drug in the treatment of pancreatic cancer. Drug uptake requires the presence of functional ENT1 in the plasma membrane. Therefore, understanding the nature of the cellular context of ENT1 is essential in defining factors that influence drug uptake (and therefore efficacy). We have determined that ENT1 is localized to caveolin-1 rich microdomains which are implicated in regulated internalization. Furthermore, we have discovered that gemcitabine treatment selects for a sub-population of drug-resistant cells which exhibit behaviours and cell biology suggestive of transformed and potentially metastatic phenotypes. We have confirmed that drug plus USMB is cytotoxically additive at a single time point (Mariglia et al. 2018) and now show that the most effective combination modality for cytotoxicity is drug treatment followed by USMB. These findings provide the basis for the further studies aimed at refining novel combination therapeutics based on well established nucleoside analog drugs plus innovative biophysical interventions, while also defining the underlying mechanistic aspects of the cellular responses.

P2064/B308

Lipocalin-2 Regulates Dna Damage Response Pathway Upon Genotoxic Stress.

A. Zablocki, L. Yammine, E. Marques, F. Terzi, M. Gallazzini; INSERM, Institut Necker Enfants Malades, Paris, FRANCE.

Genotoxic are known to cause DNA damage and subsequently inducing cell death. In response to DNA damage, cells activates the DNA damage response (DDR) which coordinate a complex interaction of

downstream pathways to determine cell fate, including coordination of DNA repair, cell cycle arrest and apoptosis. In cancer, treatments commonly use DNA-damaging drugs; however, some cancer cells are able to survive this process. This resistance has been correlated with the expression of Lipocalin-2 (Lcn2). Lcn2 is a 25kDa secreted glycoprotein known for its role in the cellular transport of lipophilic molecules such as fatty acids, iron, and steroids. Lcn2 play critical roles in several pathological organ conditions and particularly in cancer condition, it has been demonstrate that it facilitates tumorigenesis by promoting survival, growth, and metastasis. However, the mechanisms controlled by lcn2 to ensure cell survival are not known. We used kidney cells expressing Lcn2, invalidated for its expression or overexpressing Lcn2. We observed that cells expressing Lcn2 increased cell survival to genotoxic drugs. Also, we observed that kidney cancer cells expressing Lcn2 are more prone to developed resistance to genotoxic drugs as opposed to kidney cancer cells lacking Lcn2 expression. Hence, Lcn2 appears to participate to cellular mechanisms responsible for genotoxic stress survival. To evaluate whether Lcn2 may regulate the DDR, we have monitored the effect of Lcn2 knockdown (KD) on the activation status of DDR proteins. We observe that Lcn2 KD decreases genotoxic induced ATM phosphorylation, and P53 subsequent activation. This resulted in an increase of the blockage of the cell cycle in S-phase normally observed upon genotoxic stress. Interestingly, using comet assay experiment, we showed that Lcn2 does not seem to impact the amount of DNA breaks induced by genotoxic stress neither on the expression of γH2AX, a marker of DNA repair. Together, these results suggest that Lcn2 expression allows cell survival when exposed to genotoxic stress probably through an increase of the DDR pathway activity.

P2065/B309

Combinatorial Application of Doxorubicin and Delta-tocotrienol Induces Apoptotic and Autophagic Death on Colorectal Cancer Cells.

S. Loh[1], S. Tham[1], C. Mai[2], J. Fu[3]; [1]School of Biosciences, University of Nottingham Malaysia, Jalan Broga 43500 Semenyih, Selangor, MALAYSIA, [2]School of Pharmacy, International Medical University, Bukit Jalil 57000 Kuala Lumpur, MALAYSIA, [3]Malaysian Palm Oil Board, Bandar Baru Bangi 43000 Kajang, Selangor, MALAYSIA.

Doxorubicin (Dox) has been widely used in chemotherapy for treating various cancers, including the colorectal cancer. However, the effectiveness of Dox is often limited by high-dose toxicity and tendency of resistance development. As an approach to augment the effectiveness of Dox, delta-tocotrienol (δT3) was applied in a combination aiming to study the anticancer effects on colorectal cells. The scope of this study included the in *vitro* evaluations of antiproliferative effects, morphological changes, DNA damages, cell cycles and protein expression profiles in relation to apoptosis and autophagy. The combined treatment of delta-tocotrienol and doxorubicin (δT3 + Dox) resulted pharmacological synergisms on a couple of colorectal cancer cell lines and particularly exerted significant anti-clonogenic survivals on Caco-2 and SW48 cells even at low concentrations. Morphologically, the Caco-2 and SW48 cells treated with low-concentration δT3 + Dox exhibited apoptotic features and great cellular stress. This combined treatment increased apoptosis rate, DNA damages (single and double stranded breaks) and enhanced DNA fragmentation. Mitochondrial membrane permeabilization (MMP) was observed on Caco-2 and SW48 cells treated with δT3 + Dox. The inhibition of MMP using cyclosporine a successfully suppressed cell death suggesting that the combined treatment targets at mitochondria. Despite activations of caspase-8 and -3 were detected, the application of caspase inhibitors was unable to improve cell viability signifying the possibility of caspase-independent cell death occurrence. Besides, the combined treatment induced an enhanced autophagy in the treated cancer cells as evidenced by the

formation of acidic vacuolar organelles as well as increments of monodansylcadaverine intensity and microtubule-associated protein 1A/1B light chain 3 (LC3)-II expression. The involvement of autophagic cell death is further confirmed when the application of autophagy inhibitors, namely 3-methyladenine and bafilomycin A1 successfully reverted cell death. Overall, current findings supported that δT3 + Dox combined treatment exerted both apoptosis and autophagy on Caco-2 and SW48 cells, where these multitargeted actions are highly imperative for treating the invasive type of colorectal cancer in the future.

P2066/B310

Inducible Degron Dependent Depletion of the RNA Polymerase I Associated Factor PAF53 Demonstrates It Is Essential for Cell Proliferation and Allows for the an alysis of Functional Domains.

R. McNamar, K. Rothblum, Z. Abu-Adas, L. Rothblum; University of Oklahoma Health Sciences Center, Oklahoma City, OK.

The regulation of ribosome biogenesis (RB) plays a central role in maintaining cellular homeostasis and supporting cell growth. The rate-limiting step in this process is transcription of the ribosomal RNA genes by RNA polymerase I (Pol I). Dysregulation of RB can contribute to pathologies such as cancer, cardiac hypertrophy, and ribosomopathies. Further, many chemotherapeutic drugs inhibit either rDNA transcription or rRNA processing, but have many off-target effects that limit their usefulness. Many pathways play a role in the regulation of rDNA transcription. Two mammalian factors that are involved in this regulation are **P**olymerase **A**ssociated **F**actor (PAF53) and PAF49. The purpose of this study is to determine the role(s) the PAFs play in regulating rDNA transcription and characterize the downstream physiological effects of directly inhibiting this process. To rapidly degrade PAF49/53, a novel system that utilizes CRISPR/Cas 9 and an auxin inducible degron was used. This allowed us to carry out in *vitro* biochemical and "genetic" studies of PAF49/53 in mammalian cells. Through the use of this system, our data show that PAF53 is required for rDNA transcription and cell proliferation. In addition, the three domains of PAF53 are each necessary but not sufficient to support wild-type levels of cell growth. The C-terminal tandem winged helix domain was only responsible for 20-30% of PAF53 function, while the linker region in combination with the N-terminal heterodimerization domain was able rescue cell proliferation by approximately 80%. Our lab has also defined a second DNA-binding domain in PAF53 that had not been discovered. Moreover, we have found a putative helix-turn-helix motif within this domain that is responsible for the DNA-binding activity. These findings are significant because they aid in further understanding the process of rDNA transcription by Pol I and the physiological consequences of inhibiting this process, *i.e.* nucleolar stress and cell arrest and/or death. They will also contribute to the discovery of novel drug targets that could be utilized in effective cancer and ribosomopathy treatments.

P2067/B311

CDK7 Inhibitor BS-181 Induces Extrinsic Apoptosis Via TRAIL/DR5 Upregulation That Is Preferentially Provoked in G_1-arrested Cells in Human Acute Leukemia Jurkat Cells.

S. Park[1], W. Kim[2], J. Yeom[2], H. Oh[2], Y. Choi[2], D. Jun[3], Y. Kim[1]; [1]Kyungpook National University, Daegu, KOREA, REPUBLIC OF, [2]Daegu Science High School, Daegu, KOREA, REPUBLIC OF, [3]Astrogen Inc., Daegu, KOREA, REPUBLIC OF.

Chemotherapy resistance in human T-cell acute lymphoblastic leukemia (T-ALL), an aggressive neoplasm, results in poor prognosis despite advances in treatment modalities. We found that treatment of T-ALL Jurkat clone (JT/Neo) with the CDK7 inhibitor BS-181 induced extrinsic apoptosis via TNF-related apoptosis-inducing ligand (TRAIL)/death receptor 5 (DR5) upregulation, BID cleavage, BAK activation, mitochondrial membrane potential loss, caspase-8/caspase-9/caspase-3 activation, and PARP cleavage. BCL-2-overexpression (JT/BCL-2) abrogated these BS-181-induced apoptotic events, except for DR5 upregulation. Although CDK7-mediated activating phosphorylation of CDK1 (Thr-161) and CDK2 (Thr-160), and CDK1/2- and CDK4/6-preferred retinoblastoma phosphorylation at Thr-821/826 and Ser-795, respectively, were attenuated in BS-181-treated JT/Neo and JT/BCL-2 cells, only the latter exhibited G_1-arrest. The late G_1-blocking agent hydroxyurea augmented BS-181-induced apoptosis and BS-181-induced FITC-Annexin positive apoptotic cells represented mostly those in sub-G_1 and G_1 phases, indicating preferential BS-181-induced apoptosis in G_1-arrested cells. Exogenously added recombinant TRAIL (rTRAIL) synergized BS-181-induced apoptosis only in Jurkat clone A3 (wild-type) but not in I2.1 (FADD-deficient) and I9.2 (caspase-8-deficient) clones. The synergistic effect of rTRAIL on BS-181 cytotoxicity was not observed in normal peripheral T cells. These results demonstrated that BS-181 antitumor activity is mainly induced by extrinsic TRAIL/DR5-dependent apoptosis, and that BS-181 and rTRAIL in combination may hold promise for T-ALL treatment.

P2068/B312

Regulation of Expression of Oct3/4 by Farnesoid X Receptor and Liver X Receptors in Renal Cells and Feedback Regulation of the Expression of Oct3/4 and Its Upstream Factor Elavl2 in Renal Adenocarcinoma Cells.

T. Fujino[1], K. Sugizaki[1], H. Lee[2], M. Hayakawa[2]; [1]Tokyo university of pharmacy and life sciencens, Hachioji, JAPAN, [2]Tokyo university of pharmacy and life sciences, Hachioji, JAPAN.

In the present study, we have found that nuclear receptors FXR and LXRs, originally characterized as regulatory factor which is involved in cholesterol/bile acid homeostasis, regulates the expression of Oct3/4, a marker for cell differentiation, in normal renal cell-derived cell line HK-2 and renal adenocarcinoma cell line ACHN. Down-regulation of Oct3/4 expression by activating FXR and LXRs occurred only in normal renal cell-derived HK-2 cells. Inverse agonist for LXRs-induced down-regulation of Oct3/4 in renal adenocarcinoma ACHN cells is a transient event arising from the loop regulation between Oct3/4 and its upstream factor ELAVL2. Given that mutation of the ELAVL2 structure possibly causes the loop regulation between Oct3/4 and ELAVL2, repairment of the ELAVL2 mutation is useful for the cancer therapy since it brings to cancel the system for keeping undifferentiated state of renal adenocarcinoma cells. Moreover, we revealed that LXR alpha and LXR beta regulate their expression each other. Although LXR beta-specific agonist is assumed to be the seeds for anti-arteriosclerotic drug only stimulating reverse cholesterol transport, it is needed that reveal the complex mechanism of regulation of LXR alpha and LXR beta for the development of such the anti-arteriosclerotic drug.

P2069/B313

Novel Post-translational Modification of Pml Sensitizes Sulforaphane (sfn)-induced Cell Cytotoxicity.

N. Alhazmi, C. Pai, A. Albaqami, H. Wang, X. Zhao, S. Guo, M. Chen, P. Hu, K. Starost, O. Hajihassani, M. Miyagi, H. Kao; Case western reserve university school of medicine, Cleveland, OH.

Sulforaphane (SFN) is a natural compound and a promising therapeutic that induces apoptosis in cancer cells and inhibits cancer cell proliferation and tumorigenesis in various mouse models of cancer. However, our understanding of the mechanism by which SFN achieves its anti-tumorigenic activity is far from complete, in part, due to the lack of identification of SFN direct targets. We show that SFN redistributes the subcellular localization of the promyelocytic leukemia protein (PML), a well-established tumor suppressor, and inhibits the proliferation of MCF-7 and MDA-MB-231 breast cancer cells, and MCF-10A breast epithelial cells. PML is a stress sensor and an essential constituent of the highly dynamic PML nuclear bodies (NBs). Unexpectedly, loss of *PML* inhibits proliferation and migration of MCF-7 cells, and sensitizes the ability of SFN-mediated inhibition of cell proliferation, migration, and invasion. Consistently, overexpression of PML1, the most abundant *PML* spiced isoform in MCF-7 cells, increases cell proliferation, migration, and invasion. Mechanistically, SFN modifies several cysteine residues in PML, including C204, and impairs nuclear localization and NB formation. As a result, the mutant C204A is defective in nuclear localization, NB formation, and the colocalization with Daxx, Sumo1, and Sumo2/3, and is defective in its ability to inhibit proliferation, migration, and invasion of MCF-7 breast cancer cells. Together, our data reveal a novel mechanism in which SFN inactivates PML to elicit its cytotoxic activity.

P2070/B314

Cancer “Cross-talk” with Endothelial Cells Results in PSMA Expression.

T. A. Zeigler, 14623, I. M. Evans, 14623; Rochester Inst Technol, Rochester, NY.

Angiogenesis provides nutrients and oxygen to cancer cells allowing them to flourish and often metastasize. If blood vessel recruitment and angiogenesis can be prevented, the cancer’s growth and spread might well be limited. The endothelial cells lining blood vessels vascularizing tumors overexpress an integrated transmembrane protein, Prostate-Specific Membrane antigen (PSMA), whose function has not been completely elucidated. The goal of this study was to elucidate why PSMA was expressed on tumor vasculature and not on normal vasculature. Our hypothesis is that tumor cells secrete factors and interact with endothelial cells within blood vessels resulting in PSMA expression. This study explored the effects of different cancer media on the expression of PSMA on human umbilical vein endothelial cells (HUVECs). The media were collected from a variety of cancer cell lines including prostate cancer C4-2 (PSMA+), prostate cancer PC-3 (PSMA-) and triple-negative breast cancer (MDA-MB 231). All experiments were done using growth-factor containing Matrigel on which cells were plated. Controls included HUVECs growing without cancer-conditioned medium, or not on growth-factor containing Matrigel. Targeted Molecular Imaging Agents (TMIAs), which bind to the PSMA receptor identified PSMA positive cells using confocal microscopy. The results demonstrated PSMA is induced in HUVEC cells growing in conditioned medium from each cell line; however the induction of PSMA was greatest with breast cancer cell conditioned medium. These studies should help elucidate the role of PSMA in angiogenesis and determine the factors involved in induction of the PSMA receptor on HUVECs by different cancer media. Targeting blood vessels vascularizing tumors and expressing PSMA may provide a method to limit or eradicate angiogenesis and thus limit the growth of the tumor.

P2071/B315

Investigation of the Cytotoxic Effects of Pro-apoptotic and Tumor Selective Piperidones.

L. Contreras[1], S. S. Karki[2], U. Das[2], J. Dimmock[2], R. J. Aguilera[1]; [1]The University of Texas at El Paso, El Paso, TX, [2]University of Saskatchewan, Saskatoon, SK, CANADA.

In vitro screening of compound libraries has led to the discovery of piperidones with significant potential as anti-cancer drugs. Piperidones, P3, P4, and P5, have potent cytotoxic activity and selectively kill cancer cells. In addition, we observed that these compounds induce cell death through apoptosis in leukemia HL-60 cells. This was revealed by significant phosphatidylserine externalization and activation of the executioner caspase, caspase-3. The intrinsic pathway of apoptosis was implicated in the mechanism of action of these compounds as shown by depolarization of the mitochondria and generation of reactive oxygen species. An alysis of the cell cycle profile revealed that these compounds also cause DNA fragmentation. Additionally, compounds P4 and P5 cause arrest at the G2/M phase. Finally, we found that these compounds and other similar compounds induce apoptotic activity by proteasome inhibition as shown by accumulation of poly-ubiquitinated proteins after compound treatment. Our results display a tumor selective cytotoxic effect that is mediated by both cell cycle and protein degradation mechanisms.

P2072/B316

Cervical Cancer Cells That Have Acquired Fgf13-Dependent Cisplatin-resistance Are Selectively Killed by Histamine Receptor H1 an tagonists.

N. Matsumoto[1], M. Ebihara[1], T. Okada[2], T. Imamura[1]; [1]Tokyo University of Technology, Tokyo, JAPAN, [2]National Institute of Advanced Industrial Science and Technology, Ibaragi, JAPAN.

[Objectives] HeLa cisR cells, established from HeLa S cells by culturing them in cisplatin-containing medium, have autonomously acquired resistance to cisplatin and other platinum anticancer drugs. The strongly upregulated expression of fibroblast growth factor 13 (FGF13/FHF2) gene and protein in HeLa cisR cells was responsible for cisplatin resistance (Okada et al., Sci Rep. 2013; 3:2899). Thus, FGF13 appears to be a promising research target in order to overcome cisplatin resistance. Here we aimed at identifying compounds that are able to exert cytotoxic effects on HeLa cisR cells, thereby understanding the mechanisms by which FGF13 confers cisplatin resistance. [Methods] HeLa cisR cells and HeLa S cells were tested for their proliferation potential in the presence of various compounds. Compounds selected by this screening were examined in detail for their cytotoxicity and effects on cellular gene expression. [Results] Cloperastine, an approved antitussive drug with histamine receptor H1 antagonist activity, selectively kills cisplatin resistant HeLa cisR cells. Cloperastine was less cytotoxic toward cisplatin-sensitive parental HeLa S cells. Interestingly, FGF13-knocked-down line of HeLa cisR cells, that are cisplatin sensitive, could survive in the presence of Cloperastine at concentrations cytotoxic for HeLa cisR cells. Furthermore, Desloratadine and Clemastine, other histamine receptor H1 antagonists, demonstrate similar effects as Cloperastine. Other histamine receptor antagonists, i.e., H2 antagonist Nizatidine, H3 antagonist Pipolisant and H4 antagonist JNJ-7777120, exerted no or weak cytotoxicity to HeLa cisR cells. These results prompted us to examine the combined effects of cisplatin and Cloperastine on the mixed culture of HeLa S and HeLa cisR cells, and we found that this treatment killed both of these cells. [Conclusions and Discussion] HeLa cisR cells, the cervical cancer cells that have acquired cisplatin-resistance in an FGF13-dependent manner, are specifically killed by Cloperastine and other histamine

receptor H1 antagonists. The present findings will not only help us identifying the molecular mechanism involved in the FGF13-dependent cisplatin-resistance, but also will be practically valuable in treating cancers in which cisplatin-sensitive and cisplatin-resistant cells co-exist.

P2073/B317

Apoptotic Effect of Lambertianic Acid Via Suppression of Signal Transducer and Activator of Transcription 3 Phosphorylation and P65 Acetylation Mediated by Microrna134.

J. JUNG, D. Sim, H. Lee, E. Im, J. Hwang, S. Kim; Kyung Hee University, Seoul, KOREA, REPUBLIC OF.

Apoptotic effect of lambertianic acid via suppression of signal transducer and activator of transcription 3 phosphorylation and p65 acetylation mediated by microRNA134 Deok Yong Sim[$], Ji Hoon Jung[$], Hyo-Jung Lee, Eunji Im, Jisung Hwang and Sung-Hoon Kim [$] These authors contribute equally to the work. As p300-mediated RelA/p65 hyperacetylation by signal transducers and activators of transcription 3 (STAT3) is critical for NF-κB activation, in the current study, the apoptotic mechanism of lambertianic acid (LA) was explored in relation to STAT3 phosphorylation and RelA/p65 acetylation in MCF-7, DU145, PC-3, and MDA-MB-453 cells. LA significantly increased the cytotoxicity, sub G 1 population, and the cleavage of poly (ADP-ribose) polymerase (PARP) in MDA-MB-453 or PC-3 cells (STAT3 mutant), more than in the MCF-7 or DU145 cells (STAT3 wild). Consistently, LA inhibited the phosphorylation of STAT3 and nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB), and disrupted the interaction between p-STAT3, p300, NF-κB, and RelA/p65 acetylation (Ac-RelA/p65) in the MCF-7 and DU145 cells. Also, LA reduced the nuclear translocation of STAT3 and NF-κB via their colocalization, and also suppressed the protein expression of XIAP, survivin, Bcl-2, Bcl-xL, vascular endothelial growth factor (VEGF), Cox-2, c-Myc and mRNA expression of interleukin 6 (IL-6), and tumor necrosis factor-α (TNF-α) in MCF-7 cells. Conversely, IL-6 blocked the ability of LA to suppress the cytotoxicity and PARP cleavage, while the depletion of STAT3 or p300 enhanced the PARP cleavage of LA in the MCF-7 cells. Notably, LA upregulated the level of miRNA134 and so miRNA134 mimic attenuated the expression of pro-PARP, p-STAT3, and Ac-RelA, while the miRNA134 inhibitor reversed the ability of LA to reduce the expression of Ac-RelA and pro-PARP in MCF-7 cells. Overall, these findings suggest that LA induced apoptosis via the miRNA-134 mediated inhibition of STAT3 and RelA/p65 acetylation.

P2074/B318

Efficacy Assessment and Mechanism Exploration of Kruppel Like Factor 2 Targeting Intervention Strategy for Non Small Cell Lung Cancer Therapy.

C. Wu, Male, C. Pan, J. Wang; Taipei Med University, Taipei, TAIWAN.

Non-small cell lung cancer (NSCLC), the most common type of lung cancer, has the problems such as less sensitivity to chemotherapy and resistance to tyrosine kinase inhibitors. Kruppel-like factor 2 (KLF2) has been reported to have the potential activities in tumor suppression and immune regulation. The expression level of KLF2 is lower in NSCLC and negatively correlated with the stages of tumor progression and lymph node metastasis. To date, not only no KLF2-promoting compounds have been developed, but no related studies on its anti-tumor efficacy in vivo have been verified. Therefore, the purposes of this study were focused on the potential and related mechanisms of KLF2 applied as a targeted molecule for NSCLC therapy. Our data indicated that the intervention of lovastatin markedly up-regulated protein expression of KLF2 in A549 human non-small cell lung cancer cells. Moreover, KLF2 siRNA intervention could significant inhibit serum-induced cell growth in A549 cells. The analysis result

of the Ingenuity pathway analysis (IPA) showed that several intracellular molecules, such as AKT, mTOR and FOXO1, maybe the potential upstream regulators to involve in KLF2 expression. Besides, the experimental data also evidenced that lovastatin can suppress activations of AKT and mTOR proteins as well as to reduce protein expression of FOXO1. In summary, these results suggested that intensifying KLF2 expression could apply as a feasible therapeutic strategy to improve NSCLC therapy, and statinoid compounds have potential to be developed as KLF2 activator. In addition, activations or expressions of AKT-mTOR pathway and FOXO1 may be attributed to suppression of KLF2 in NSCLC cells, such as A549 cells.

Cytotoxic Effects of Ajoene on Adherent and Non-adherent Cancer Cell Lines.

A. Witanis, S. Vetrone; Whittier College, Whittier, CA.

Ajoene Abstract Garlic is a common ingredient with a long history of human use both as a food and a medicine. When garlic is processed, allicin molecules are released and a chemical reaction occurs forming ajoene, an organosulfur compound. Previous studies have shown ajoene to have anti-cancerous properties such as inhibiting cell proliferation, inducing apoptosis, and reducing adhesion in solid tumor cancer cells. Based on these previous findings, we hypothesize that treating non-adherent (leukemia and myeloma: Jurkat, RPMI 8226, and CML) and adherent (prostate and breast: LNCAP and MCF7) cancer cell lines with ajoene will result in lower viability due to increased apoptosis induced by the compound. In this study, these cells were plated and exposed to varying concentrations of ajoene ranging from 20 to 120 μM and assessed for viability, cytotoxicity and apoptosis. Our findings indicate that cell viability was statistically reduced in a dose responsive manner in all non-adherent cell lines when exposed at the lower concentrations of 20 to 80 μM ajoene exposure, while the adherent cell lines required a higher exposure of 120 μM. In order to begin to elucidate the manner in which cell death was being mediated by ajoene exposure, we exposed cancer cells to 120 μM ajoene and monitored them over a 48 hr period using a biochemical assay that distinguishes between apoptosis and necrosis. These results show that ajoene exposure induces apoptosis initially and then it is followed by secondary necrosis in all studied cell lines. Moreover, with the exception of the CML line, ajoene appears to cause greater amounts of cell death via these pathways than positive control cisplatin. Currently real time-PCR and western blots are being performed to further support the cell death mechanistic findings.

P2076/B320

Vitamin D Can Enhance the Effects of Anti-tumor Treatment in Prostate Tumor Cells.

K. Igarashi, Y. Yui, Y. Nishizawa, H. Nakagawa, **S. Sasagawa**; Research Institute, Nozaki Tokushukai Hospital, Daito, OSaka, JAPAN.

The incidence rate of prostate cancer has been rapidly increased since the mid-1990s and is thought that due to the improvement of detection sensitivity using the PSA test, longevity medicine, changing the dietary habit, and so on. Recent cohort studies regarding vitamin D for cancer prevention have shown that vitamin D concentration in plasma was inversely associated with the risk of multiple cancers, but beneficial effect on prostate cancer progression is under dispute among the researchers. To dissect this issue at the molecular and cellular level, we investigated the molecular basis and cellular response of prostate cancer cell triggered by VD3 treatment. In this study, we identified that IGFBP3 induced by VD3-VDR axis was responsible for the suppression of cell growth and IGFBP3 improved the effect of

docetaxel, one of the first-line agents for prostate tumor treatment, in LNCaP cells. We also found that Bcl-2 protein expression level was down-regulated by VD3 treatment in an IGFBP3 independent manner. These data suggested that VD3 treatment could positively contribute to prostate tumor treatment. Additionally, we also found that transient VD3 treatment-induced prolonged IGFBP3 expression and IGFBP3 induction level seemed to be adjusted by checking protein concentration, expecting the existence of positive-feedback loop for IGFBP3 retention. In conclusion, VD3 treatment in combination with active surveillance or chemotherapy would be helpful to improve the outcome of patients with prostate cancer.

P2077/B321

Morin Increases Pannexin 2 Expression and Induces Apoptosis in U87 and U251 Glioblastoma Cells.

S. Liu, W. Lin, **Y. Liang**, Y. Chiu, H. Lee, J. Wu, H. Wang; Natl Yang-Ming University, Taipei, TAIWAN.

Glioblastoma multiforme (GBM) is the most common and aggressive malignant primary brain tumor in human. Pannexin 2 is a member of pannexin family that mainly presents in endomembrane system. Recent work suggests that pannexin 2 reduces cell proliferation and regulates apoptosis. Morin, a flavonoid originally isolated from figs and members of the moracea family, has previously shown to possess anti-tumor activities and induce apoptosis in several human cancer cell lines. In this study we examined the cytotoxic effects of morin in the U87 and U251 human glioblastoma cells by MTT assay and the ability of morin inhibiting single cells to grow into colonies by colony formation assay. We also evaluated anticancer potential of morin (300 μM) through induction of apoptosis in U87 and U251 cells by Western blot and annexin V-FITC fluorescence microscopic analyses. Morin reduced both the viability and the colony formation ability of U87 and U251 cells in a dose- and time-dependent manner. An nexin V-FITC fluorescence microscopy showed that morin induced apoptosis in U87 and U251 cells. Morin treatment also increased the expression levels of cleaved caspase-3 and pannexin 2 in U87 and U251 cells as demonstrated by Western blot and immunofluorescence microscopic analyses. Moreover, blocking the activation of caspase-3 by caspase inhibitor z-DEVD-FMK inhibited the morin-induced increase in pannexin 2 levels in U251 cells. These results suggest that morin may have potent anticancer activities against U87 and U251 cells via upregulating pannexin 2 to cause apoptosis.

P2078/B322

The Nicotinic Acetylcholine Receptor Modulator 4R as a Treatment for Non-small Cell Lung Carcinoma.

E. Castro-Rivera, Y. Sepulveda Martínez, V. A. Eterovic, Y. Ferrer-Acosta; Universidad Central del Caribe, Bayamon, PUERTO RICO.

Introduction: **Lung cancer** is the leading cause of cancer deaths worldwide, with 85% of new cases classified as non-small cell lung carcinoma (NSCLC) and a patient survival rate <5%. While most treatments remain cytotoxic-platinum based, novel non-toxic compounds like the 4R cembranoid have shown antiangiogenic, anticancer and antitumorigenic activity. We **aim** to study the potential of 4R against NSCLC via the modulation of nicotinic acetylcholine receptors (nAChRs) and **hypothesize** 4R will decrease cancer progression by inhibiting the α7nAChRs signaling in lung tumor and endothelial cells. *Methods:* 4R effect on tumor growth in *vivo* was evaluated using the Lewis Lung Carcinoma (LLC) mouse model; C57BL/6J mice were monitored for 12 days and tumors were evaluated for volume and angiogenesis markers (Western Blot). NSCLC cells (LLC and A549) were evaluated for: α7nAChR expression (Flow Cytometry and Western Blot), cell viability after 4R exposure (MTT assay or propidium

iodide staining), proliferation and apoptosis markers (Western Blot). *Results:* Treatment with 4R significantly reduce tumor size in *vivo*, while (1) no significant difference was observed in PECAM-1 (pro-angiogenic marker) expression; and (2) no effect on tumor cell viability was observed in *vitro*. Both NSCLC cells, show α7nAChR expression, while 4R treatment of A549 seemed to affect cell viability and deregulate (proliferation and apoptotic) protein expression. *Conclusions:* 4R significant tumor reduction suggests this drug to be a potential non-toxic treatment or adjuvant therapy against NSCLC. Although the mechanism of action is yet to be elucidated, it does not appear to involve a decrease in angiogenesis or a direct effect on tumor cells' viability. Experiments to assess the effect of 4R in NSCLC cells migration and invasion are currently ongoing. *Acknowledgments:* This work is supported by the NIH NINDS SNRP grant number 5U54NS083924-03, the NIH NIMHD and the NIH NIAID grant number U54MD007587, and the PR-INBRE program Supported by an Institutional Development Award (IDeA) from the NIH NIGMS grant number 5P20GM103475-17. Approved by IACUC.

Understanding the Underlying Mechanisms of Cell Death in Mitotically Arrested Cancer Cells.

N. Ashraf, R. Kassim, C. Shuster; New Mexico State University, las cruces, NM.

Anti-mitotic drugs represent a common strategy for cancer chemotherapy by inducing prolonged prometaphase delay and cell death. However, studies both in vitro and in xenograft tumor models indicate that cancer cells display a high degree of heterogeneity in their responses to mitotic arrest, from dying during mitosis to surviving mitotic failure and continuing to progress through the cell cycle. Thus, understanding the basis for this variation may prove valuable for developing more effective anti-mitotic chemotherapeutic strategies. Based on reports suggesting that signaling pathways that regulate survival might account for a cell's ability to survive mitotic arrest, we asked whether inhibition of the PI3-kinase pathway affected the kinetics of apoptosis in cells exposed to a KSP inhibitor. Simultaneous inhibition of KSP and PI3K/AKT induced apoptosis more effectively than mitotic arrest or PI3K/AKT inhibitors alone, and tracking of individual cell fates revealed that cells subjected to the combinatorial treatment died significantly sooner than cells subjected to KSP inhibition alone. To determine whether these cells died during mitosis or during mitotic slippage, we employed a membrane-tagged caspase biosensor co-expressed with fluorescent tubulin or cyclin B, which enabled us to determine cell cycle status during which cells died in response to mitotic delay. In our hands, HeLa cells typically died during mitotic slippage, and tracking of cells expressing these biosensors displayed a narrow range of cellular responses, from apoptosis during mitotic arrest to mitotic slippage and cell survival. However, we found that mitotic arrest in combination with PI3K inhibition dramatically shifted the dynamics of cell death from apoptosis during mitotic slippage to apoptosis during mitotic arrest. Thus, the acceleration of cell death induced by PI3K inhibition was due to a shift in when cells died relative to mitotic progression, rather than an acceleration of the kinetics of mitotic slippage. Together, these results not only shed insights into the possible reasons to why cells respond differently to mitotic delay, but also suggest a strategy whereby anti-mitotic interventions may be optimized.

P2080/B324

Localization of Porphyrin TMP in B16F1 Mouse Melanoma Cells and Its Potential Use in Photodynamic Therapy.

M. Habdas[1], J. Habdas[2], P. Habdas[1], C. King-Smith[1]; [1]Saint Joseph's University, Philadelphia, PA, [2]University of Silesia, Katowice, POLAND.

Photodynamic therapy (PDT) is a treatment that uses photosensitizing agents and specific wavelengths of light to kill cancer cells. The photosensitizing agents produce reactive oxygen species when exposed to light, which induce cell death when the reactive oxygen species bind to target sites. The effectiveness of PDT depends on the localization of the photosensitizing drug inside cancer cells. The ideal drug delivery should enable the selective accumulation of the photosensitizing drug within the diseased tissue and the delivery of therapeutic concentrations of drugs to the target site, with little uptake by healthy cells. Photosensitizing porphyrins, whose molecules contain a flat ring of four linked heterocyclic groups, are a typical choice for the photosensitizing agents. In this study we tested a novel porphyrin called TMPyP4 (TMP) using fluorescent organelle probes to determine its subcellular localization in B16F1 mouse melanoma cells. We discovered that TMP localizes to the endoplasmic reticulum in cells treated with 3.0 μg/mL over a 1-hour period. Future studies will examine TMP localization in other organelles, and test the effectiveness of TMP in causing light-stimulated cell death in B16F1 cells.

P2081/B325

Stat3 Contributes to Thermotolerance through Induction of Hsp105 in Mammalian Cells.

Y. Saito, M. Matozaki, R. Yasutake, S. Munira, Y. Kaibori, A. Yukawa, M. Tada, Y. Nakayama; Kyoto Pharmaceutical University, Kyoto, JAPAN.

Themotolerance is one of the mechanisms that maintain homeostasis of mammalian cells. Pretreatment with a non-lethal heat shock induces thermotolerance, which causes cell resistance against subsequent lethal heat shock. Thermotolerance is associated with the synthesis and cellular accumulation of heat shock proteins (Hsps), including Hsp70 and Hsp27. We previously showed that the expression of Hsp70 is regulated by the cytokine signaling transcription factor Stat3. However, the role of Stat3 in thermotolerance is not known. In this study, we examined the possibility that Stat3 regulates thermotolerance development. Western blot analysis using anti-phospho-Stat3 (Tyr705)-specific antibody revealed that non-lethal mild heat shock induces the Stat3 phosphorylation in HeLa cells and HepG2 cells. The heat shock-induced Stat3 phosphorylation was inhibited by the JAK tyrosine kinase inhibitor AG490. Furthermore, AG490 partially suppressed the mild heat shock-induced thermotolerance and the induction of Hsp105, Hsp70, and Hsp27, suggesting that heat shock stimulates the JAK-Stat signaling pathway for development of thermotolerance. Mild heat shock-induced phosphorylation, Hsps induction, and thermotolerance were suppressed by the Stat3 inhibitor Stattic, confirming that Stat3 is involved in thermotolerance development. We further demonstrated that the knockdown of Hsp105 decreases the mild heat shock-induced thermotolerance using HeLa cells stably expressing Hsp105-specific shRNA or non-targeting shRNA. These findings indicate that the activation of Stat3 signaling pathway is required for the development of thermotolerance through the induction of several Hsps including Hsp105. The acquisition of thermotolerance is a problem of hyperthermia treatment. These results suggest that Stat3 inhibition may be useful target for hyperthermia cancer therapy.

P2082/B326

RNAi-mediated Downregulation of LAT1/SLC7A5 Expression and Function in Human Colon Cancer Cells.

A. C. N. Oliveira[1], C. Carneiro[1], P. J. Kennedy[1], M. P. Serrão[2], **P. Soares-da-Silva**[1,2]; [1]Phyzat Biopharmaceuticals, Porto, PORTUGAL, [2]MedInUP – Center for Drug Discovery and Innovative Medicines, University of Porto, Porto, PORTUGAL.

Overexpression of L-type amino acid transporter 1 (LAT1/SLC7A5) helps support the continuous growth and proliferation of cancer cells through mTOR activation and has been suggested to be a marker of colorectal cancer prognosis and metastatic potential (Cancer Sci*99*: 2380-2386, 2008; anticancer Res 30: 4223-4227,2010; Oncol Lett 14: 7410-7416, 2017). The present study examined the effect of *LAT1* gene downregulation by RNA interference on the mRNA and protein expression, on the cellular function of the transporter and cell proliferation of human colon cancer HCT-116 cells. siRNAs targeting human *LAT1* sequences PB-8603-111t (Phyzat), SI31011000 (Qiagen) and HSS112005 (Invitrogen) and negative control siRNA commercial sequences NC-SI03650318 and NC-SI03650325 (Qiagen) were tested. HCT-116 cells were transfected with 25 nM siRNAs complexed with Lipofectamine 2000® or Injectin®, and their effects upon LAT1 mRNA expression (RT-qPCR), protein abundance (western blot), inward transport of [^{14}C]-L-leucine and cell proliferation (calcein fluorescence) were evaluated after 72 h. [^{14}C]-L-leucine accumulation in HCT-116 cells was reduced in the presence of the LAT1 inhibitor BCH in a concentration-dependent manner. LAT1 mRNA expression was reduced by 47%, 62% and 73% after treatment with SI31011000, HSS112005 and PB-8603-111t siRNA sequences, respectively, while LAT1 protein expression was reduced to around 50%. This effect was accompanied with a reduction of [^{14}C]-L-leucine accumulation in HCT-116 cells. Moreover, LAT1 downregulation decreased cell proliferation, particularly when treated with PB-8603-111t. The negative control siRNAs were devoid of effects on the parameters measured. Importantly, intra-tumoral injections of PB-8603-111t caused a decrease in relative tumor volume in immune deficient mice injected subcutaneously with HCT-116 cells. In conclusion, we expect the anti-LAT1 siRNA PB-8603-111t to decrease tumor growth and metastasis potential in human colon cancer. Part of this work was developed within the SIRNAC project, co-financed by NORTE2020, PT2020 and the European Union.

P2083/B327

RNAi-mediated Downregulationof ASCT2/SLC1A5 Expression and Function in Human Colon Cancer Cells.

C. Carneiro[1], A. C. N. Oliveira[1], P. J. Kennedy[1], M. P. Serrão[2], **P. Soares-da-Silva**[2,1]; [1]Phyzat Biopharmaceuticals, Porto, PORTUGAL, [2]MedInUP – Center for Drug Discovery and Innovative Medicines, University of Porto,, Porto, PORTUGAL.

Overexpression of alanine/serine/cysteine transporter 2 (ASCT2/SLC1A5) helps support the continuous growth and proliferation ofcancer cells through mTOR activation and has been suggested to be a marker of colorectal adenocarcinoma prognosis (Anticancer Res 22:2555-2557,2002; Mol Imaging Biol 19:421-428,2017). The present study examined the effect of *ASCT2* gene downregulation by RNA interference on the mRNA and protein expression, transport function and proliferation of human colon cancer HCT-116 cells. siRNAs targeting human ASCT2 sequences PB-4501-134t (Phyzat) and SI00079730 (Qiagen) and negative control siRNA commercial sequences NC-SI03650318 and NC-SI03650325 (Qiagen) were tested. HCT-116 cells were transfected with 25 nM siRNAs complexed with Lipofectamine 2000® or

Injectin®, and their effects upon ASCT2 mRNA expression (RT-qPCR), protein abundance (western blot), inward transport of [^{14}C]-L-alanine and cell proliferation (calcein fluorescence) were evaluated after 72 h. Anti-ASCT2 siRNAs reduced ASCT2 mRNA expression in HCT-116 cells by 70% and 74% and ASCT2 protein expression by 44% and 63% with SI00079730 and PB-4501-134t, respectively. This effect was accompanied by a reduction of intracellular of [^{14}C]-L-alanine accumulation (by 23% and 49% with SI00079730 and PB-4501-134t, respectively). Moreover, ASCT2 downregulation decreased cell proliferation, particularly when treated with PB-4501-134t (by 78%). Importantly, intra-tumoral injections of PB-4501-134t caused a decrease in relative tumor volume in immune deficient mice injected subcutaneously with HCT-116 cells. In conclusion, we expect the anti-ASCT2 siRNA PB-4501-134t to decrease tumor growth and metastasis potential in human colon cancer. Part of this work was developed within the SIRNAC project, co-financed by NORTE2020, PT2020 and the European Union.

Effects of Acid Ceramidase Over-Expression on H295R Adrenal Carcinoma Cells.

L. Turner; Francis Marion University, Florence, SC.

The enzyme acid ceramidase has been shown to be over-expressed in some cancer cell lines and primary tumors, and enhances the ability of these cells to convert ceramide, which is often produced as a pro-apoptotic response to stress, to sphingosine, which can then be converted to the pro-survival molecule sphingosine-1-phosphate. Therefore, acid ceramidase over-expression confers a survival advantage in response to stress such as chemotherapy and radiation. Cortisol is a steroid stress hormone produced by adrenal cells in response to adrenocorticotropic hormone released by the pituitary gland. Published studies have shown that adrenocorticotropic hormone can also increase acid ceramidase expression in these cells. In order to evaluate the effects of increased acid ceramidase expression on adrenal cells, H295R adrenal carcinoma cells were engineered to have consistent high-level acid ceramidase expression. These cells were evaluated for ceramide resistance, cortisol production, and receptor expression.

NAG-1/GDF-15 Expression in Thyroid Cancer Development•

Y. Hong[1], C. Ryu[2], J. Ryu[2], S. Baek[1]; [1]Seoul National University, Seoul, KOREA, REPUBLIC OF, [2]National Cancer Center, Goyang, KOREA, REPUBLIC OF.

Thyroid cancer is one of the most common cancer in worldwide and incidence of this cancer has been increased during the last decades. In addition, unnecessary surgeries are being carried out due to no specific biomarker for the diagnose. Therefore, identification of novel biomarkers should be considered for thyroid cancer diagnosis. Antibody arrays were performed using normal and tumor tissue of thyroid cancer patient and found several biomarkers that could be used in thyroid cancer patients. Among the candidate proteins chosen based on the antibody array, NAG-1/GDF15 exhibited increased expression in normal tissues, compared to adjacent tumor tissues. Since NAG-1 is secreted protein, ELISA assay was performed using plasma of thyroid cancer patients to measure concentration of NAG-1/GDF15. NAG-1 levels increased with age as consistent with previous reports, but there was no significant difference in thyroid cancer type, sex, and BMI. Interestingly, NAG-1 expression was increased when phytochemicals and NSAIDs were treated into thyroid cancer cell line BcPAP, with dose-dependent manner. We further showed that combination treatment of lenvatinib with sulindac sulfide, or quercetin showed NAG-

1/GDF15 induction and synergistic effect on anti-cancer activity, measured by CX7 High-Content Screening (HCS) Platform. Finally, western blot analysis was performed using tissues from follicular thyroid cancer patients, and NAG-1/GDF15 expression was able to distinguish follicular adenoma (FA), follicular variant of papillary thyroid cancer (FVPTC), and follicular thyroid carcinoma (FTC). Overall, our study indicated that NAG-1 may provide a novel biomarker for the thyroid cancer prognosis and even differentiate different thyroid cancer types.

Inositol Kinase Activity of Ipmk Is Essential for Activation of ClassI Hdac.

L. Reilly, 21205, P. Guha, 21205, S. H. Snyder; Johns Hopkins University, Baltimore, MD.

IPMK (Inositol polyphosphate multikinase) is the rate limiting enzyme in inositolphosphate biosynthetic pathway. IPMK catalyze production of inositoltetraphosphate (IP4) and inositol penta phosphate (IP5), which is conserved in all the species. In mammal, IPMK can also function as a PI3Kinase. By tandem affinity purification (TAP) followed by massspectrometric analysis we found HDAC1 as an interacting partner of IPMK. Further validation by over expression and endogenous immunoprecipitation study proved the TAP data. Confocal imaging also showed IPMK/HDAC1 colocalization. Interestingly deletion of IPMK in MEF cells abolished HDAC1, HDAC2 and HDAC3 activity but made no impact on HDAC8. Interestingly, over expression of wild type IPMK can rescue HDAC activity in IPMK deleted MEFs, failed by kinase dead form of IPMK. Arabidopsis IPMK which has IP4/IP5 kinase activity but devoid of PI3Kinase activity can rescue the HDAC activity as comparable to wild type. Thus, we confirm that inositol kinase activity of IPMK influences HDAC activity.

P2087/B332

Regulation of Chromatin Structure by *Drosophila* Nrf2-Keap1 Xenobiotic Response Factors.

J. Carlson, T. Swisse, H. Deng; University of Minnesota Duluth, Duluth, MN.

The Nrf2-Keap1 pathway regulates transcriptional response to xenobiotic and oxidative stress, thereby reducing the adverse effects of these compounds on the health of an organism. According to the classic model, Keap1 interacts with Nrf2 in the cytoplasm and targets Nrf2 for ubiquitination and degradation. When xenobiotic compounds or reactive oxygen species are present, they disrupt the interaction between Keap1 and Nrf2, releasing Nrf2 to enter the nucleus and activate transcription of response genes. Although the short-term responses to xenobiotic factors are well understood, the mechanisms that mediate the effects of long-term exposure to xenobiotics on development remain unknown. It has been found that the Nrf2-Keap1 pathway can regulate normal development in *Drosophila and* mice. For example, *Drosophila* Nrf2 and Keap1 (CncC and dKeap1) regulate the synthesis of and response to ecdysone (an important hormone in metamorphosis). Elucidating other mechanisms by which Nrf2 and Keap1 can regulate development could help us understand how xenobiotics affect development and the complicated roles of Nrf2 and Keap1 in disease. Given the importance of epigenetic regulation in development, we investigated the role of CncC and dKeap1 in regulating chromatin packaging. A position effect variegation (PEV) assay uses a transcriptional reporter gene to assess heterochromatic gene silencing. PEV assays revealed that knockdown of CncC and/or dKeap1 resulted in a reduction of

gene silencing caused by pericentric heterochromatin. Knockdown of CncC or dKeap1 in embryos reduced the level of heterochromatin marker histone H3K9me2. However, knockdown of CncC or dKeap1 did not affect the expression levels of genes that encode the heterochromatin components Su(var)3-9 and HP1. These results indicate that CncC and Keap1 promote or maintain pericentric heterochromatin formation, likely at the post-transcriptional level. Thus, epigenetic regulation of chromatin may represent a novel mechanism by which the Keap1-Nrf2 xenobiotic response signaling pathway controls development. Future studies will aim to determine the interacting partners of Nrf2 and Keap1 and establish whether Nrf2 and Keap1 also regulate euchromatin structure. Elucidating the roles of Nrf2 and Keap1 will help us understand how environmental toxins may impact epigenetics, development, and human health.

The Interplay between Genomic Instability and Mitochondrial Homeostasis in the Brain.

U. Weyemi, S. H. Snyder; Johns Hopkins University School of medicine, Baltimore, MD.

Phosphorylation of histone H2AX is a major contributor to efficient DNA repair. We recently reported neurobehavioral deficits in mice lacking H2AX. Here we establish that this neural failure stems from impairment of mitochondrial function and repression of the mitochondrial biogenesis gene PGC-1α. H2AX loss leads to reduced levels of the major subunits of the mitochondrial respiratory complexes in mouse embryonic fibroblasts and in the striatum, a brain region particularly vulnerable to mitochondrial damage. These defects are substantiated by disruption of the mitochondrial shape in H2AX mutant cells. Ectopic expression of PGC-1α restores mitochondrial oxidative phosphorylation complexes and mitigates cell death. H2AX knockout mice display increased neuronal death in the brain when challenged with 3-nitropronionic acid, which targets mitochondria. This study establishes a role for H2AX in mitochondrial homeostasis associated with neuroprotection.

Epigenetic Alterations of Environmental Endocrine Disruptors Can Be Countered by Phytochemicals Resulting in Loss of Proliferation of the MCF7 Breast Cancer Cells.

B. Chatterjee[1], K. Ghosh[2], S. R. Kanade[1,2]; [1]Central University of Kerala, Kasaragod, Kerala, INDIA, [2]University of Hyderabad, Hyderabad, Telangana, INDIA.

Breast cancer is a highly mortal disease in females with its incidence is estimated to increase by 58% by 2040 according to the Global cancer observatory of IARC. Among the other factors, environmental endocrine disruptors (EEDs) are known to switch on or off breast cancer-associated genes by altering epigenetic mechanisms. The objective of the present study is to investigate the anti-proliferative mechanisms of some phytochemicals resulting in a reversal of the epigenetic alterations due to exposure of such EEDs. Using the MCF7 breast cancer cells, the alterations in the expression of the epigenetic regulators of histone and DNA including the protein arginine methyltransferase 5 (PRMT5), histone deacetylase 1 (HDAC1), enhancer of zeste homolog 2 (EZH2) and DNA methyltransferase 1 (DNMT1) by exposure to EEDs and phytochemicals alone or in combinations was analyzed by qPCR and western blotting. The results showed the induced proliferation of the MCF7 cells by the EEDs was significantly reduced when the phytochemicals were present. The expression and function of the above epigenetic enzymes upregulated by the EEDs was reversed by the phytochemicals which result in significant global loss of the repressive histone methylation marks (H3K27me3 and H4R3me2s),

decreased enrichment of these marks along with demethylation of the CpG islands located within the promoters of p21, p53, and BRCA1 in the MCF7 cells within 24 hours. It was therefore hypothesized that the increased level of repressive epigenetic factors in the EED-exposed cells was reversed by phytochemicals (including brazilin, curcumin, epigallocatechin gallate, ellagic acid, and resveratrol) used in the study resulting in the restoration of the above anti-proliferative genes contributing to the loss of proliferation of the malignant MCF7 cells. In summary, the findings of the present study reveal novel epigenetic mechanisms critical for induced cell proliferation by such environmental chemicals could be reversed by the dietary phytochemicals with anticancer properties.

P2090/B335

Dynamic Interplay between De-novo DNA Methylation and Chromatin Structure during the Loss of Pluripotency.

F. Olmeda[1], S. Clark[2], T. Lohoff[2], W. Reik[2], **S. Rulands**[1]; [1]Max Planck Institute for the Physics of Complex Systems, Dresden, GERMANY, [2]The Babraham Institute, Babraham, UNITED KINGDOM.

During early development exit from pluripotency and priming for differentiation into somatic lineages is associated with genome-wide de novo DNA methylation. As a result of these processes cells carry distinct epigenetic marks that are associated with their fate during later stages of development and adulthood. But how are these epigenetic marks robustly established? Combining novel methods from single-cell multi-genomics and theoretical biophysics we infer the mechanisms governing de-novo methylation via DNMT3 enzymes. We show that the establishment of DNA methylation is a collective process involving feedback ranging over large genomic domains. Surprisingly, de-novo methylation follows generic dynamics which are self-similar in time and space. We demonstrate how these epigenetic marks are established through the interplay between chemical and topological modifications of the DNA and show how such processes provide a proofreading mechanism for the establishment of methylation marks. Our work sheds new light on epigenetic mechanisms involved in cellular decision making. It also highlights how mechanistic insights into the molecular processes governing cell-fate decisions can be gained by the combination of methods from single-cell multi-genomics and theoretical biophysics.

P2091/B336

The Stag2-cohesin Functions in Brain Development.

N. Cheng[1], M. Kanchwala[2], C. Zhao[3], Q. Lu[3], C. Xing[2], H. Yu[1]; [1]Howard Hughes Medical Institute, University of Texas Southwestern Medical Center, Department of Pharmacology, Dallas, TX, [2]University of Texas Southwestern Medical Center, McDermott Center for Human Growth and Development, Department of Bioinformatics and Department of Clinical Sciences, Dallas, TX, [3]Cincinnati Childrens Hospital, Department of Pediatrics, Brain Tumor Center, Division of Experimental Hematology and Cancer Biology, Cincinnati, OH.

Mutations of the cohesin components and regulators result in developmental diseases with multisystem dysfunction in human, which collectively referred to as cohesinopathes. Recently, familiar germline mutations in the X-linked gene STAG2 were found in a novel type of cohesinopathy that features in intellectual deficiency. Cohesin is a ring-shaped protein complex that entraps and tethers DNA segments. Other than mediating sister-chromatid cohesion, it also promotes DNA damage repair, and regulates transcription. In this study, we created a brain-specific Stag2 conditional knockout mouse

model. We discovered that the cohesion subunit Stag2 plays an important role in the mouse brain development and myelination, through promoting transcription in oligodendrocytes. Stag2 CNS-specific knockout mice fail to thrive. The CKO were born at normal mendelian ratio. However, the CKO present growth retardation and premature death while the floxed control litter mates grow up normally. Till four weeks old, about half of the CKO died, with the rest CKO mice weighing only half of the control mice and dying within three months. Despite having lower plasma Igf-1 level, Stag2 CKO display normal feeding and drinking. Meanwhile, the Stag2 CKO pups present neurological defects: forepaw and hindlimb clasping, and the ataxia-like behavior. Using RNA sequencing, we further discovered that cholesterol biosynthesis and myelination was repressed during development in CKO. By Mass spectrometry, we found that all major cholesterol precursors are at lower levels in CKO. In *situ* hybridization confirmed that the myelin mRNA levels are reduced in P14 CKO. Our Electron Microscopy results also showed the myelination deficiency in CKO brains. Although, oligodendrocyte progenitor cells (OPCs) number counting in CKO is comparable to Ctrl. We found OPC differentiation in *vitro* displayed abnormalities. In *vitro* differentiated oligodendrocytes from Stag2 CKO have significant fewer branching process than the control. This suggests that Stag2 deficient oligodendrocytes are able to form but have impaired function in myelinating axons. Our study proved that a cohesin subunit plays important roles in the development of mammals by regulating transcription of a specific cell type.

P2092/B337

Partitioned Heritability and Functional Enrichment Reveal Ovarian Cancer Risk Variants in Histotype-specific Enhancers That Disrupt Transcription Factor Binding Sites.

P. Peng[1], S. G. Coetzee[1], J. Tyrer[2], A. L. Reyes[1], J. Plummer[1], R. I. Corona[1], K. Lawrenson[1], J. Seo[3], M. L. Freedman[3], B. P. Berman[1], P. Pharoah[2], D. J. Hazelett[1], S. A. Gayther[1], M. R. Jones[1]; [1]Cedars-Sinai Medical Center, Los an geles, CA, [2]University of Cambridge, Cambridge, UNITED KINGDOM, [3]Dana-Farber Cancer Institute, Boston, MA.

Genome wide association studies (GWAS) have identified 41 regions associated with risk of epithelial ovarian cancer (EOC). Given that the vast majority of these variants lie in the non-coding genome, and that regulatory landscapes are highly tissue specific, we hypothesized that EOC risk alleles disrupt regulatory regions and function through their interaction with epigenomic features in cell types relevant to EOC. We applied computational tools to identify functional mechanisms at GWAS risk loci for EOC. We first estimated the heritability explained by common SNPs for each EOC histotype and found that the current known risk loci of high grade serous ovarian cancer (HGSOC) account for approximately 6% of narrow sense heritability (h_g^2) Moreover, we partitioned SNP-heritability across non-cell-type-specific functional categories and observed a significant contribution of regulatory elements to EOC heritability, e.g. Promoter (p = 0.016), and Super-enhancer (p = 0.02). To understand how risk variants residing in regulatory elements affect cancer development through the epigenomic landscape, we collected epigenomic datasets for a total of 121 cell and tissue types, from public resources (Roadmap Epigenomics and ENCODE) and in-house generated ChIP-seq. We identified significant enrichment of EOC risk variants in cell and tissue specific active regulatory elements marked by H3K27Ac. Intriguingly, credible causal SNPs for HGSOC were enriched in H3K27Ac only in HGSOC tumors, and depleted in ovarian surface epithelium demonstrating that germline risk variants for EOC are located within regulatory elements that are active in tumor, rather than precursor normal tissues, but also add to the existing evidence that ovarian surface epithelium are unlikely the cell of origin for HGSOC. We further examined the effect of credible causal variants within H3K27Ac regions in EOC related cell types on

transcription factor binding sites. The most frequently broken motif was REST, which is disrupted by 19 SNPs and has been implicated as both a tumor suppressor and an oncogene. Overall, these systematic analyses guide comprehensive interpretation of EOC risk variants. Functional annotation with epigenomic data from relevant cell types can identify putative causal regulatory elements and transcription factor binding sites that are disrupted by risk variants for EOC.

P2093/B338

Actin Alignment Enhanced in Endothelial Cells Under Shear Stress Due to Decreased Nuclear Stiffness.

B. Danielsson[1], K. Tieu[1], T. Raisch[1], M. Surratt[1], K. Dahl[2], D. Conway[1]; [1]Virginia Commonwealth University, Richmond, VA, [2]Carnegie Mellon University, Pittsburgh, PA.

Nuclear shape and architecture play an important role in how the cell responds to physiological forces. Aberrant structural changes in the nucleus are seen in several human diseases such as cancer, laminopathies, heart disease, and muscular dystrophy. We therefore sought to examine how changes in nuclear structure and chromatin condensation affect the endothelial cell (EC) response to shear stress. Human Umbilical Vein Endothelial Cells (HUVECs) were treated with histone deacetylase inhibitor, trichostatin a (TSA), to increase euchromatin, softening the nucleus, and a histone demethyltransferase inhibitor, methylstat, to increase heterochromatin, hardening the nucleus. In addition, we also used VEGF, previously shown to increase chromatin mobility, to soften the nucleus. HUVECs were exposed to both oscillatory and laminar shear stress, in the presence and absences of these modifications, and assayed for DNA damage and actin alignment in the direction of flow. We observed that both TSA- and VEGF-treated cells, had faster cell alignment under laminar shear stress than condensed DNA or wildtype. HUVECs treated with TSA and VEGF align parallel in the direction of flow after 24 hours, whereas the wildtype cells (untreated) only align after 72 hours. In contrast, no alignment was observed in the methylstat group at 72 hours, suggesting that increased chromatin condensation results in ECs that cannot properly adapt to shear stress. Significant phosphorylation of H2AX, a marker for DNA damage, was detected in cells treated with methylstat under laminar and oscillatory flow, suggesting that a stiffer nucleus is more prone to DNA damage. In conclusion, this data shows that changes in nuclear stiffness affects the ability of endothelial cells to adapt and regulate force.

P2094/B339

Simple Sequence Repeats -Deciphering Functions in the Genome.

F. Athar, R. K. Mishra; CSIR-CENTRE FOR CELLULAR and MOLECULAR BIOLOGY (CSIR-CCMB), Hyderabad, INDIA.

Simple Sequence Repeats (SSRs) or Microsatellites are short tandem repeats of 1-6 nucleotide motifs with their repetitive unit occurring anywhere between 10-20 times. SSRs occur in most organisms, in coding and non-coding DNA but their functions are unknown.In the human genome, they are twice as abundant as the protein-coding DNA. Studies suggest that SSRs may have essential roles in gene regulation and genome organisation. Recently, the disease associated SSRs have been shown to occur in CpG island rich chromatin boundaries and cause topological disruptions on expansion. Chromatin domains in the genome are defined by DNA elements called Insulators/boundary elements. The globin insulator, the *Drosophila* Gypsy insulator and the boundaries of *Drosophila Hox* loci are well-known insulators. Repeats can function as enhancer-blockers preventing communication between a promoter and an enhancer or as barrier elements protecting transgenes from position-dependent silencing. The

GATA-repeat is shown to have enhancer blocking activity in *Drosophila* and human cell lines. As interesting candidates for such function, we selected 23 human SSRs based on their 'length preference' to study their cis-regulatory potential. Using cell-based functional assays to study their cis-regulatory potential, I found that the 23 SSRs modulated promoter activity in six different cell lines, in a cell-type-dependent manner. 15 of 23 SSRs showed insulator activity in K562 cell line. Though many insulator proteins in *Drosophila* are known, the CCCTC-repeat binding factor, CTCF is the only insulator protein identified in vertebrates. Electrophoretic Mobility Shift Assays (EMSA) using nuclear extracts from human cell lines revealed that these SSRs bind specific proteins. Using affinity purification with proteomics, identifying novel SSR-binding proteins may provide insights into their roles as organisers and regulators of the genome.

P2095/B340

Set1/COMPASS Protects Active Euchromatin Against Heterochromatin Invasion by Disrupting Suv39/Clr4 Activity and Nucleosome Stability.

R. A. Greenstein[1], R. R. Barrales[2,3], N. A. Sanchez[1], J. E. Bisanz[1], S. Braun[2,3], B. Al-Sady[1]; [1]University of California, San Francisco, San Francisco, CA, [2]Ludwig Maximilians University of Munich, Martinsried, GERMANY, [3]International Max Planck Research School for Molecular and Cellular Life Sciences, Martinsried, GERMANY.

Critical to the health and viability of the cell, is the ability to protect active euchromatin regions from invasion by gene-repressive heterochromatin in order to avoid deleterious transcriptional silencing. Heterochromatin, a conserved nuclear ultrastructure, is canonically found at constitutive loci including pericentromere and subtelomere regions where it has structural and genome defensive roles. In addition, facultative heterochromatin domains are also found interspersed in active euchromatin, where they regulate gene expression critical to creating and maintaining cell types. While it is known that heterochromatin and euchromatin harbor mutually exclusive information, the spatial encoding of and mechanisms by which euchromatic signals contain ectopic heterochromatin spreading remain opaque. Using a genetically encoded fluorescence-based spreading sensor system and global chromatin analysis, we investigated ectopic heterochromatin invasion in single fission yeast cells. We found that genes themselves can act as barriers to heterochromatin invasion and identified Set1/COMPASS as a gene-based, negative regulator of heterochromatin spreading via a genetic screen. Multi-locus validation confirmed that at least part of this genic barrier function is locally encoded by Set1 on actively transcribed genes and is not dependent on Set1 altering gene transcript levels. Genome wide, the major role of Set1 in protecting euchromatin from heterochromatin invasion occurs at small domains known as heterochromatin islands, which are interspersed in gene-rich euchromatin and regulate specifiers of cell fate. Set1 functions through at least two pathways to direct this gene protection activity - inhibiting catalysis by Suv39/Clr4 and disrupting nucleosome stability. Taken together, these results describe a mechanism for spatial encoding of euchromatic signals that regulate the expansion of heterochromatin domains.

P2096/B341

Heterochromatin Methylation Regulates Gnomic Stability.

C. Herlihy, A. Manning; Worcester Polytechnic Institute, Worcester, MA.

Heterochromatin methylation regulates genomic stability Cancer is typically considered a genetic disease where gene deletions or mutations are responsible for cancer-promoting changes within the cell. However, deregulation of epigenetic mechanisms is also prevalent in a variety of cancer contexts, and is increasingly appreciated as a contributing factor in tumorigenesis. Epigenetic modifiers regulate the placement and removal of covalent modifications on histones to orchestrate the recruitment of effector proteins and influence the compaction and accessibility of chromatin. In this way, deregulation of histone modifying enzymes can have dramatic consequences for gene expression and chromatin architecture. Epigenetic marks of constitutive heterochromatin are both increased and decreased in different subsets of cancers. However, while previous studies have demonstrated that *loss* of methylation that marks constitutive heterochromatin compromises mitotic fidelity, the impact of *increased* methyl marks at constitutive heterochromatin on cancer cell biology remains unclear. Here we show that alteration of both H3K9 and H4K20 methylation corrupts genomic instability. This loss of genomic stability resulting from altered heterochromatic methylation suggests that cancer-relevant epigenetic changes in constitutive heterochromatin regulation may underlie genomic instability seen in many different cancer contexts.

P2097/B342

Influence of the Epigenome on Chromatin Motions.

M. Locatelli[1], P. Kefer[2], G. Holzwarth[2], K. Bonin[2], P. Vidi[1]; [1]Wake Forest School of Medicine, Winston Salem, NC, [2]Olin Physical Laboratory - Wake Forest University, Winston Salem, NC.

Dynamic changes in chromatin organization maintain proper nuclear functions that include gene expression, DNA replication and genome maintenance. The movements of chromatin fibers themselves are thought to play important roles in the regulation of these fundamental processes. For instance, motions of DNA breaks are necessary for the onset of genomic translocations driving the initiation, progression and recurrence of certain cancers. Yet the mechanisms controlling chromatin mobility are still poorly understood. Here, we investigated the involvement of the epigenome in chromatin motions to better understand the functional significance of chromatin dynamics for genome function. We developed a method based on structured illumination to track and quantify the motions of chromatin microdomains in live cells. This method allow the tracking of photoactivated chromatin reporter (PACR) arrays produced with a diffractive optical element (DOE). This method allowed us to demonstrate a transient drop in chromatin motions after DNA damage induced by the radiomimetic drug bleomycin (BLM), or by ionizing radiations (IR). These results have been confirmed by computational simulations, showing that the motions observed are minimally influenced by noise. To further understand the role of the epigenome on chromatin motions, we investigated the motions of compacted chromatin in cells treated with histone demethylase inhibitors, and of relaxed chromatin in HDAC inhibitors-treated cells. Epigenetic sensors recognizing different histone modifications were used to assess the effect of drugs on chromatin statut, and to evaluate the motions of condensed compared to relaxed chromatin at the single cell level. Treatment of U2OS cells with dimethyloxalylglycine (DMOG), which inhibits H3K9 demethylases, led to an accumulation of H3K9me3 and showed a reduced chromatin diffusion. Hence, chromatin compaction is apparently leading to a measurable decrease in mobility. Our first results

suggest that the epigenome plays a role in the mobility of the chromatin. These results represent a first step toward the identification of chromatin motion regulators, and could help predict the biogenesis of genomic translocation.

P2098/B343

Modulation of Swi/Snf Mediated Developmental Programming by Bardet-Biedl Syndrome Proteins: Insights into the Etiology of Mckusick-Kaufman Syndrome and Congenital Heart Disease.

D. C. Slusarski, M. Rebagliati, T. Westfall; University of Iowa, Iowa City, IA.

Swi/Snf chromatin-remodeling complexes play crucial roles in development, stem cell biology and tumor suppression. Moreover, mutations in Swi/Snf chromatin remodeling proteins are associated in a significant way with congenital heart defects (CHD). Epigenetic regulators like Swi/Snf affect thousands of downstream target genes, making it difficult to identify the crucial target genes whose mis-regulation contributes to CHD. Smarcc1 (BAF155) and Smarcc2 (BAF170) subunits are core scaffolds that coordinate the assembly of all Swi/Snf complexes. Our published findings identified protein-protein interactions between Smarcc1 and the MKKS/BBS6 protein, a gene associated with both McKusick-Kaufman Syndrome, and Bardet-Biedl Syndrome. We show that BBS6 binds to and modulates the subcellular partitioning of SMARCC1 and that independent manipulation of either bbs6 or smarcc1 activity in zebrafish have shared and highly specific effects on the heart transcriptome, including effects on genes required for development of the heart. This study investigates the 1) biogenesis of the Swi/Snf complex and 2) the downstream developmental impacts relative to heart development. 1) Using transgenic zebrafish and knockout cell lines, we identified additional interactions between Smarcc1 and the other BBS-chaperonin proteins BBS10 and 12 as well as with the chaperonin CCT3, a subunit of the multi-protein CCT/TRiC complex, suggesting that the BBS chaperonin complex assists in the assembly of a SMARCC1-containing SWI/SNF subcomplex. 2) Congenital heart disease (CHD) affects ~2% of newborns each year and many, if not the majority of CHD defects, are the consequence of abnormal development of the outflow tract, OFT. We find that independent manipulation of either bbs6 or smarcc1 activity disrupts the formation of the OFT in zebrafish. We also find precocious activation of key genes involved in heart differentiation, including, *isl2b*, a gene required for outflow tract development. Swi/Snf complexes with different Smarcc1 to Smarcc2 ratios are associated with distinct cell states. Generally, ES-cells and some progenitors have Smarcc1-enriched Swi/Snf complexes; while more differentiated cells (post-mitotic and some progenitors) tend to be enriched for Smarcc2. Our work, showing precocious activation of developmental genes in the context of reduced Smarcc1 levels in zebrafish suggests that this dichotomy also applies to the developing heart.

P2099/B344

Chromatin Maturation Following Asymmetric Replication Coupled Nucleosome Assembly in *Drosophila*Adult Stem Cells.

J. Snedeker, X. Chen; Johns Hopkins University, Baltimore, MD.

One of the major questions in developmental biology is how cells acquire different cell fates, and in particular how cell fate is determined during the asymmetric cell division of adult stem cells. Previously, our lab found that old and new histones H3 and H4 are segregated asymmetrically during the division of Germline Stem Cells. This could theoretically allow for direct reprogramming of the epigenome of the two cells. Mechanistically, this asymmetry is initially generated during DNA replication wherein old and

new histones are differentially deposited on sister chromatids due to both delayed lagging strand synthesis and coordinated replication fork progression. Following this dramatically asymmetric replication coupled nucleosome assembly, histone modifications as well as old and new histones are asymmetrically segregated on the forming sister chromatids. This generates, for example, a more than five-fold asymmetry in H3K27me3 segregating to the leading strand and H3K14ac towards the lagging strand as observed at the single molecule level on superresolved chromatin fibers. However, by mitosis the sister chromatids contain comparable levels of histone modifications. This predicts that there is a novel chromatin maturation program in stem cells, during which histone modification are selectively written on the histone modification depleted sister chromatid. The kinetics of this post-replicative maturation to globally symmetric levels are distinct for each histone modification as observed at both the single molecule level using chromatin fibers and globally in the whole nuclei using Edu pulse chases. While this program does generate comparable global levels for every observed histone modification, local asymmetries between sister chromatids can be observed at specific regions using superresolved mitotic chromosome spreads. Altogether, this suggests that stem cells not only have dramatic asymmetries in histone segregation, but that this is coupled to a unique chromatin maturation program that generates globally symmetric histone modification levels while specifically retaining certain asymmetries.

Chromatin and Chromosome Organization 2

P2100/B345

The Effect of Chromatin Structure on the Susceptibility to Double Strand Breaks and Choice of Repair Pathway Used.

J. Ross, C. Heitmiller, R. C. Burgess; Stevenson University, Owings Mills, MD.

Cells are constantly being exposed to threats such as radiation, chemicals, and internal damage, the genome is at risk for DSB. If left unrepaired, the damage could result in mutations or cell death. When DSBs do occur, the cell has 3 pathways; apoptosis, non-homologous end joining, and homologous repair. The purpose of this study is to determine how DSB susceptibility and repair mechanism differs around the genome, and to determine if the chromatin environment affects these outcomes. In this experiment, tetracycline-inducible CRISPR will be used to induce DSBs in the gene regions of yeast cells to compare the DSB frequency and repair at different sites. DSB frequency was measured using quantitative PCR across break sites. DSBs would be reflected in a decrease in product as the amplification would increase at uncut sites and drop at cut sites. Preliminary data shows that repressed genes have higher levels of DSB at 3h of DSB induction than that of active genes. This suggests that chromatin environment of the cut site could affect the susceptibility of that site to DSBs. The high amount of DSB formation in the repressed genes could also be a result less efficient repair mechanisms than active genes. More trials are needed to investigate this relationship. Repair mechanism was measured using survival analysis, which tests if cells become resistant to the continuous DSBs at the cut site due to imprecise repair of the CRISPR recognition site. The percentage of survivor colonies (compared to total cells) estimates the mutation frequency of the gene. Preliminary results suggest that active chromatin locations might generally have fewer survivors, but more data and genomic loci must be examined. For example, a DSB in the coding region of the inactive *SEO1* gene (0.1 mRNA/cell), showed a high frequency of survivors after cutting. Survivor analysis had a mean percent survivors of 53%, with the lowest trial having 36% survivors and the highest trial having 92% survivors. Sequencing of the DSB region is underway to

explore this relationship as well as determine if there is a correlation between specific histone modifications and mutation frequency. This research will reflect how the different areas and structures of the genome are more susceptible to DSB and faulty repair which could lead to further mutation. Studying this deepens our understanding of genomic change in terms of how DSB repair can be altered by chromatin packaging.

Misregulation of Linker Histone Variants in Glioblastoma.

A. Saha, M. Bui, S. Baek, Y. Dalal; National Cancer Institute, NIH, Bethesda, MD.

Glioblastoma (GBM) is the most common primary malignant brain tumor. The current standard of care includes maximal surgical resection followed by radiotherapy and chemotherapy. This disease remains deadly, with a dismal 5-year survival rate of 5.5%. In order for meaningful advances in the treatment, a thorough understanding of its phenotypic heterogeneity and associated epigenetic profile is required. Chromatin dysregulation is commonly observed in many cancers, including GBM. The role of linker histones, which play a key role in higher order chromatin organization, and which can dramatically alter the chromatin landscape, remains poorly understood. Previous reports have shown that loss of linker histone variant, H1.0, correlates with tumor progression and differentiation status. Interestingly, when we used patient samples to test H1 levels using a pan H1 antibody, a significant increase in H1 content was observed. Based on our TCGA database analysis of H1 variant expression in GBM, we found that H1 was significantly overexpressed in a variant specific manner. Since patient samples are limited, we used a model system of GBM cell lines to further investigate H1 variant overexpression induced chromatin changes in the GBM context. Following confirmation that the H1 variant protein content recapitulates the expression data, in patient samples and GBM cell lines, we used custom-made variant specific antibodies to, to generate the first comparative genome wide profile of H1 variant occupancy in GBM cell lines. Preliminary data shows an overall increase in specific binding, with a shift of H1 binding preference to specific genic regions. This change in binding preference was pronounced in the GBM cells especially at some gene regulatory regions like promoters, which may indicate a role of H1 in driving specific oncogenic changes. Taken together this indicates that variant specific changes in H1 expression and distribution may widely influence the chromatin landscape and also elicit GBM specific expression in the transcriptome.

Molecular Mechanisms for the Protection of Sister Chromatid Cohesion at Mitotic Centromeres.

F. Wang; Zhejiang University, Hangzhou, CHINA.

Sister chromatid cohesion mediated by the ring-shaped multi-subunit cohesin complex is fundamental for precise chromosome segregation. Early in mitosis, while the bulk of cohesin is removed from chromosome arms by its antagonist Wapl, cohesin at centromeres is retained to ensure chromosome biorientation until anaphase onset. It remains to be determined how centromeric cohesin is protected against Wapl in mitosis. We find that the mitotic histone kinase Haspin associates with the cohesin complex through interaction with the cohesin regulatory subunit Pds5B, which is required to ensure proper centromeric cohesion (Zhou L et al., Curr Biol, 2017). Haspin also phosphorylates Wapl to inhibit the binding of Wapl to Pds5B, thereby antagonizing Wapl-mediated cohesin release (Liang C et al., EMBO Rep, 2018). Moreover, heterochromatin protein 1 (HP1) binds Haspin and facilitate its

centromeric localization, thereby linking centromere heterochromatin to sister chromatid cohesion (Yi Q et al., EMBO Rep, 2018). We reveal a positive feedback mechanism formed between the cohesin protectors Haspin and Sgo1 that ensures proper assembly of the functional inner centromere during mitosis (Liang C et al., J Biol Chem, 2019). We further dissect Aurora B kinase activity-dependent and -independent functions of the chromosomal passenger complex in regulating sister chromatid cohesion (Yi Q et al., J Biol Chem, 2019). Our studies provide mechanistic insights into how different factors in the complex centromere signaling network are specialized to meet the multiple challenges encountered on the road to accurate chromosome segregation in mitosis. We also suggest a causal link between centromeric cohesion defects and chromosomal instability in cancer cells.

Live Cell Monitoring of Genome Variation Caused by Physical and Molecular Factors.

K. ZHU[1], Y. XIA[2], J. Irianto[3], J. An drechak[1], L. Dooling[1], C. Pfeifer[1], D. Discher[1]; [1]University of Pennsylvania, Philadelphia, PA, [2]Stanford University, San Francisco, CA, [3]Florida State University, Tallahassee, FL.

Live cell monitoring of genome variation caused by physical and molecular factors Kuangzheng Zhu*[1], Yuntao Xia*[1], Jerome Irianto[1], Jason C. An drechak[1], Lawrence J. Dooling[1], Charlotte R. Pfeifer[1], and Dennis E. Discher[1] Molecular & Cell Biophysics Lab[1], Correspondence: *discher@seas.upenn.edu* * These authors contributed equally. Cancer cells and pluripotent stem cells frequently exhibit gains or losses of entire chromosomes and chromosome segments, with the typical terminal analysis by genomics suggesting that aneuploid variation is ongoing and especially variable within solid tumors. Here, we quantify aneuploidy-inducing perturbations by live cell fluorescence monitoring of changes in housekeeping gene expression from specific chromosomes in human cancer lines and normal diploid iPS cells. Inhibition of the spindle assembly checkpoint (SAC) and knockdown of DNA repair factors cause chromosome mis-segregation to increase several-fold above a low baseline level, and both perturbations also generate several-fold more rare fluorescent-null cells. Loss of chromosomes with loss of fluorescence is confirmed by single cell karyotyping, SNP arrays on stable isolated clones, and single cell transcriptomics that show downregulated expression of genes on lost chromosomes. Tumor growth in mice also generates rare fluorescent-null cells, as do teratomas generated from iPS cells, and flattened mitotic cells in tumors that are known to cause chromosome mis-segregation are mimicked in vitro by confinement and shown to produce fluorescent-null cells. Viability, selection, and altered expression can thus be tracked to reveal physical and molecular mechanisms of genome variation. Xia Y, Zhu K, *et al*. "Live cell monitoring for factors affecting genome variation." *bioRxiv* 50815 (2018).

P2104/B349

Daf2, a Novel RNA Binding Protein, Functions in Heterochromatin Assembly.

H. Ban, **F. Li, 10012-1732**; Department of Biology, New York University, New York, NY.

Heterochromatin is a transcriptionally silenced domain in eukaryotic genome. Histone 3 lysine 9 methylation (H3K9me) is an epigenetic hallmark of heterochromatin. In fission yeast, RNA interference (RNAi) plays an important role in H3K9 methylation. Heterochromatin can be breifely transcribed during S phase. Heterochromatin transcripts are processed into siRNAs which promote H3K9 methylation in heterochromatin. Histone hypoacetylation mediated by histone deacetylases (HDACs) is another conserved epigenetic mark of heterochromatin. How RNAi and histone hypoacetylation are coordinated

during DNA replication to modulate heterochromatin assembly remains to be elucidated. Previously, we showed that Dpb4, a subunit of DNA polymerase epsilon complex, is important for the recruitment of HDAC to heterochromatin during S phase. Here using mass-spectrometry, we identified a novel RNA-binding protein Daf2 that interacts with Dpb4. We observed that H3K9me level at heterochromatin is compromised in the absence of Daf2. The siRNA generation is also defective in the *daf2* mutant. In addition, we found that Daf2 is required for the enrichment of Chp1, a subunit of RITS complex required for RNAi pathway, in heterochromatin. Importantly, we discovered that Daf2 physically interacts with heterochromatic transcripts as well as Chp1 in *vivo,* suggesting a direct role of Daf2 in RNAi-mediated heterochromatin formation. Furthermore, we showed that histone acetylation is increased whereas the association of the Sir2 histone deacetylase with heterochromatin is reduced in the deletion mutant of *daf2*. Togehther, our evidence suggests that Daf2 facilitates the assembly of heterochromatin by coordinating RNAi pathway and HDAC during DNA replication. This study discovers a novel role of DNA replication machinery in epigenetic inheritance of heterochromatin silencing.

P2105/B350

ALT Suppression Requires Localization of ATRX to PML Bodies Downstream of DAXX Binding of Histone H3.3.

S. F. Clatterbuck Soper, P. S. Meltzer; Genetics Branch, Center for Cancer Research, National Cancer Institute, Bethesda, MD.

To counteract the end-replication problem, proliferating cells must enact a program of telomere maintenance. In normal dividing cells, telomeres are lengthened in an RNA-templated manner through the action of the ribonucleoprotein telomerase, but in 10-15% of tumors telomeres are lengthened through a DNA-templated process termed Alternative Lengthening of Telomeres or ALT. ALT is associated with mutations in the ATRX/DAXX/H3.3 histone chaperone complex, which is responsible for deposition of non-replicative histone variant H3.3 at heterochromatic regions of the genome including telomeres. Mutations in this complex result in aberrant telomeric chromatin, but it remains unclear whether H3.3 deposition specifically is required for ALT suppression. To address this question directly, we utilized the G292 cell line, in which ATRX is wild type but DAXX has undergone a fusion event with the non-canonical kinesin KIFC3[1]. The DAXX-KIFC3 fusion binds ATRX but fails to localize to nuclear PML bodies. Restoration of wild-type DAXX in G292 localizes ATRX and abrogates ALT. Using this model system, we tested the ability of a DAXX H3.3 binding mutant, DAXX-Y222E, to suppress ALT. The DAXX-Y222E mutant does not robustly suppress ALT-associated PML bodies (APBs), an ALT hallmark. Surprisingly, we found that DAXX-Y222E, though properly localized itself, fails to bind ATRX and localize it to nuclear PML bodies. To follow up, we tested a panel of DAXX variants with cancer associated missense mutations in the histone binding domain. We found that the DAXX mutants vary in their capacity to localize with ATRX, while a mutation that allows DAXX to bind H3.2 or H3.3 promiscuously forms foci with ATRX at frequencies similar to wild type DAXX. Notably, we find that the ability of the DAXX mutants to suppress APBs correlates with the extent to which they localize with ATRX. We speculate that these mutants represent a range of H3.3 binding affinities and propose that DAXX binding of H3.3 is upstream of complex formation with ATRX. These results imply a requirement of H3.3 for ALT suppression apart from its deposition and provide for the first time direct characterization of the biochemical defects of DAXX mutations found in human cancers. 1 Yost, K. E. et al. Rapid and reversible suppression of ALT by DAXX in osteosarcoma cells. Sci Rep 9, 4544, doi:10.1038/s41598-019-41058-8 (2019).

P2106/B351

Large-scale Chromatin Organization in Mammalian Cells.

P. Bazantova[1], M. Dalecka[2], E. Smirnov[1], A. Schrofel[3], A. Benda[2], D. Cmarko[1]; [1]Institute of Biology and Medical Genetics, First Faculty of Medicine, Charles University and General University Hospital in Prague, Albertov 4, 128 00, Prague, CZECH REPUBLIC, [2]Imaging Methods Core Facility at Biocev, Faculty of Science, Charles University, Albertov 6, 128 43, Prague, CZECH REPUBLIC, [3]VIB, Center for Structural Biology and Structural Biology Brussels, Vrije Universiteit Brussel, Building P1T, room 0.02 Pleinlaan 2 1050, Brussels, BELGIUM.

The cell nucleus is site of important processes such as DNA replication and repair and synthesis, maturation, and transport of RNA. These processes take place in non-membrane chromatin-containing dynamic domains. It is generally agreed that chromosomes occupy a particular region of the nucleus called chromosomal territories (CT). Conversely, the interchromatin compartment - the DNA-poor nuclear space that surrounds individual CTs - remains the subject of debate. The aim of our research is to analyze the distribution of DNA in the nuclear space, including large-scale three-dimensional (3D) chromatin arrangement in cell nuclei. We want to contribute to the discussion of chromatin architecture of the interphase nucleus. Light microscopy and fluorescent labels can provide an estimate of chromatin compaction and organization at specific genomic loci. For higher-resolution analysis, electron microscopy is required. We used a combination of focused ion-beam milling (FIB) and scanning electron microscopy (SEM) where a few-nanometers layer of material is removed from the top of the resin-embedded mammalian cells and the freshly cut block face is then scanned by electron microscope. This process is repeated automatically until a sufficient sample volume has been scanned. To visualize chromatin, the cells were treated by the pre-embedding method based on the extraction of RNA and blocking of carboxy and amino groups by methylation and acetylation where the chromatin, finally stained by uranyl, is observed as a highly contrasted structure. Our 3D reconstruction of chromatin arrangement showed occurrence of the condensed/inactive chromatin - decondensed/active chromatin - DNA-free interchromatin region organization of chromatin. Morphometric analysis of the nuclear regions containing DNA showed that DNA/chromatin occupies about half of the total nuclear volume, i.e. A significant part of nucleoplasm belongs to the interchromatin compartment. Furthermore, the analysis of distribution of DNA revealed approximately 40 % of chromatin domains associated with nuclear periphery (perinuclear chromatin) and about 30 % of chromatin domains associated with nucleolus (chromatin containing ribosomal genes). Our results demonstrate that the approach perpformed on nuclei with specifically contrasted chromatin offers an extraordinary opportunity for study of the nuclear architecture in *situ*. This work was supported by the Grant Agency of Czech Republic (19-21715S), by Charles University (Progres Q28). We acknowledge the Imaging Methods Core Facility at BIOCEV, institution supported by the Czech-BioImaging large RI projects (LM2015062 and CZ.02.1.01/0.0/0.0/16_013/0001775, funded by MEYS CR) for their support with obtaining imaging data presented in this work.

CENP-A Preserves Genome Integrity during Alpha-satellite DNA Replication by R-loops Suppression at Human Centromeres.

S. Giunta, 10065; Rockefeller University, New York, NY.

Centromeres are composed of repetitive alpha-satellite DNA with high sequence homogeneity between the higher order repeat (HOR) blocks. Homologous recombination has been postulated to play an active role in maintaining the repeat structure, but also implies that this process must be tightly regulated to avoid rearrangements, which could change the centromere size and strength, triggering genome instability (Black & Giunta, 2018). Using the centromere chromosome-orientation fluorescence in *situ* hybridization (Cen-CO-FISH; Giunta, 2018), we previously showed that the centromere-specific histone H3 variant CENP-A is important for maintaining centromere integrity (Giunta & Funabiki, 2017). Although these results indicate the presence of active mechanism that prevents rearrangements at alpha-satellites, the mechanism by which centromere instability is induced under these circumstances is unknown. Using an auxin-induced degron that allows rapid degradation of a tagged protein (Hoffmann et al., 2016), we found that removal of CENP-A from chromatin specifically upon entry in S-phase, but not during G2 or mitosis, leads to centromere instability accompanied with accumulation of γ-H2AX and increased recombination. Single molecule DNA replication assay shows impaired replication fork progression upon CENP-A depletion with accumulation of DNA-RNA hybrids at the centromere. HOR-associated alpha-satellites are actively transcribed into long non coding RNAs (McNulty et al., 2017). Indeed, replication-transcription conflicts may trigger centromere instability as depletion of CENP-A results in a significant increase in centromeric RNA during replication. Delayed centromere replication into mitosis resulted in frequent anaphase chromosome bridges, and ensuing chromosome breakage and translocations at the centromeric regions in the following cell cycle. In addition to serving as template for mitotic assembly of the kinetochore, our work points toward a novel role for CENP-A in coordinating replication and transcription of alpha-satellites to maintain the integrity of centromeres and chromosomes.

P2108/B353

Radiation Induced DNA Damage and Repair Effects on 3D Genome.

J. T. Sanders, T. F. Freeman, Y. Xu, R. Golloshi, M. A. Stallard, R. S. Martin, A. S. Balajee, R. P. McCord; University of Tennessee,Knoxville, Knoxville, TN.

The three-dimensional structure of chromosomes plays an important role in gene expression regulation and also influences the repair of radiation-induced DNA damage. Genomic aberrations that disrupt chromosome spatial domains can lead to diseases including cancer, but how the 3D genome structure responds to DNA damage is poorly understood. Here, we investigate the impact of DNA damage response and repair on 3D genome folding using Hi-C experiments on wild type cells and ataxia telangiectasia mutated (ATM) patient cells. Fibroblasts, lymphoblasts, and ATM-deficient fibroblasts were irradiated with 5 Gy X-rays and Hi-C was performed after 30 minutes, 24 hours, or 5 days after irradiation. 3D genome changes after irradiation were cell type-specific, with lymphoblastoid cells generally showing more contact changes than irradiated fibroblasts. However, all tested repair-proficient cell types exhibited an increased segregation of topologically associating domains (TADs). This TAD boundary strengthening after irradiation was not observed in ATM deficient fibroblasts and may

indicate the presence of a mechanism to protect 3D genome structure integrity during DNA damage repair.

P2109/B354

Confirmation of Genomic DNA Double-strand Break Hotspots in Forum Domains Termini.

I. Alembekov, 107370; EIMB, Mscow, RUSSIAN FEDERATION.

Forum domains are large fragments (typically 50-250 kb) of genomic DNA isolated from different species by pulsed field gel electrophoresis without any nuclease treatment (Tchurikov and Ponomarenko, 1992). Later was shown that such fragmentation non-random and represents some kind of genome functional and structural organization. Unique distribution pattern do not correlate to another chromatin organizations, like polytene banding, SARs/MARs, Pc domains. Significant part of forums contain group of genes with coordinate expression implying their functional role. Dedicated procedure to capture genomic DNA double strand breaks (DSBs) that contribute to the forum domains formation was developed (RAFT DNA library, Tchurikov *et al*., 2011). High throughput sequencing (NGS) of the library allowed precisely map and characterize DSB hotspots. Based on NGS data and more straightforward genomic DNA preparation we undertake study of particular hotspots to gather additional confirmation for DSBs in *D. melanogaster* S2 cells. The first approach implemented used real time PCR (qPCR) to quantify target containing a hotspot *vs* adjacent target free from DSBs. Cloning of a pair of targets in plasmid as a whole gives a DNA preparation that does not have any hotspot-specific DSBs and contains two targets in exactly one-to-one quantity. Hence, relative quantity of DSBs in genomic DNA can be inferred by discrepancy between PCRs of a pair of targets from expected at equimolar condition (no DSBs). It is obvious that a template DNA with DSB between a pair of PCR primers does not yield full length transcription products needed to sustain exponential growth. Transcripts growth and resources demand for such DNA templates expected to be linear and will not significantly distort exponential growth from true templates. QPCR data obtained with DNA intercalating dye from three hotspots, namely 2L:5, 3L:4.46, 3R:7.98, shows occurrence of DSBs at standard S2 growth conditions (z-score, $p < 0.05$). Interestingly, 2L:5 became more enriched with DSBs during physiological stress (heat shock, z-score, $p < 0.05$). In the second approach primer extension procedure on genomic DNA was employed. Radiolabeled primer elongating on genomic DNA gives single stranded products to be abrupted at 5` end of a DNA break. Preliminary results are somewhat different from RAFT library sequencing results. Typically, NGS of the library gives significant break counts on full hotspot width (some hundreds bps). However, with primer extension on 3R:7.98 and 2L:5 minus strands much narrower genomic DNA hotspots was observed. Details to be discussed during the meeting. The reported study was funded by RFBR according to the research project No. 18-34-00892.

P2110/B355

The Disordered Regions of Heterochromatin Protein-1 Paralogs Regulate Dna Compaction and Dna Induced Phase Separation.

M. Keenen, G. Narlikar, S. Redding; UCSF, San Francisco, CA.

Chromatin structure is related to transcriptional output. Repressed genes are sequestered from active genes into regions of dense compacted DNA. These dense domains in *vivo* are associated with Heterochromatin protein-1 (HP1). HP1 concentrates DNA and chromatin into phase separated droplets in *vitro*, suggesting a potential mechanism of DNA organization in *vivo.* We utilize DNA curtains and

confocal microscopy to investigate HP1-mediated compaction of DNA and reconstituted chromatin substrates. We identify the key regions of the HP1α paralog required for multivalent interactions and phase separation. The internal hinge region of HP1 was purified and found to compact DNA faster and induce DNA-driven droplet formation at lower concentrations than the full length protein, suggesting autoregulation. We find this regulation is provided by the disordered C-terminus of HP1, as truncation of the C-terminal extension leads to increased compaction rates and lower critical concentrations of DNA-driven droplet formation. Further, the N-terminal extension exhibits positive regulation. Finally, we find that sequence differences in the disordered regions of the three human paralogs (α, β, γ) regulate DNA compaction, suggesting the differential association with transcription states in *vivo* could be due to intrinsic biochemical differences.

Regulatory and Non-Coding RNAs

P2111/B357

Novel Scarna Processing and the Formation of Regrnps.

M. Logan, D. McLaurin, M. Hebert; University of Mississippi Med Ctr, Jackson, MS.

Non-coding RNAs are important in cellular function. A specific class of non-coding RNA, small Cajal Body-specific RNA (scaRNA), is responsible for guiding modification of small nuclear RNA (snRNA) in the Cajal Body (CB). CBs are subnuclear domains that take part in the biogenesis of many different types of ribonucleoproteins (RNPs), including scaRNPs. Modification of snRNA by scaRNPs is necessary for proper snRNP activity and spliceosome function. Since 2004 only 3 scaRNAs (scaRNA 2, 9, and 17) out of the 30 known scaRNAs have been found to be processed into fragments that accumulate in the nucleolus. We hypothesize that these RNA fragments complex with proteins and form regulatory RNPs (regRNPs). We further hypothesize that the scaRNA fragment component of regRNPs base pairs with the small nucleolar RNA (snoRNA) component of small nucleolar RNPs (snoRNPs). Interaction of regRNPs with snoRNPs alters the rRNA modification activity of snoRNPs. Differences in the level of rRNA modification in ribosomes is the main contributor of ribosome heterogeneity. It is possible that rRNA modification can be altered in different disease states resulting in ribosomes with differential fidelity and regRNPs are important components in this process. We have found by Northern blotting that an additional 5 scaRNAs (scaRNA 5, 6, 7, 10, and 12) can be processed into smaller fragments. Unlike the fragments generated from scaRNA 2, 9, and 17, the fragments from scaRNA 5, 6, 7, 10, and 12 are all around 200 nts in length. We speculate that these fragments were not detected previously due to the positioning of the probes used to detect the scaRNAs. Interestingly, all 8 processed scaRNAs contain box C/D motifs and are greater than 200 nts in length compared to scaRNAs that we have found to not be processed such as scaRNA 13 (tandem H/ACA) and scaRNA 28 (194 nts). The exact mechanism for the internal processing of scaRNAs is unknown and is a current topic of investigation. Like the fragments derived from scaRNA 2, 9, and 17, we hypothesize that scaRNA 5, 6, 7, 10, and 12 processed fragments form regRNPs that can impact scaRNP modification of snRNA or affect the level of rRNA modification in the nucleolus through interactions with the snoRNA component of snoRNPs. Further work will include examining the impact of regRNPs on snoRNP and scaRNP activity and defining the components that control scaRNA processing.

P2112/B358

Novel Role of Trna-derived Fragments in Protein Arginylation.

I. Avcilar Kucukgoze[1], J. Wang[1], H. Gamper[2], Y. Hou[2], D. Dong[1], A. Kashina[1]; [1]University of Pennsylvania, Philadelphia, PA, [2]Thomas Jefferson University, Philadelphia, PA.

Posttranslational modifications are fundamental processes that expand the functional diversity of the proteome. Arginylation mediated by arginyltransferase ATE1 is a posttranslational modification of emerging importance that regulates mammalian embryogenesis, cell migration, and normal brain function, and has been recently proposed as a global biological regulator. However, the molecular mechanism of arginylation is elusive. Our preliminary results showed that while arginylation is very specific to Arg-tRNA^{Arg} its reactivity is similar towards all mouse tRNA^{Arg} isoacceptors, suggesting ATE1 interaction with tRNA^{Arg} is determined by its targeting toward the tRNA^{Arg} acceptor stem. In support, tRNA^{Arg} stem structures conjugated to Arg are capable of mediating in *vitro* arginylation. Since these stem structures bear resemblance to predicted tRNA-derived fragments (tRF) known to be generated in cells via the action of RNaseT2, we next tested the possible involvement of tRF^{Arg} in arginylation. Our data show that RNaseT2 is capable of cleaving the arginyl-tRNA^{Arg}, and this cleavage product is capable of mediating arginylation with similar efficiency to the intact Arg-tRNA^{Arg}. Moreover, our tRNA- and tRF-Seq results showed that the ratio of tRNA^{Arg} to tRNA^{Arg}-derived tRF is significantly higher in Ate1 knockout cells compared to wild type, suggesting that lack of arginylation inhibits tRF^{Arg} generation. We propose that tRF^{Arg} can potentially be dedicated solely to arginylation, which enables this modification to maintain its levels even in the high background from protein synthesis. Our study suggests that generation of physiologically important tRFs can potentially play a critical role in a switching mechanism between protein translation and arginylation in vivo, and points to the new role of tRFs in protein modifications.

P2113/B359

A Complex Containing Mettl5 and Trmt112 Installs*N*^{6}-methyladenosine on 18s Ribosomal Rna.

S. Nachtergaele, C. Sepich, C. He; University of Chicago, Chicago, IL.

Ribosomal RNAs (rRNAs) have long been known to carry modifications, including numerous sites of 2'*O*-methylation and pseudouridylation, as well as *N*^{6}-methyladenosine (m^{6}A), *N*$^{6,6-}$dimethyladenosine, and others. While the functions of many of these modifications are unclear, some are highly conserved and occur in regions of the ribosome critical for mRNA decoding. Both 28S rRNA and 18S rRNA carry m^{6}A, and while ZCCHC4 has been identified as the methyltransferase responsible for the 28S rRNA m^{6}A site, the methyltransferase responsible for the 18S rRNA m^{6}A site has remained a mystery. We have identified METTL5 as the enzyme responsible for installing m^{6}A at position 1832 of human 18S rRNA. The small multifunctional methyltransferase subunit TRMT112 enhances METTL5 stability and activity, as demonstrated both by protein expression and in vitro activity assays. This m^{6}A site is located on the 3' end of 18S rRNA, which may become surface exposed in the context of a translating ribosome and thus may play a regulatory role in translation. In addition to its role as an rRNA methyltransferase, sequencing of METTL5-bound RNAs suggests that it may have other RNA substrates. While recent work has focused heavily on m^{6}A modifications in mRNA and its roles in mRNA processing and translation, deorphanizing putative methyltransferase enzymes is revealing previously unappreciated regulatory roles for m^{6}A in noncoding RNAs as well.

P2114/B360

A Novel Role for the Rab-6.2 GTPase in Regulating Small RNAs and Ras Signaling in *C. Elegans*.

S. Gagnon[1,2], K. Gauthier[1,2], C. E. Rocheleau[1,2,3]; [1]Research Institute of the McGill University Health Center, Montréal, QC, CANADA, [2]Department of Cell Biology, McGill University, Montréal, QC, CANADA, [3]Department of Medicine, McGill University, Montréal, QC, CANADA.

Epidermal growth factor receptor (EGFR)/Ras/MAPK signaling promotes cell growth and can drive tumorigenesis when overactive. *Caenorhabditis elegans* vulva development can model this pathway as signaling from the EGFR homolog LET-23 induces the vulval cell fate in vulva precursor cells (VPCs). The RAB-6.2 GTPase has an established role in retrograde trafficking, and we initially hypothesized that it would play a similar role in the VPCs to regulate EGFR trafficking and Ras signaling. While EGFR trafficking is unaffected in *rab-6.2(-)* mutants, we found that a *rab-6.2* deletion suppresses the under-induced phenotypes of signaling-defective mutants, suggesting an antagonistic function of RAB-6.2 in Ras signaling. In addition, *rab-6.2(-)* mutants display decreased expression of transgenic arrays, hinting at a role for RAB-6.2 in transgene silencing, a process regulated by small RNAs. In fact, VPS-52, a RAB-6.2 effector, promotes activity of the *let-7* microRNA family, known to repress Ras in *C. elegans* and mammals. We hypothesize that RAB-6.2 supports the activity of the *let-7* miRNA family, and through this negatively regulates Ras signaling. In line with this, we found that deletion of the *let-7* family member *mir-48* suppresses the under-induced phenotype of signaling-defective mutants, suggesting that *mir-48* antagonizes Ras signaling, in line with a RAB-6.2/*let-7* family regulatory axis. Furthermore, *rab-6.2(-)* enhances the usually weak phenotypes of *daf-19*, *cel-1*, and *unc-73* RNAi, suggesting hypersensitivity to RNAi, which can result from increased availability of small RNA machinery in a background with reduced miRNA activity. Overall, our results pose RAB-6.2 as a regulator of small RNAs and Ras-mediated vulva induction, and suggest that miRNAs underlie this. These findings could expand our understanding of the functions of RAB GTPases and provide insight into the spatial regulation of small RNA biogenesis and function.

P2115/B361

Defining the Molecular Mechanism of a Long Noncoding RNA That Enhances Intestinal Epithelial Antiparasitic Defense.

N. W. Mathy, A. Gong, M. Li, X. Zhang, X. Chen; Creighton University School of Medicine, Omaha, NE.

The intestinal parasite *Cryptosporidium parvum* is a major cause of diarrheal disease, particularly in developing countries, and additionally remains a significant AIDS-related opportunistic pathogen. Currently, no fully effective treatment exists. Long noncoding RNAs (lncRNAs) can act as key modulators of diverse cellular processes through interactions with DNA, RNA, and proteins. LncRNAs have been identified that play a role in the innate inflammatory response, however, the functional mechanism has been elucidated only in a select few. The objective of this study was to identify lncRNAs induced upon *C. parvum* infection, determine whether these lncRNAs contribute to epithelial defense, and if so, elucidate the underlying molecular mechanism. To this end, a microarray was performed in the intestinal epithelial cell line, IEC4.1, infected with *C. parvum to* compare with uninfected controls. An alysis of the microarray identified 1,385 significantly differentially expressed lncRNA upon *C. parvum* infection. One lncRNA, referred to as lncRNA-25B here, was induced 2.3 fold upon *C. parvum* infection in *vitro*, 2.8 fold using a well-established cryptosporidiosis infection model in neonatal mice, and 2.1 fold using an *ex vivo* murine enteroid model. Interestingly, overexpression of lncRNA-25B significantly

reduced *C. parvum* infection burden compared to empty vector control, while knockdown of lncRNA-25B significantly increased the infection burden compared to a scrambled siRNA. RNAseq analysis revealed knockdown of lncRNA-25B resulted in the dysregulation of defense genes, many of which were target genes of NF-κB, suggesting a role for lncRNA-25B in the regulation of NF-κB signaling. RNA immunoprecipitation demonstrated a physical interaction between NF-κB p65 and lncRNA-25B, and that this interaction is increased 2.7 fold following *C. parvum* infection. In conclusion, these experiments have identified a *C. parvum* induced lncRNA which was found to impact the parasite infection burden through interactions with NF-κB p65 and subsequent modulation of defense genes. Future experiments will investigate how lncRNA-25B may facilitate NF-κB signaling to promote epithelial antimicrobial defense.

Localized Regulation of RNAi-lncRNA Interactions by Epithelial Adherens Junctions.

M. C. Bridges, J. Nair-Menon, J. Yoon, A. Kourtidis; Medical University of South Carolina, Charleston, SC.

The adherens junctions (AJs) are essential architectural elements of epithelial tissues. Compromised junctional integrity is a common precursor to colon cancer. Recently, we identified a novel mechanism whereby the AJs of non-transformed colon cells recruit the microprocessor and RISC, core elements of the RNAi machinery, as well as miRNAs, to suppress oncogenic mRNAs. Knockdown of the AJ component, PLEKHA7, disrupts this RNAi-mediated signaling program, leading to pro-tumorigenic cell transformation. Interestingly, PLEKHA7 RNA-CLIP and subsequent RNA-Seq analysis identified association with numerous long non-coding RNAs (lncRNAs). While a number of lncRNAs have been associated with tumorigenesis, the underlying mechanisms of their regulation during tumor progression are still unclear. As lncRNAs can interact with the RNAi machinery, we hypothesize that the AJs regulate lncRNAs via this localized RNAi mechanism. Examination of PLEKHA7-depleted cells by RNA-seq revealed differential expression of 49 junction-associated lncRNAs. From this set, the top upregulated lncRNA is MIR17HG, an oncogenic polycistronic host transcript of the miR-17-92 cluster. Junctional localization of MIR17HG was confirmed by RNA-FISH. Adherens junctions destabilization by E-cadherin knockdown also led to the upregulation of MIR17HG, demonstrating the role of junctional integrity in MIR17HG suppression. Data from AGO2 knockdown, antago-miR, and miRNA mimetic experiments show that PLEKHA7 suppresses the levels of the MIR17HG transcript through the junction-associated RISC and miRNAs. PLEKHA7 depletion also results in increased levels of a subset of MIR17HG hosted miRNAs, including miR-19a and miR-19b, both known cancer promoters. We observe extensive mis-localization or loss of PLEKHA7, co-existent with mis-localization of junctional RNAi machinery, in colon cancer tissues and cell lines. Ectopic expression of PLEKHA7 in aggressive colon cancer cells that lack endogenous PLEKHA7 expression, suppressed MIR17HG levels, as well as anchorage independent growth. We are currently examining the role of MIR17HG as a functional intermediate of PLEKHA7's loss on colon cell transformation. In summary, our data point towards a novel mechanism of lncRNA regulation that tethers epithelial architecture with cell behavior.

Non-coding Rna as Modulator of *V*irulenceIn Streptococcus Pneumoniae and Potential Role as Epidemiology Biomarker.

A. Martynova[1,2], O. Olexenko[2], E. Kocyurbij[2], E. Vorobiova[3], O. Chulakova[2], L. Semeikina[4], O. Pavlova[2]; [1]Far Eastern Federal University, Vladivostok, RUSSIAN FEDERATION, [2]Pacific State Medical University, Vladivostok, RUSSIAN FEDERATION, [3]Regional centre of immunoprophilaxis, Vladivostok, RUSSIAN FEDERATION, [4]Center of hygiene and epidemiology, Vladivostok, RUSSIAN FEDERATION.

Small noncoding RNAs (sRNAs) play important roles in gene regulation in both prokaryotes and eukaryotes. As the dynamics of functioning of CiaRH (the two-component regulatory system which is responsible for β-lactam resistance, maintenance of cell integrity, competence and virulence) of Streptococcus pneumoniae is poorly studied, the aim of our study was to define role of potential of smallRNA in CiaRH mechanism and overall in pathogenesis of pneumococcal infection. Matherials and methods: we isolated RNA from Streptococcus pneumonia TIGR4 strain, then transcriptional start points were determined by 5'-RACE as described previously using the same RNA adapter and gene-specific primers, in vitro CiaR binding, and in vivo analysis of CiaR-mediated regulation. Results: promoters were identified to be directly controlled by the response regulator CiaR. The genes that are transcribed from these promoters included ciaRH, loci that are predicted to be involved in the modification of teichoic acids (lic), in sugar metabolism (mal, man), stress response (htrA), chromosome segregation (parB), protease maturation (ppmA) and unknown functions. Ten of the regulon are activated by CiaR, and one was found to be controlled negatively. Five strongest promoters of the CiaR regulon drive expression of small RNAs. These small RNAs, designated csRNAs for cia-dependent small RNAs, are non-coding, between 60 and 71 nt in size, and show a high degree of similarity to each other. Conclusion: many of the identified sRNAs have important global and niche-specific roles in virulence what constitute the most comprehensive analysis of pneumococcal sRNAs and provide the first evidence of the extensive roles of sRNAs in pneumococcal pathogenesis.

Regulatory Role of Xist Rna during Mouse Hematopoiesis.

T. Yang, J. Ou, E. Yildirim; Duke University School of Medicine, Durham, NC.

Xist noncoding RNA is essential for initiation of X chromosome inactivation (XCI) which results in transcriptional silencing of one of the two X chromosomes in female cells equalizing X-linked gene expression between female and male mammals. Initiation of XCI relies on several epigenetic processes including recruitment of Polycomb Repressive Complex 2 and subsequent deposition of repressive histone modification, Histone 3 Lysine 27 trimethylation (H3K27me3). XCI is stably maintained with continuous Xist expression in epiblast cells and in adult tissues. Nevertheless, we have little understanding on the significance of Xist expression during the XCI maintenance and how this process influences lineage specification or cellular states during development. In mice, hematopoietic lineage develops around embryonic day 10.5 representing an ideal developmental stage to study affects of Xist during XCI maintenance. Notably, targeted deletion of Xist in hematopoietic stem cells (HSCs) results in female-specific hematopoietic defects including expansion of LSK+ stem cells, depletion of long-term HSCs and maturation and proliferation defects in mature cells. Xist mutant mice exhibit bone marrow deficiency coupled with 100% penetrant blood cancers in the form of mixed myeloproliferative and myelodysplastic syndrome (MPN/MDS). Here, we investigated the cellular basis for hematopoietic

defects that are observed in blood-specific Xist knockout mice and examined how Xist deficiency influenced the transcriptome and distribution of H3K27me3 during hematopoiesis. We found that Xist deletion leads to distorted proportion of LSK+ stem cell subpopulations, which presented altered cell cycle activity. Notably, Xist mutant LSK+ stem cells showed significant upregulation of X-linked genes and depletion of H3K27me3 on the Xi suggesting that Xist is necessary for maintenance of transcriptional silencing and PRC2 activity on the Xi. These results suggested that Xist-mediated maintenance of XCI is specifically critical for hemostasis and cell cycle regulation of LSK+ stem cell population. We propose that in LSK+ stem cells, Xist deficiency leads to differential expression of X-linked genes that trigger downstream signaling events resulting in altered cell cycle activity and subsequent bone marrow deficiency. Future studies addressing the functional relevance of individual X-linked genes that are differentially regulated in Xist mutant LSK+ stem cells will provide mechanistic insights causally linking XCI to female-specific blood malignancies.

Dicier: a Fine-tuned Bioinformatics Pipeline to Detect Micro-RNA Chimeric Reads.

A. Grioni, G. Georgakilas, P. Alexiou; Central European Institute of Technology, Brno, CZECH REPUBLIC.

MicroRNAs are short non-coding RNAs (~22nt) that associate with Argonaute proteins and mediate regulatory silencing of target RNAs. The identification of RNA targets is guided by complex sequence and structured interactions between miRNA loaded AGO protein and the target RNA. Binding of identified targets can lead to repression of translation or even deadenylation and RNA degradation. Each miRNA has potentially thousands of binding sites on the transcriptome, and each mRNA contains dozens of potential miRNA binding sites. The Ago-miRNA regulatory function plays central roles in several processes including tissue development and various diseases such as diabetes, cancer and heart disease among others. Cross-Linking Immuno-Precipitation (CLIP) is a molecular biology method that has been extensively used in recent years to locate transcriptomic regions where proteins bind mRNA. Next-Generation Sequencing (NGS) combined with CLIP allowed a massive identification of those binding sites (CLIP-Seq). A major drawback of CLIP-Seq techniques when dealing with AGO-miRNA binding is that it is impossible to know which miRNA sequence, out of hundreds expressed, is responsible for each binding. Recently, an improvement of CLIP-Seq techniques was achieved with crosslinking, ligation, and sequencing of hybrids assay, which increased the yield of hybrid sequences between mRNA and its miRNA binding sites (chimeric sequences). These sequences contain both parts of the miRNA and target site thus unambiguously defining the miRNA responsible for each hybrid binding. However, the identification of chimeric sequences from CLIP experiments lacks up-to-date bioinformatics strategies. We have developed ‘DICIER’, a pipeline for the identification of miRNA:binding site chimeric reads from CLIP-Seq experiments. ‘DICIER’ maps raw reads to the reference genome and retrieves ambiguous alignments as candidate chimeric sequences. Those chimeric sequences are broken into two subsequences to first match a database of miRNA sequences and then to find the corresponding miRNA-binding site at the genomic level. ‘DICIER’ output a table of miRNA and mRNA binding-site connections, which can be used as a reference for further studies. We benchmarked ‘DICIER’ on both CLASH and CLIP-Seq public datasets, and we identified N=250000 candidate miRNA-mRNA binding-sites connections. Despite the majority of those connections were originated from CLASH experiments, the increased sensitivity of ‘DICIER’ allowed the identification of chimeric reads from CLIP-seq in a proportion of up to 5% of total sample reads. **This research has been financially supported by the Ministry of Education, Youth and Sports of the Czech Republic under the project CEITEC 2020 (LQ1601).**

The Role of LncRNA-75 in TGF-β Signaling and Breast Cancer Progression.

J. Lee, F. Chen, W. Li, A. Vinogradsky, Y. Kang; Princeton University, Princeton, NJ.

The progression of breast cancer to the metastatic stage has severe clinical implications, adversely affecting survival compared to non-metastatic growths. Previous research has implicated long noncoding RNAs (lncRNAs)—defined as noncoding RNA transcripts greater than 200 nucleotides in length—in cancer progression, although the majority of lncRNAs have not been well characterized. We performed microarray analysis to identify lncRNAs exhibiting significant expression changes in cancerous cells, and which functioned in the context of the TGFβ signaling pathway. This pathway was selected because it plays critical, yet disparate roles in cancer progression by suppressing cell proliferation while simultaneously promoting the epithelial-mesenchymal transition (EMT), a hallmark of metastasis. From this screen, lncRNA75 was selected for further study as it was significantly upregulated. To better understand the role of lncRNA75, we performed a siRNA knockdown in *vitro in* MCF10A cells, and observed cell cycle arrest in lncRNA75 siRNA KD cells. This cell cycle arrest was increased upon addition of TGFβ ligand, suggesting an additive effect. To determine if lncRNA75 is directly induced by TGFβ, we cloned the lncRNA75 promoter into a luciferase reporter plasmid and measured luciferase activity following treatment with SB431542 (a TGFβ inhibitor) and TGFβ. We observed a significant increase in luciferase activity following TGFβ treatment, suggesting that the promoter contains one or more TGFβ binding elements, and isolated this binding region to a 2kb segment of the promoter. This also suggests that lncRNA75 is upregulated in response to TGFβ signaling, as shown by the dramatic increase in promoter activity. To determine a mechanism by which lncRNA75 might affect cancer progression, we performed RNA immunoprecipitation and determined that YBX1, an RNA binding protein with oncogenic properties, interacts with lncRNA75. In summary, we have identified a novel lncRNA, lncRNA75, that suppresses cell proliferation when depleted and is upregulated by TGFβ through interaction with the lncRNA75 promoter. We have also identified an interaction with the oncogenic protein YBX1. Future work, including in *vivo* experimentation and analysis of epithelial-mesenchymal transition markers, will allow us to further clarify the role of lncRNA75 in cancer progression and develop it as a potential therapeutic target.

Deciphering Circular Rna Axes in Early-onset Breast Cancer Using a Breast Epithelial Risk-progression 3d Culture Model.

N. Naser Al Deen[1], N. Atallah Lanman[2,3], S. Chittiboyina[4], S. Lelièvre[4,2], H. zu Dohna[1], M. AbouHaidar[5], R. Talhouk[1]; [1]The American University of Beirut- Biology Department, Faculty of Arts and Sciences, Beirut, LEBANON, [2]Purdue University - Center for Cancer Research, West Lafayette, IN, [3]Purdue University- Department of Comparative Pathobiology, West Lafayette, IN, [4]Purdue University- Department of Basic Medical Sciences, College of Veterinary Medicine, West Lafayette, IN, [5]University of Toronto - Department of Cell and Systems Biology, Toronto, ON, CANADA.

One of known circular RNAs (circRNAs) functions is to sponge microRNAs (miRNA). Studies reported dysregulated mRNA-circRNAs-miRNAs axes as biomarker signatures in breast cancer (BC). However, signatures in early-onset BC have not been characterized, while its incidence increased drastically worldwide. We used our 3D breast epithelial risk-progression HMT-3522 S1 (S1) culture model to

identify dysregulated post-transcriptional axes. S1 (non-neoplastic) cells form fully-polarized epithelium and closely mimic normal*in vivo* mammary epithelial morphology, while (pre-tumorigenic) Cx43KO-S1 (S1 silenced with shRNA for gap junction Cx43) lose epithelial polarity, multi-layer and mimic tumor-initiated in *vivo* mammary epithelial morphology. We performed circRNA microarray (Arraystar Human circRNA Array V2) and detected 75 significantly upregulated and 46 significantly downregulated circRNAs (Fold Change > 2) in 6 samples of Cx43KO-S1 versus S1 cells in 3D. We then selected 10 upregulated and 8 downregulated circRNAs for validation. Of these, hsa_circ_0007961 and hsa_circ_0081481 were most significantly upregulated while hsa_circ_0060055, hsa_circ_0005185, hsa_circ_0083442 and hsa_circ_0077755 were most significantly downregulated by RT-qPCR. We focused on "possible" sponging activity of validated circRNAs to their predicted (*in silico*) target miRNAs, and compared their dysregulation to our validated published miRNA datasets (Nassar et al., 2017). When circRNAs are upregulated, they downregulate function of their sponged miRNAs, hence preventing them from deregulating their target mRNAs. For upregulated **hsa_circ_0007961** (originating from **SPRED2** mRNA), its predicted **miR-99a-3p** was indeed downregulated in young Lebanese BC patient tissues and matched US patients, and predicted miR-653 possessed treatment potential in BC cells. For the second upregulated **hsa_circ_0081481** (originating from **FBXO24**mRNA), its predicted **miR-3960** was exclusively dysregulated in young Lebanese BC patients. For downregulated hsa_circ_0077755 (originating from **Cx43** mRNA), its predicted **miR-182** was commonly upregulated in young Lebanese and matched US patients and predicted **miR-203a-3p** was reported as promising prognostic biomarker in triple negative BC. Additionally, all predicted miRNAs targeted by all detected circRNAs were mostly enriched in pathways in cancer. Thus, our 3D risk-progression culture model might help delineate post-transcriptional axes to better understand early-onset BC initiation. We reveal three validated axes: i) SPRED2/hsa_circ_0007961/miR-99a-3p or miR-653-5p, ii) FBXO24/hsa_circ_0081481/miR-3960 and iii) Cx43/hsa_circ_0077755/miR-182 or miR-203, which could serve as potential biomarker signatures in early-onset BC.

P2122/B368

Determining Long Noncoding RNA Interactions in Stem Cells Using Automated Image an alysis and Single Molecule RNA-fluorescent in Situ Hybridization.

B. Kesler, G. Neuert; Vanderbilt University, Nashville, TN.

Human diseases are often caused by abnormal biological processes within specific cell types or individual cells within a tissue, yet most studies have focused on cell populations and ignored possible differences between individual cells. One reason is a lack of easily implemented and broadly applicable experimental and computational approaches for microscopy image acquisition and analysis. We propose an approach in which we optimize the experimental data acquisition prior to analysis to generate high quality images that are easier to analyze computationally. The images are then processed and analyzed in parallel to determine cellular and nuclear boundaries, which allows for single-cell quantification of features of interest. We applied our approach to investigate mammalian antisense long noncoding RNAs (lncRNAs) Tsix and Xist. These transcripts have been previously shown to have inhibitory interactions, though multiple possible mechanisms have been proposed. By utilizing two-color, single-molecule RNA-FISH and our image acquisition and analysis pipeline, we were able to quantify Tsix and Xist at single-cell and single-molecule resolution in more than 8000 cells. Our analysis revealed that there was no significant colocalization of Xist and Tsix molecules, which provides evidence against previously proposed mechanisms of inhibition involving the binding of the two transcripts. We also found that

anticorrelation between Xist and Tsix was only apparent when investigating the sites of transcription, which suggests mechanisms of inhibition in *cis* based on the act of transcription. This data demonstrates the importance of single-cell, allele-specific analysis when investigating noncoding RNA interactions. Our generalizable pipeline can be applied for further quantitative investigation of antisense transcription for other genes across diverse species, cell types, and imaging modalities.

Identification of Serum MicroRNA Signature Associated to Interstitial Lung Abnormalities in Asymptomatic Subjects > 60 Years Old.

B. Ortiz-Quintero[1], E. G. Ramírez-Salazar[2], S. Ramírez-Rodriguez[1], I. Buendía-Roldan[1], K. Martínez-Espinosa[1], M. Selman[1]; [1]Instituto Nacional de Enfermedades Respiratorias, Ismael Cosío Villegas, Mexico, MEXICO, [2]Instituto Nacional de Medicina Genómica, Mexico, MEXICO.

Background: Interstitial lung abnormalities (ILAs), diagnosed by high resolution computed tomography, are observed in around 9% of older asymptomatic subjects, mainly smokers. Some of them may progress to lung fibrosis. The mechanisms associated to ILAs development and progression are unknown. Identifying biomarkers of this subclinical disease status is relevant for early diagnosis and to predict outcome. Circulating microRNAs (miRNAs) have emerged as regulators of pathogenic mechanisms and potential non-invasive biomarkers for lung diseases. Levels of circulating miRNAs in ILA are still unknown. *Aim*: to identify the serum miRNAs expression pattern associated to ILA in a cohort of respiratory asymptomatic Mexican subjects older than 60 years. *Methods*: from a lung-aging study cohort in Mexico City (n=826), we identified patterns of ILA in 81 subjects that were compared with 112 asymptomatic individuals randomly selected from the same cohort (Ctrl). For the screening phase, serum miRNA profiles were analyzed in a cohort of 24 subjects with ILA and 24 controls, by using TaqMan MicroRNA Arrays containing probes for 366 miRNAs. Differentially expressed miRNAs in ILAs vs. Ctrl were identified ($p \leq 0.05$ and FoldChange > 2) and selected candidates were validated with RT-qPCR in the serum of 57 ILAs and 88 Ctrl (independent cohort). *Results*: We found seven serum miRNAs significantly up-regulated in ILAs compared to Ctrl: miR-502-3p ($p < 0.0001$), miR-193a-5p ($p < 0.0001$), miR-200c-3p ($p < 0.003$), miR-16-5p ($p < 0.003$), miR-34a-5p ($p < 0.005$), miR-126-3p ($p < 0.004$) and miR-21-5p ($p < 0.002$). Common pathways regulated by these miRNAs include TGF-beta, Wnt, mTOR, Insulin, MAPK signaling and cancer pathways. In addition, several studies have associated overexpression of miR-200c, miR-34a-3p and miR-21 to senescence. Receiver-operator characteristic (ROC) curve analysis indicated that miR-193a-5p (AUC: 0.750), miR-502-3p (AUC 0.710) and miR 21-5p (AUC 0.855) have acceptable diagnostic value. *Conclusions*: This study provides potential miRNAs candidates as non-invasive biomarkers and molecular targets to better understand the putative pathological mechanisms associated to ILA.

VAPB Proteomic Mapping by Rapamycin-dependent Targeting of APEX2 Identifies Binding Partners at the Inner Nuclear Membrane.

C. James[1], M. Müller[2], M. W. Goldberg[3], C. Lenz[4], H. Urlaub[5], R. H. Kehlenbach[1]; [1]Department of Molecular Biology, Faculty of Medicine, GZMB, Georg-August-University, Goettingen, GERMANY, [2]Department of Molecular Biology, Faculty of Medicine, GZMB, Georg-August-University, Goettingen, GERMANY, [3]School of Biological and Biomedical Sciences, Durham University, Durham, UNITED KINGDOM, [4]Bioanalytics Mass Spectrometry Group, Max Plank Institute for Biophysical Chemistry, Goettingen, GERMANY, [5]Bioanalytical Mass Spectrometry Group, Max Plank Institute for Biophysical Chemistry, Goettingen, GERMANY.

VAPB (vesicle-associated membrane protein-associated protein B) is an integral endoplasmic reticulum (ER) protein that is present at several contact sites of the ER. We now show by immunoelectron microscopy and a rapamycin-based dimerization assay that VAPB also localizes to the inner nuclear membrane (INM). The engineered ascorbate peroxidase (APEX2) has been effectively employed in mammalian cells to identify protein-protein interactions.Using a modified APEX2-approach with rapamycin-dependent targeting of the peroxidase to a protein of interest, we identified proteins that are in close proximity to VAPB. In combination with stable isotope labeling with amino acids in cell culture (SILAC), followed by co-immunoprecipitation assays, we confirmed many well-known interaction partners of VAPB at the ER and also identify proximity partners at the INM. Hence, rapamycin-APEX2-mediated proximity labeling of VAPB neighboring proteins provide insights into the VAPB interactome at the ER and the INM.

P2125/B372

Barrier to Autointegration Factor: a Well-regulated Mechanism to Repair Nuclear Ruptures.

C. T. Halfmann[1], R. M. Sears[1,2], A. Katiyar[3], B. W. Busselman[1,2], L. K. Aman[1], Q. Zhang[4], T. P. Lele[3,5,6], K. J. Roux[1,7]; [1]Enabling Technologies Group, Sanford Research, Sioux Falls, SD, [2]Basic Biomedical Sciences, Sanford School of Medicine, University of South Dakota, Vermillion, SD, [3]Department of Chemical Engineering, University of Florida, Gainesville, FL, [4]Department of Mechanical and Aerospace Engineering, University of Florida, Gainesville, FL, [5]J. Crayton Pruitt Family Department of Biomedical Engineering, University of Florida, Gainesville, FL, [6]Institute for Cell and Tissue Science and Engineering, University of Florida, Gainesville, FL, [7]Department of Pediatrics, Sanford School of Medicine, University of South Dakota, Sioux Falls, SD.

The nuclear envelope (NE) enables a well-regulated and critical barrier between the cytosol and nucleus. Transient loss of this cytoplasmic/nucleoplasmic barrier via mechanical forces exerted on the NE and/or intrinsic loss of structural integrity compromises genomic integrity. Remarkably, cells are capable of rapidly repairing ruptures of the NE. Barrier-to-autointegration factor (BAF), a DNA-binding protein involved in post-mitotic NE reformation and cytosolic viral regulation, rapidly and substantially binds to nuclear DNA exposed to the cytosol upon rupture. This accumulation of BAF subsequently recruits components involved in NE reconstitution, including LEM-domain proteins, membranes, and the ESCRT-III membrane repair complex. Loss of BAF prevents recruitment of these components, resulting in a failure to restore the barrier function of the NE. Similarly, simultaneous loss of multiple transmembrane

LEM-domain proteins, but not the ESCRT-III complex, also prevent repair of NE ruptures. BAF's DNA-binding is regulated via phosphorylation by vaccinia-related kinases (VRKs). Loss of VRK1, but not VRK2, leads to prolonged hyperaccumulation of BAF at nuclear ruptures, impacting the repair process and suggesting that BAF may also function to compact DNA at rupture sites to mitigate the loss of subcellular compartmentalization, effectively acting as a 'clotting factor'. Collectively, these studies reveal a well-regulated response to nuclear ruptures that enables cell viability following this seemingly catastrophic cellular injury.

P2126/B373

Nuclear Rupture as a Potential Shared Mechanism of Nuclear Envelope-associated Progeria.

R. Sears, K. Roux; Sanford Research, Sioux Falls, SD.

Specific mutations in any one of the genes encoding A-type lamins, barrier-to-autointegration factor (BAF), and LEMD2 have been reported to cause progeria, a premature aging disease with variable phenotypes. These three nuclear envelope proteins are all capable of physically interacting with each other. It is therefore reasonable to hypothesize that there is a shared mechanism of disease underlying these nuclear envelope-associated progerias. We have recently demonstrated that BAF localizes to sites where the nuclear envelope is ruptured and is required to recruit A-type lamins and transmembrane LEM-domain proteins, including LEMD2, to repair the nuclear envelope. Nuclear ruptures result from exposure to mechanical forces on the nucleus and/or a weakened nucleoskeleton that compromises the integrity of the nuclear envelope and leads to the loss of nucleocytoplasmic compartmentalization. Under normal conditions, nuclear ruptures are rapidly repaired to stop the unrestricted exchange of cellular constituents between the cytosol and nucleus that is reported to, among other likely consequences, lead to DNA damage and a block in the cell cycle. Here we show that, compared to wild-type BAF, progeric BAF exhibits a reduced residency at sites of nuclear rupture suggestive of an impaired ability to bind to DNA. Compared to wild-type lamin-A, progeric lamin a exhibits a substantially delayed and reduced accumulation at sites of nuclear rupture. Collectively, these results begin to support the hypothesis that progeria-associated mutations in A-type lamins, BAF, and LEMD2 lead to an enhanced propensity for nuclear rupture and/or compromised nuclear rupture repair, contributing to progeria phenotypes including increased DNA damage and cellular senescence.

P2127/B374

Lipid Droplets Deform Nucleus and Cause Mislocalization of Dna Repair Factor.

I. L. Ivanovska, M. Tobin, C. Pfeifer, D. E. Discher; University of Pennsylvania, Philadelphia, PA.

We have shown previously that high nuclear curvature imposed by pores or probes or else by small micronuclei correlates with nuclear rupture and subsequent mislocalization of multiple DNA repair factor and DNA damage. This is especially true for high rates of deformation. Lipid droplets formation in cells undergoing adipogenesis also indent nuclear lamina but if bending of the lamin filaments can cause nuclear envelope rupture, similar to one caused by a stiff probe is not clear. Here we investigate oleic acid induced lipid droplets in U2OS cells and their impact on the nucleus. Abundance of lipid droplets increased DNA repair factors mislocalization in both 2D culture and pore migration assay. Viscoelastic behavior of fat is a key to understand how lipid droplets interact physically with nucleus so here we used micropipette aspiration experiments on tissue and cellular level which revealed that fat tissue is highly

elastic, it can sustain high stresses but eventually ruptures with oil content leaking out of the cell membrane.

P2128/B375

Factors Promoting Nuclear Envelope Assembly in the Absence of Cmp7.

I. Lee[1], E. Stokasimov[1], N. Dempsy[1], J. Varberg[2], E. Jacob[1], S. L. Jaspersen[1], D. Pellman[1]; [1]Dana-Farber Cancer Institute, Boston, MA, [2]Stowers Institute for Medical Research, Kansas City, KS.

In diverse organisms, the nuclear envelope (NE) undergoes dynamic restructuring that requires membrane fusion mechanisms to maintain NE integrity. Defective NE integrity is linked to aging, genome instability and cancer. Recently, the ESCRT system was found to promote membrane fusion during NE assembly and repair. ESCRT is activated at the NE when the ESCRT adapter CHMP7/Cmp7 interacts with the inner nuclear membrane protein, LEMD2/Lem2. However, in the systems studied to date, the loss of Cmp7 only partially compromises NE integrity, suggesting unknown parallel mechanisms. To identify such mechanisms, we studied postmitotic NE assembly in *S. japonicus,* an unusual fission yeast that undergoes partial mitotic NE disassembly. *S. japonicus* cells lacking Cmp7 have compromised NE integrity, but are viable in normal growth conditions. A genetic screen was performed to identify mutations that enhance the sealing of NE membranes in the absence of Cmp7. We identified gain-of-function mutations in another ESCRT adapter, Alx1, which overlaps with Cmp7 at the NE. Unexpectedly, loss-of-function mutations in Lem2 and a mutation in its interacting partner Nur1 also enhanced NE integrity of *cmp7Δ* cells. This may be explained by the fact that in the absence of Cmp7, Lem2 formed aggregates that may interfere with ESCRT-independent NE sealing. Additionally, the screen results suggest an important role for lipid composition in NE sealing. Based on these findings, we discuss models for ESCRT-independent NE sealing.

P2129/B376

Phase Separation by Membrane Protein Lem2 Controls Escrt-mediated Nuclear Envelope Reformation.

A. Von Appen[1], D. LaJoie[2], I. Johnson[1], M. Trnka[3], A. Burlingame[3], K. Ullman[2], A. Frost[1]; [1]UCSF - Department of Biochemistry and Biophysics, San Francisco, CA, [2]Huntsman Cancer Institute, University of Utah, Salt Lake City, UT, [3]UCSF - Department of Pharmaceutical Chemistry, San Francisco, CA.

The open mitosis strategy employed by many eukaryotes requires dramatic membrane remodeling. For proper chromosome segregation, the nuclear envelope dissociates from chromatin and retracts into the contiguous endoplasmic reticulum (ER). At mitotic exit, ER-derived membranes return to chromatin and spread to reform the nuclear envelope within approximately 12 minutes. In a series of dynamic events, the cell must coordinate spindle microtubule disassembly with nuclear envelope sealing. Here, we combine in vivo and in vitro approaches, including light and electron microscopy, to study the molecular principles of nuclear envelope reformation. Our data show how the two-pass inner nuclear membrane protein, LEM2, directs microtubule remodeling and nuclear envelope sealing via the Endosomal Sorting Complexes Required for Transport (ESCRT) pathway. LEM2's amino-terminal proline-arginine-rich low-complexity domain undergoes liquid-liquid phase separation to coat spindle microtubules. LEM2s activity is further spatially restricted to the chromatin disks by a direct binding between the LEM motif and the chromatin-associated barrier-to-autointegration factor (BAF). Once condensed, LEM2 tethers the reforming nuclear envelope the to the spindle and recruits the ESCRT-II/ESCRT-III hybrid protein CHMP7 via LEM2's carboxyterminal winged-helix domain. Together LEM2 and CHMP7 copolymerize

around microtubule bundles to form a molecular “O-ring” that promotes nuclear compartmentalization and initiates downstream ESCRT factor recruitment. These results demonstrate how multivalent interactions of a transmembrane protein - including those that mediate phase separation and coordinate localized ESCRT polymerization - enable mitotic spindle disassembly and promote membrane fusion. Consequently, defects in this pathway compromise spindle disassembly, nuclear integrity, and genome stability.

P2130/B377

The Coordinated Assembly of a Functional Nuclear Envelope After Mitosis Requires the Transmembrane Nucleoporin NPP-22/NDC-1.

M. Mauro, R. Nguyen, S. Bahmanyar; Yale University, New Haven, CT.

During nuclear reformation after open mitosis, nuclear pore complexes (NPCs) assemble from smaller subcomplexes onto chromatin to generate a functional nuclear envelope (NE). To initiate NPC assembly, the recruitment of the essential scaffold nucleoporins (Nup160/107 complex) by the DNA-binding nucleoporin MEL-28/ELYS is followed by recruitment of transmembrane nucleoporins and their associated membranes. In *C. elegans* embryos, MEL-28/ELYS recruits the protein phosphatase PP1c to the nuclear periphery to provide the signal that initiates nuclear assembly and growth. However, how NPC assembly coordinates with membrane recruitment during nuclear formation remains unclear. Here, we use *C. elegans* embryos to demonstrate that loss of the transmembrane nucleoporin *ndc-1*delays, but does not inhibit, the formation of a functional NE after mitosis. While the initial recruitment of ER-derived membranes, MEL-28/ELYS and scaffold nucleoporins to the reforming NE occurs normally in *ndc-1* RNAi-depleted embryos, the onset of nuclear transport is significantly delayed. Furthermore, the speed of nuclear expansion is slower in *ndc-1* RNAi-depleted embryos leading to reduced nuclear size. These embryos contain lowerlevels of MEL28/ELYS and the essential scaffold nucleoporins (Nup160, Nup133, and Nup85). These data suggest that NDC-1 controls the timely maturation of nascent NPCs to direct NE formation and growth by stabilizing scaffold nucleoporins. Consistent with this idea, reduced nuclear size, but not the delayed onset of nuclear transport, in *ndc-1* RNAi-depleted embryos can be partially rescued by deletion of *cnep-1 to* increase nuclear membrane incorporation after mitosis. Thus, NDC-1 is required for the formation of transport competent NPCs after mitosis, likely through its role in stabilizing scaffold nucleoporins rather than a role in membrane recruitment to initiate NPC assembly. We suggest that NDC-1 controls the concentration of scaffold nucleoporins, which allows for the coordinated maturation of NPCs to drive assembly and growth of a functional NE during nuclear reformation.

Can Nuclear Envelope Transmembrane Proteins Tether Pluripotency.

A. Sivakumar, J. I. de las Heras, E. C. Schirmer; University of Edinburgh, Edinburgh, UNITED KINGDOM.

A vast majority of Nuclear Envelope Transmembrane Proteins (NETs) are tissue-specific. These tissue-specific NETs maintain tissue-specific 3D genome organization. Furthermore, interfering with the expression of NETs impairs differentiation. TMEM 120A and B, enriched in adipose tissue, are important for adipogenesis while NET39, TMEM38A and WFS1, enriched in muscles, are important for myotube formation. Although a functional basis for relocation of genes during lineage specification has been reported, the components of the nuclear envelope that might have a role in orchestrating this are

unclear. We hypothesize that as cells progress from their pluripotent state through differentiation into defined lineages, they acquire different NET signatures which might bring about the coordinated changes in genome organization. During exit from pluripotency of mouse embryonic stem cells, we found that certain genetic loci containing pluripotency genes like Triml1, Zfp42 and Nanog show rapid movement from the nuclear interior towards the periphery, suggesting that reorganisation of the genome is among the very first of events occurring during lineage specification. Ectopic expression of some tissue-specific NETs in these cells leads to a reduction in pluripotency as measured by morphological differences and loss in alkaline phosphatase activity. Finally, the loss of pluripotency is coupled with genome organization changes observed during exit from pluripotency. We are currently investigating which NETs and/or their post translational modifications might drive the reorganization of the genome during exit from pluripotency and whether ectopic expression of tissue-specific NETs can aid in lineage commitment.

P2132/B379

Understanding the Mechanism Behind Membrane Fusion during Pronuclear Meeting in *C. Elegans* Embryo.

R. Maheshwari, M. Rahman, O. Cohen-Fix; NIH/NIDDK, Bethesda, MD.

In a just fertilized *C. elegans* embryo, to restore ploidy, the nuclear envelope (NE) of the haploid genomes (a.k.a pronuclei) must disassemble to allow mixing of the two parental genomes. Interestingly, while proteins associated with the NE disassemble, the pronuclear membranes persist after pronuclear meeting. It is still unclear how these membranes are breached to allow parental chromosome mixing. To understand this, we have used Focused-Ion Beam Scanning Electron Microscopy (FIB-SEM) of nuclear membranes of early 1-cell embryos. The FIB-SEM data revealed the presence of unique membrane junctions, where the two pronuclei fuse. These membrane junctions are not observed at the pronuclear interface in *plk-1*^{ts} embryos, which are defective in parental chromosomal mixing. To address the mechanism behind junction formation, we explored the role of the ER fusion machinery, and in particular the role of ATLN-1 (human atlastin1 homolog). Dilution RNAi of atlastin showed, at low penetrance, paired nuclei formation, an indication of defective pronuclear fusion. To better control the extent of ATLN-1 downregulation, I used the auxin-induced degradation system for the temporal degradation of *atln-1* in early embryos. Auxin-mediated degradation of a degron-tagged *atln-1* led to paired nuclei formation in nearly 100% of the observed 1-cell embryos, suggesting its role in pronuclear membrane fusion. Further, GFP tagged endogenous ATLN-1 showed that it localizes to the ER, NE, and centrosomes in *C. elegans* embryos. We found that ATLN-1 is also present at the interface of the two pronuclear membranes. Together, these results suggest that atlastin-mediated membrane fusion is required for pronuclear membrane permeabilization, allowing for parental chromosome mixing. Surprisingly, ATLN-1 is only required for LMN-1 (*C. elegans* lamin) disassembly at the metaphase, not for NPP-1 (a nuclear pore complex protein). My future goal is to do FIB-SEM to examine the membranes at the interface of the pronuclear membranes in the *atln-1* depleted early stage embryos.

P2133/B380

Maternal and Paternal Genome Mixing in the *C. Elegans* Zygote Involves Stepwise Pronuclear Fusion and Fenestration of Pronuclear Membranes.

M. M. Rahman[1], A. Harned[2], I. Chang[2], R. Maheshwari[1], K. Narayan[2], O. Cohen-Fix[1]; [1]National Institute of Diabetes and Digestive and Kidney Diseases, NIH, Bethesda, MD, [2]Frederick National Laboratory for Cancer Research, NCI, NIH, Frederick, MD.

In a fertilized embryo, maternal and paternal genome that are initially present in two separate pronuclei must mix in a process that requires nuclear envelope breakdown (NEBD). NEBD in the zygote is poorly understood, especially in mammals where visualizing the process is challenging. It is assumed that once the parental pronuclei are in close apposition NEBD is initiated. In *C. elegans,* once the maternal and paternal pronuclei meet, a gap is formed in the juxtaposed membranes, close to the metaphase-aligned chromosomes. This membrane gap is critical for parental genome mixing. Recently, we reported that in *C. elegans,* partial depletion of the conserved Polo-like kinase, PLK-1, leads to the formation of paired-nuclei with separated parental genomes due to a failure in gap formation in the NEs between the two pronuclei. The structure of NE membrane gap and the signals that promote its formation are unknown. To understand this process we used two techniques, live-cell fluorescence microscopy and electron microscopy, specifically Focused Ion Beam - Scanning Electron Microscopy (FIB-SEM). Live-cell fluorescence images revealed that a stable interface is formed between two juxtaposed pronuclear membranes, and that at metaphase the interface retains both inner and outer nuclear membrane proteins. Zygotes were collected at different stages of mitosis and subjected to high-pressure freezing prior to FIB-SEM. Interface membranes reconstructed from SEM images taken at 9 nm resolution revealed that the interface is composed of only two membranes that are flanked by a novel type of membrane junction, a 3-way sheet junction, present between the opposing pronuclei at metaphase. Three-way sheet junctions reduced the number of pronuclear membranes in the interface from four parental membranes to two. An alysis of multiple prometaphase- and metaphase-stage embryos by FIB-SEM uncovered a second type of membrane junction between the outer nuclear membranes of the two opposing pronuclei. In contrast, *plk-1* mutant zygotes were devoid of junctions, indicating that junction formation is a prerequisite for mixing of parental genomes. We hypothesized that proteins involved in endoplasmic reticulum (ER) remodeling may be involved in junction formation. Our preliminary data suggest that Atlastin, a protein known for its role in ER-ER homotypic fusion, is required for the process.

P2134/B381

Autonomous Asymmetric Nuclear Division Generates Daughter Nuclei with Distinct Identities during Neuroblast Divisions in the Fly.

C. Roubinet, I. White, B. Baum; MRC-LMCB, UCL, London, UNITED KINGDOM.

Asymmetric cell division generates cellular diversity through unequal partitioning of cell fate determinants. Fly neural stem cells rely on asymmetric cell division to generate a self-renewing stem cell and a smaller differentiating sibling cell. Although the role of the cortical polarity on cell fate has been well documented, the contribution of the nuclear division in this context remains to be explored. Here, using live cell imaging of asymmetric divisions in intact and dissociated brains, together with electron microscopy, mutant analysis and drug treatments, I show that the nucleus compartment retains its identity during division. Second, I show that nuclear division does not require cell division, but is rendered asymmetric by the asymmetric division furrow. Third, I find that the generation of two

daughter nuclei with a distinct size and composition occurs in two-steps - establishment and growth. Finally, I show how the coupling of nuclear division with the release of cortical cell fate determinants help to establish two different nuclear identities that contribute to generation of distinct cell fates during a neuroblast division.

P2135/B382

The Escrt-iii Complex Mediates the Reorganization of the Meiotic Nuclear Envelope in Budding Yeast.

B. Koch, H. Yu; Florida State University, Tallahassee, FL.

The nuclear envelope separates the nucleoplasm from the cytoplasm in eukaryotic cells. Embedded into the nuclear envelope, the nuclear pore complexes (NPCs) are large multi-subunit structures that form an aqueous channel, allowing for passage between the nucleus and cytoplasm. Unlike higher eukaryotes, budding yeast undergoes closed mitosis and meiosis with little to no detectable nuclear envelope breakdown. In higher eukaryotes, nuclear envelope breakdown serves as part of a mechanism to rid the nucleus of unwanted material or senescence factors, such as old or damaged NPCs. In mitosis, budding yeast retains these potentially harmful factors in the mother cell through asymmetric cell division, with the daughter cell gaining a full replicative lifespan. Cleavage of the membrane at the bud neck by the different Endosomal Sorting Complexes Required for Transport (ESCRT) complexes is required for this asymmetric division and results in the mother cell having a finite replicative lifespan. However in budding yeast meiosis, the age of the mother cell is irrelevant, four haploid gametes are produced without any of the mother's unwanted material or senescence factors. Meiosis therefore serves as a reprogramming and/or rejuvenation process. Recent studies have found this rejuvenation depends on the meiotic reorganization of the nuclear envelope, which clusters the senescence factors, including oxidatively damaged protein aggregates, rDNA circles and NPCs, during meiosis II into a centralized cellular compartment, termed the fifth compartment, distinguished from the four gametes formed after meiosis. However, the mechanism for this nuclear reorganization has yet to be determined.Here we show that the clustering of NPC components in anaphase II occurs as an active sequestration process mediated by Chm7 and Heh1, components associated with the ESCRT-III complex. Chm7-Heh1 has been shown to function in mitotic yeast cells to seal the nuclear envelope upon defective NPC formation, and also to serve as a constriction factor at the bud neck of dividing cells. In meiosis, these ESCRT-III components are required for the constriction of old NPCs to the fifth compartment. We propose that the sequestration of senescence factors, such as old NPCs, is mediated by the ESCRT-III complex, enabling these unwanted or damaged components to be excluded from rejuvenated gametes. Our work may provide a mechanistic understanding of nuclear envelope reorganization and cell rejuvenation.

Nucleocytoplasmic Transport

Composition and Properties of XPO1-dependent Nuclear Export Signals.

O. Rymarenko, D. Görlich; Max Planck Insitute for Biophysical Chemistry, Göttingen, GERMANY.

Exportin 1 (XPO1, also known as Crm1) mediates one of the most versatile protein transport pathways of the eukaryotic cells. It transports hundreds of different proteins and protein complexes from the nucleus to the cytoplasm. XPO1 is able to recognize such a vast and diverse set of cargos thanks to the ability to bind a peptide motif called a nuclear export signal (NES). Despite more than two decades of

extensive research, the features that contribute to a NES's ability to recruit XPO1 remain poorly understood. To gain comprehensive understanding of the composition rules for the NESs, we employ phage display combined with high-throughput DNA sequencing. Such approach allows us to cover the entire sequence space for the peptides of appropriate length and to analyze contributions of any residue at each position of the motif. We discovered numerous features that affect, positively or negatively, the ability of a peptide to bind to XPO1. We confirm the discovered contributions of various residues at specific positions in *vivo*. Armed with the dataset covering the entire sequence space for a NES motif, we rationally design peptides to have the highest possible propensity for binding XPO1. Indeed, we confirm that the interactions of the designed peptides with XPO1 cannot be disrupted even using a competitive suicide inhibitor of XPO1. We characterize the interaction of one of these peptides with XPO1 using X-ray crystallography. We see numerous interactions from residues at different positions contributing to an unprecedentedly strong binding to XPO1. We show that the designed peptides act as XPO1 inhibitors themselves in *vivo*. Finally, we propose an inclusive way of sequence-based NESs prediction. By assessing a clearly defined contribution of each residue at each position of a potential NES, we can provide an accurate prediction of XPO1 binding propensity for any sequence of residues. Ability to predict potential NES for any protein based on its sequence is useful in studying new proteins and characterizing their transport and logistics. XPO1 is one of the major drug discovery targets for treatment of different cancer types and is involved in various viral infections including HIV-1. Thus, we expect that our data might prove useful in medical research.

P2137/B384

Nuclear Pore Complex Scaffold Experiences Conformational Changes in *Vivo in* Response to Transport State.

J. Pulupa, H. Prior, S. M. Simon; Rockefeller University, New York, NY.

Recent breakthroughs in structural studies have provided a wealth of information about the architecture of the nuclear pore complex (NPC). However, measuring the dynamics of nucleoporins (Nups) in *vivo* remains highly challenging. By using polarized-total internal reflection fluorescence microscopy (pol-TIRFM), we have measured the orientations and dynamics of Nup-mEGFP fusion proteins in *vivo.* Our measurements have shown that components of the NPC scaffold assume distinct conformational states under various transport conditions. We developed imaging tools that allow us to visualize protein dynamics within diffraction-limited puncta in *vivo. By* rapidly switching the polarization of our excitation light between two orthogonal polarizations, we can measure the orientation of mEGFP. We conjugated mEGFP to several Nups via rigid alpha helical linkers and used the orientation of the mEGFP to report on the orientation of the Nups of interest. Using this technique, we measured the orientations of domains within NUP133, NUP54, NUP93, and NUP58. After confirming that the mEGFP reports on the orientation of our Nup of interest, we then used these conformational sensors to measure the orientations and dynamics of Nups within different parts of the NPC. Using CRISPR/Cas9, we replaced all endogenous copies of the Nups with our mEGFP-Nup fusion proteins and were able to confirm that the NPCs were functional in *vivo*. Under conditions of cargo depletion, the NPC assumed one distinct conformation. Under conditions of excess cargo, the NPC was driven into an alternate state. We modulated the transport state in a number of ways: starving cells, using drugs to block export, using dominant negative proteins, and finally by introducing nuclear transport factors directly to the nuclear periphery by permeabilizing the plasma membrane while leaving the nucleus intact. Under each of these perturbations, we found that most regions of the NPC do not shift their orientation in response to cargo,

but specific domains of the inner ring complex are reorganized with altered in *vivo* transport state. Our results suggest that the NPC experiences a large-scale conformational change in response to cargo translocation. In addition, our results demonstrate how fluorescence polarization microscopy is a powerful tool for monitoring the organization and dynamics of proteins in *vivo and* in *vitro*.

Uncovering the Role of O-GlcNAc Modification in Nuclear Pore Complexes by Live-cell Measurement of Nuclear Transport Rates.

T. Yoo, Z. G. Levine, S. Walker, T. J. Mitchison; Harvard Medical School, Boston, MA.

The nuclear pore complexes selectively facilitate the transport of proteins with nuclear localization or export signals (NLS/NES), while limiting the traffic of other macromolecules. The nuclear pore components are remarkably rich in Ser/Thr-linked monosaccharides, O-linked β-N-acetyl glucosamine (O-GlcNAc), particularly within the intrinsically disordered FG-repeat regions. The O-GlcNAc-rich FG-repeats are known to be indispensable for the signal-dependent nuclear transport. Previous study showed that O-GlcNAc modification modifies the permeability and structure of in vitro-formed hydrogel derived from FG domains. However, the role of O-GlcNAc of nuclear pore complexes in nuclear transport is still unclear. Here we develop an imaging-based technique that quantitatively measures the rates of signal-dependent nuclear import and export in live cells. Using the technique, we found that the nuclear transport rate in cells is significantly altered after perturbations of O-GlcNAc transferase (OGT) or O-GlcNAcase (OGA), a single pair of enzymes that controls the O-GlcNAc modification. The change is bidirectional in a manner correlated with the level of O-GlcNAc modifications in the nuclear pore complexes. Interestingly, the nuclear import rate increases more dramatically with elevated O-GlcNAc level than the nuclear export rate does. We are further investigating the mechanism underlying the differential changes in nuclear import and export rates upon O-GlcNAc perturbations and its implications in the control of compartmentalization of nucleocytoplasmic shuttling proteins, nutrition sensing, and cellular stress response.

P2139/B386

The Mechanosensitivity of Nucleocytoplasmic Transport Is Governed by Increased Active Transport Both into and Out of the Nucleus.

I. An dreu[1], I. Granero-Moya[1], M. Molina[1], V. González-Tarragó[1], J. Kechagia[1], P. Roca-Cusachs[1,2]; [1]IBEC, Barcelona, SPAIN, [2]UB and Ciber, Barcelona, SPAIN.

Mechanical force drives fundamental processes in health and disease, and regulate transcription. Increasing evidence shows that the cell nucleus responds to force, for instance by increasing nuclear import of the transcriptional regulator YAP [1]. However, whether nucleocytoplasmic transport is a mechanosensitive process, the mechanism involved, its applicability to different cargoes, and its molecular specificity remain unknown. Here we show that nuclear force promotes active versus passive transport in both directions, making nucleocytoplasmic transport mechanosensitive. We carried out static and dynamic measurements on proteins of different molecular weights (thereby regulating diffusivity through nuclear pores) containing nuclear import signals (NLS) or nuclear export signals (NES) of different strengths. We observe that both active import and export increase with nuclear force, either applied directly (via AFM) or indirectly (by plating cells on substrates of different rigidities). Further, we show that the force-dependent steady state localization of the protein depends on a balance between

active transport and passive diffusion. Finally, we show the applicability of this mechanism to different transcriptional regulators that enter or exit the nucleus with force. Our study shows a general mechanism by which cargoes specifically respond to nuclear force by entering or exiting the nucleus, which the cell uses as a control of mechanosensitive transcription. [1] Elosegui-Artola et al., Force Triggers YAP Nuclear Entry by Regulating Transport across Nuclear Pores, Cell (2017), https://doi.org/10.1016/j.cell.2017.10.008

P2140/B387

Nuclear Size Is Determined by Its Content, Not Its Envelope.

C. B. Moffatt, M. Arya, O. Cohen-Fix; National Institutes of Health, Bethesda, MD.

Nuclear size regulation is a fundamental biological process conserved from single-celled eukaryotic organisms to human cells. Within a given cell type, nuclear size scales with cell size to produce a fairly constant ratio. The dysregulation of the nucleus-to-cell volume ratio (N:C volume ratio), is a hallmark for many cancerous cells. However, the exact mechanisms regulating nuclear size are unknown. Previous work in Xenopus and fission yeast suggests nucleocytoplasmic transport as an important process regulating nuclear size: increasing nuclear protein import and inhibiting its export enlarges nuclear size. However, this did not seem to be the case in budding yeast. Nonetheless, given a previous finding from our lab that the nuclear envelope does not determine nuclear size, we revisited the possibility that the amount of protein in the nucleus regulates its size. To test this, we inhibited the well-conserved general nuclear export protein Crm1 using Leptomycin B (LMB). Importantly, inhibition of export led to an increase in nuclear volume and a concomitant increase in the N:C volume ratio. These data suggest that nuclear size is dependent on its content. We next asked if this increase in nuclear volume relies on continued nuclear membrane synthesis. We inhibited fatty acid synthesis (a phospholipid precursor), which is known to block nuclear growth in other expansion phenotypes. Blocking membrane synthesis had no significant effect on the increase in nuclear growth seen with LMB treatment, suggesting that in the presence of LMB, nuclear expansion is independent of lipid availability. These data raise several questions: Is nuclear size determined by the total amount of nuclear protein or by the accumulation of specific proteins? Do cells normally control nuclear size by regulating the amount of protein in the nucleus, or is it a passive consequence of the amount of nuclear protein synthesized by the cell? How do the cells accommodate an expanding nucleus without available lipids? Our efforts toward answering these questions will be discussed.

P2141/B388

Formin-mediated Regulation of Nuclear Morphology in Actin-intact *Xenopus* Extracts.

S. Mishra, D. Levy; University of Wyoming, Laramie, WY.

Xenopus egg extracts are a useful system to study the regulation of nuclear morphology because the levels and activities of extract components are easily manipulated. In order to form nuclei in egg extracts, demembranated sperm is added as a DNA source, and cycloheximide blocks progression into mitosis. Generally, extract is also supplemented with cytochalasin to depolymerize F-actin and prevent extract gelation and contraction. Nuclei assembled in cytochalasin-treated egg extracts tend to be roughly spherical. Because F-actin has been shown to affect nuclear morphology and growth in other systems, we tested if dynamic F-actin affects in vitro nuclear morphology using actin-intact extracts lacking cytochalasin. Indeed, we observed that nuclei in actin-intact extracts were often blebbed with a

bilobed morphology. Interestingly, the larger nuclear lobe usually lacked Hoechst-staining DNA and exhibited higher actin signal, fewer nuclear pores, and reduced lamin staining. By co-staining for F-actin and nuclear pores, we identified a strong intranuclear actin signal juxtaposed to the nuclear envelope. Through various inhibition experiments, we determined that the bilobed nuclear morphology and enrichment of F-actin at the nuclear envelope were dependent on formins, that nucleate unbranched F-actin filaments, but not on myosin or Arp2/3. These data suggest that formin-mediated intranuclear F-actin dynamics underlie the bilobed nuclear morphology observed in actin-intact extracts. We are continuing to test this hypothesis in extracts and in vivo in *Xenopus* embryos.

P2142/B389

Macronuclear Shape Change in the Giant Ciliate, *Stentor Coeruleus*.

R. M. McGillivary, P. Sood, W. F. Marshall; University of California, San Francisco, San Francisco, CA.

A fundamental question relating to cellular spatial patterning is how nuclei are shaped within cells. The giant ciliate *Stentor coeruleus* provides a unique opportunity to investigate the mechanisms behind nuclear shape, because *Stentor* takes this aspect of the nucleus to the extreme: *Stentor* can reach 1 mm in length, and it possesses a correspondingly gigantic macronucleus shaped like a string of spherical beads. During cell division, the macronucleus dramatically changes shape before dividing amitotically into the two daughter cells. The macronucleus condenses into single sphere, extends, and renodulates in 2-3 hours near the end of cell division. We can experimentally induce this macronuclear shape change by causing *Stentor* to regenerate its oral apparatus. The morphological events during regeneration are similar to cell division, including the cycle of shape changes performed by the macronucleus. It is unclear how this extreme macronuclear shape change is regulated. While microsurgical and electron microscopy studies addressed this question in the past, we have had virtually no molecular insight into this feat of subcellular morphogenesis. Our first molecular foothold into this question comes from an RNAi screen of genes differentially expressed during regeneration in *Stentor*. We found that a homolog of the nuclear exportin gene CSE1 was among the top differentially expressed genes during this process. In yeast, CSE1 is required to export importin-alpha from the nucleus. In humans it is reported that CSE1 also co-localizes with microtubules. We tested the function of this gene in *Stentor* using RNAi. Knockdown of CSE1 results in *Stentor* with clumped and irregularly shaped macronuclear nodes, suggesting CSE1 plays a role in elongation of the macronucleus. Immunofluorescence of CSE1 in *Stentor* results in punctate staining in the cytoplasm with no staining in the macronucleus during the early stages of cell division and regeneration. When the macronucleus is condensed, CSE1 puncta appear in the interior of the macronucleus. Previous electron microscopy studies have shown that the elongating macronucleus is surrounded by a transient microtubule mesh, and contains nuclear envelope-bound channels full of microtubules. Given CSE1's known roles in other systems, we are currently investigating whether CSE1 facilitates macronuclear elongation by interacting with these transient microtubule structures or by another mechanism involving nuclear transport.

P2143/B390

Pcid2 Influences Brca1/bard1 Localization and Centrosome Duplication through It'S Functions in Nuclear Protein and Mrna Export.

K. K. Resendes, T. Gatesman, A. Arrigo, A. Arrigo; Westminster College, New Wilmington, PA.

Nuclear protein export has an emerging role in the regulation of centrosome duplication, a function that involves interaction of centrosomal proteins with the Crm1 nuclear export factor. The protein PCID2, first identified as an mRNA export factor, also functions in Crm1 mediated protein export, with PCID2 siRNA knockdown slowing the rate of export. In addition, PCID2 has been localized to the centrosome. Despite the fact that PCID2 is poised to be a cell cycle regulator through potential combination of it's centrosomal and nuclear export roles, the function of PCID2 at these locations has not been well characterized. We sought to elucidate a potential link between these roles of by exploring PCID2's involvement in the export of particular cargo known to transit between these the nucleus and centrosome. Our studies focus on BRCA1 and BARD1 as potential PCID2 nuclear to centrosomal cargo, as these DNA damage repair proteins transit from the nucleus to the centrosome in a Crm1 dependent manner, particularly in times of cellular stress. Knockdown of PCID2 caused a 10% increase in the nuclear retention of BRCA1, with a concomitant 40-fold decrease in centrosomes exhibiting BRCA1 localization. These results suggest a role for PCID2 in the export of the BRCA1 protein from the nucleus and in it's subsequent localization to the centrosome. Conversely, BARD1 nuclear levels decreased by nearly 20% in the absence of PCID2, which was accompanied by a 40-fold decrease in BARD1 positive centrosomes. These effects appear to stem from a 50% drop in BARD1 protein levels in PCID2 knockdown cells, suggesting a potential role for PCID2 in the export of BARD1 mRNA rather than protein, with failure to export contributing to loss in protein expression. Additionally, altered transport of BRCA1/BARD1 due to PCID2 knockdown had an unexpected effect on centrosome duplication. Rather than the increase in centrosome number seen with BRCA1/BARD1 knockdown, loss of PCID2 led to a four-fold reduction in cells with an aberrant number of centrosomes (3 or more). Furthermore, treatment with inducers of excess centrosome duplication led to an increase in PCID2 positive centrosomes. Together these results suggest a positive role for PCID2 in centrosome duplication. This unexpected outcome is potentially due to the use of non-breast cancer cells. Our ongoing studies include characterizing the function of PCID2 in breast cancer cells, and it's relationship with BRCA1 and BARD1 in that environment as well as investigating the role of PCID2 in BARD1 mRNA export. Determining how PCID2 influences the cellular localization of the BRCA1/BARD1 complex will help to elucidate the mechanism of PCID2's effect on centrosome duplication and therefore determine it's potential impacts on cell cycle regulation and tumor development.

P2144/B391

How Cellular Stress Alters the Subcellular Localization of Oncomodulin.

K. Murtha, L. Climer, Y. Yang, D. Simmons; Baylor University, Waco, TX.

Oncomodulin (OCM) is an EF-hand calcium-binding protein expressed in outer hair cells (OHCs) of the cochlea, macrophages and neutrophils, and a subset of placental cells. Despite its unique expression, the mechanism by which OCM influences Ca^{2+}-signaling pathways, and how it may differ from its more ubiquitous alpha isoform (α-parvalbumin, αPV), remains elusive. Deletion of OCM in C57Bl/6 mice produces no observable phenotype at 1 month. However, by 4 months, these mice are essentially deaf, as measured by auditory brainstem response (ABR) threshold shifts and loss of distortion product

otoacoustic emissions (DPOAEs). OCM mutants exhibit OHC loss and distinct morphological changes. These observations suggest that OCM promotes the survival of OHCs throughout adulthood. Interestingly, we have observed nuclear expression of OCM in OHCs from wild-type aged mice. Therefore, we hypothesize that OCM has a unique function within OHCs and can promote cell survival during stress conditions. In order to understand the mechanism behind OCM's ability to promote cell survival, we used in *vitro* analyses. Calcium-related cellular stressors were used to induce nuclear localization of exogenous GFP-tagged OCM. DS16570511, a small-molecule mitochondrial calcium uniporter (MCU) inhibitor, and thapsigargin, an inhibitor of the sarco/endoplasmic reticulum Ca^{2+} ATPase (SERCA) were administered to HeLa cells transiently expressing OCM-GFP. 24 hours after treatment with these cellular stressors, we observed significantly higher amounts of OCM in the nucleus than in the cytoplasm compared to non-treated controls. In contrast, αPV, which shares over 53% sequence homology to OCM, showed a clear preference for cytoplasmic localization under the same cell stressors. Additionally, both OCM and αPV plasmids significantly increased the time course of transient Ca^{2+} signaling after stimulating HeLa cells with ATP. These results demonstrate that although OCM can buffer calcium similarly to αPV, OCM may respond to cellular stressors differently than other CaBPs and reveals the first evidence of a potential mechanism of OCM function in OHCs.

P2145/B392

Insights into the Role of Nup358 in Mirna Pathway through Its Interaction with an Rna Binding Protein.

P. Banerjee, P. Deshmukh, J. Joseph; National Centre for Cell Science, Pune, INDIA.

Nuclear envelope (NE) is a double layered membrane that encircles the nucleus, and it consists of nuclear pore complex (NPCs) that regulates transport of macromolecules between the nucleus and the cytoplasm. Each mammalian NPC contains around 30 different nucleoporins in multiple copies. Nup358 is a 358kDa nucleoporin localized to the cytoplasmic fibrils of the NPC and also to the cytoplasmic annulate lamellae (AL), subdomain of Endoplasmic reticulum (ER). Previous findings from our lab have shown association of these AL structures with two messenger ribonucleoprotein (mRNP) granules: processing bodies (P bodies) and stress granules (SGs). Further investigation revealed that Nup358 is required for microRNA (miRNA)-mediated post-transcriptional gene silencing. It has been observed that Nup358 is essential for association of target mRNA with miRNA induced silencing complex (miRISC). Moreover, it was found that Nup358 physically interacts with the components of miRISC such as AGO and GW182 proteins. Further our efforts defined the N-terminal 993 amino acids to be the minimum region within Nup358 required for its function in miRNA pathway. Extreme N-terminal region of Nup358 has an alpha helical domain harbouring three tetratricopeptide repeats (TPRs), which was previously reported to bind to single stranded RNA. Our studies using luciferase-based miRNA reporter assays revealed that the TPR region is important for miRNA pathway. We wished to investigate if mRNA export machinery coordinates with Nup358 to couple the mRNA to miRISC. We found that Nup358 interacts with DDX19 (human orthologue of yeast Dbp5), an RNA helicase involved in mRNA export by remodelling the mRNPs at the cytoplasmic side of the NPC. We also found that DDX19 interacts with the N-terminal region of Nup358. Furthermore, depletion of DDX19 impaired the miRNA pathway. These results are consistent with the hypothesis that DDX19 cooperates with Nup358 in coupling the exported target mRNA with miRISC. The studies thus will provide further insights into the mechanism by which mRNA export is linked to the miRNA-mediated suppression of mRNA translation.

P2146/B393

Dbp5 Interacts with Mex67 and Nab2 at the Nuclear Pore Complex for Specific Release during Mrnp Remodeling.

R. L. Adams[1], S. R. Wente[2]; [1]Belmont University, Nashville, TN, [2]Vanderbilt University, Nashville, TN.

Transcripts are coated with RNA binding proteins (RBPs) that dictate processes such as messenger (m) RNA localization, translation, and degradation. As mRNA proceeds through its lifecycle, the complement of associated RBPs is selectively exchanged to indicate successful processing and allow subsequent steps to take place. The major class of molecules responsible for this RBP exchange are DEAD-box proteins, which induce local ATP-dependent RNA structural changes and RBP release. However, in many cases, the mechanism for DEAD-box protein-mediated removal of specific RBPs is not fully defined. To explore this selectivity, we are studying the nuclear mRNA export process. In *Saccharomyces cerevisiae,* the mRNA export receptor Mex67 is recruited to mature nuclear transcripts allowing export of mRNA through the nuclear pore complex (NPC) to the cytoplasm. Mex67 binds transcripts through adaptor proteins such as the poly-A binding protein Nab2. When a transcript reaches the cytoplasmic face of the NPC, the DEAD-box protein Dbp5 triggers selective release of Nab2 and Mex67 from the mRNA. This imposes directionality to mRNA export while allowing the remaining nuclear-associated RBPs to function in the cytoplasm. It is unknown how Dbp5 specifically targets Nab2 and Mex67 for removal from exporting transcripts. Furthermore, in addition to its mRNA export roles at the NPC, Dbp5 has proposed functions throughout the mRNA lifecycle during cytoplasmic translation and in the nucleus, and it is unclear whether these diverse functions are interdependent. Here we have found that Dbp5 binds Mex67 and Nab2 via protein-protein interactions. Using a Split-GFP-based approach, these interactions were only detectable at the NPC and not prior to export, indicating that specificity is determined upon mRNA export. To test whether Dbp5 action at the NPC is sufficient for mRNA export, Dbp5 was anchored at the NPC cytoplasmic face to Nup159. This Nup159-Dbp5 fusion was sufficient for cell viability. Thus, for mRNA export, Dbp5 only needs to bind mRNA at the NPC. Therefore, Dbp5 has separable functions in a cell, and specific interactions direct specificity in these activities.

Structural Basis for Influenza Virus Ns1 Protein Block of Mrna Nuclear Export.

K. Zhang[1], Y. Xie[2], R. Muñoz-Moreno[3], J. Wang[1], L. Zhang[4], M. Esparza[1], B. M. A. Fontoura[1], Y. Ren[2]; [1]University of Texas Southwestern Medical Center, Dallas, TX, [2]Vanderbilt University School of Medicine, Nashville, TN, [3]Icahn School of Medicine at Mount Sinai, New York, NY, [4]School of Life Sciences, Xiamen University, Xiamen, CHINA.

Influenza viruses antagonize key immune defence mechanisms via the virulence factor non-structural protein 1 (NS1). A key mechanism of virulence by NS1 is blocking nuclear export of host messenger RNAs, including those encoding immune factors; however, the direct cellular target of NS1 and the mechanism of host mRNA export inhibition are not known. Here, we identify the target of NS1 as the mRNA export receptor complex, nuclear RNA export factor 1-nuclear transport factor 2-related export protein 1 (NXF1-NXT1), which is the principal receptor mediating docking and translocation of mRNAs through the nuclear pore complex via interactions with nucleoporins. We determined the crystal structure of NS1 in complex with NXF1-NXT1 at 3.8 Å resolution. The structure reveals that NS1 prevents binding of NXF1-NXT1 to nucleoporins, thereby inhibiting mRNA export through the nuclear pore complex into the cytoplasm for translation. We demonstrate that a mutant influenza virus deficient in

binding NXF1-NXT1 does not block host mRNA export and is attenuated. This attenuation is marked by the release of mRNAs encoding immune factors from the nucleus. In sum, our study uncovers the molecular basis of a major nuclear function of influenza NS1 protein that causes potent blockage of host gene expression and contributes to inhibition of host immunity.

Transcriptional Regulation of Ribosomal Proteins by Karyopherin Kap114p-mediated Trans-repressionunder Saline Stress.

C. Liao[1], S. Shankar[1], G. R. Ahmed[1], W. Pi[2], W. Chen[2], K. Hsia PhD[1,2,3]; [1]Institute of Molecular Biology, Academia Sinica, Taipei City, TAIWAN, [2]Institute of Biochemistry and Molecular Biology, College of Life Sciences, National Yang-Ming University, Taipei City, TAIWAN, [3]Correspondence should be addressed to K.-C. H. (e-mail: khsia@gate.sinica.edu.tw), Taipei City, TAIWAN.

Transcriptional regulation of ribosomal proteins by Karyopherin Kap114p-mediated trans-repression under saline stress Abstract Gene expression is controlled by nuclear accessibility of transcription factors that are co-regulated by transport receptors and competitive regulators. Whether nuclear import receptors have activities beyond their transport function in transcription factor-related regulatory networks has never been resolved. Kap114p, one member of the karyopherin-βs (Kap-βs) that mediate nuclear import of yeast TATA-binding protein (yTBP), exhibits a yTBP-binding affinity three orders of magnitude higher than its counterparts. Our crystal structure of Kap114p reveals an extensively negatively-charged concave surface, accounting for high-affinity basic- protein binding. Moreover, we biochemically demonstrate that Kap114p suppresses binding of yTBP with DNA and transcription factors, facilitated by two intra-HEAT-repeat inserts. Furthermore, *Kap114* knockout in yeast leads to a high-salt growth defect, with transcriptome analyses revealing that Kap114p modulates expression of genes associated with ribosomal biogenesis and protein translation by repressing yTBP binding to target promoters. Hence, apart from mediating nuclear import, Kap114p inhibits yTBP activity via a trans-repression mechanism, down-regulating protein synthesis and facilitating yeast growth under high- salinity stress.

Importins Regulating Histone Dynamics in Drosophila.

A. Dutta[1], R. A. Stephenson[1], J. M. Thomalla[1], M. Beller[2], M. A. Welte[1]; [1]University of Rochester, Rochester, NY, [2]Heinrich Heine University Düsseldorf, Düsseldorf, GERMANY.

Following synthesis in the cytoplasm, histones are handled by an elaborate network of chaperones before being incorporated into chromatin. Histones are typically rapidly imported in the nucleus and, hence the earliest cytoplasmic steps have not been very well elucidated. Here we take advantage of Drosophila oogenesis in which histone synthesis and nuclear import are separated in time. Massive amounts of the histone variant H2Av are synthesized in late-stage oocytes and dynamically stored on lipid droplets (LDs), cytoplasmic fat storage organelles. H2Av constantly exchanges between LDs, and only after fertilization are these H2Av stores gradually used to package the newly synthesized DNA in the nuclei of the embryo. In ongoing proteomic experiments, we are characterizing proteins that bind to H2Av in the cytoplasm. Because recent reports have implicated members of the importin family as cytoplasmic histone partners, we are also testing the role of specific importins in regulating H2Av dynamics. Using H2Av-Dendra and Fluorescence Recovery After Photobleaching, we find that H2Av

exchange between LDs is almost abolished in oocytes lacking Importin-9/Ranbp9, suggesting that this importin mediates H2Av transport through the cytoplasm. Using proteomic analysis, we also identified another importin, Importin α2 (Impα2), as an LD-associated protein in Drosophila embryos. Intriguingly, Impα2 is largely cytoplasmic in early-stage embryos but becomes a major LD protein by the cellularization stage. This relocalization correlates with a major transition in H2Av dynamics from rapid exchange between LDs to static binding. To determine whether these two processes are functionally linked, we are identifying how Impα2 binds to LDs. This binding is likely via the LD protein Jabba, as Impα2 recruitment to LDs is abolished in *Jabba* mutants and Impα2 and Jabba physically interact in cultured cells, as assessed by luciferase complementation assay. Jabba is also known to anchor H2Av to LDs, but H2Av and Impα2 binding are separable. We have generated a Jabba construct that specifically lacks the ability to interact with Impα2 and will determine if flies expressing this construct display altered histone dynamics. In summary, we have identified two different importins as candidate regulators of cytoplasmic histone H2Av.

Importin β/7 Promotes Nuclear Import of the RNA-binding Protein FUS and Prevents Its Phase Separation.

I. Baade, R. Kehlenbach; Georg-August-University Göttingen, Göttingen, GERMANY.

Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disease that is characterized by nuclear loss and cytoplasmic aggregation of RNA-binding proteins such as FUS (fused in sarcoma). A key factor in disease pathology is defective nucleocytoplasmic transport. ALS-associated mutations in the nuclear localization signal of FUS have been shown to reduce binding to its nuclear import receptor transportin and impair FUS import. Recently, transportin was reported to not only function as a FUS import receptor but also as a molecular chaperone to prevent and even reverse aberrant phase separation of FUS. Using transport assays in permeabilized cells, we demonstrate that nuclear import of FUS is not only mediated by transportin but also by the importin β/7 heterodimer. Binding assays suggest that FUS binds directly to several nuclear import receptors in a RanGTP-sensitive manner. Similar to transportin, importin β/7 functions as a chaperone for FUS and keeps it in solution. Taken together, our results suggest that nuclear import and chaperoning of FUS is not only mediated by transportin but also by importin β/7 and possibly other nuclear transport receptors.

Heterogeneous Nuclear Ribonucleoprotein A2B1 Regulates and Is Regulated by Cellular Copper Status.

C. McCann, N. Hasan, S. Lutsenko; Johns Hopkins School of Medicine, Baltimore, MD.

Copper (Cu) is an essential cofactor of enzymes involved in numerous cellular processes, such as respiration, antioxidant defense, neurotransmitter production, and myelination. Cu misbalance is implicated in several human diseases, and as such, Cu homeostasis is tightly regulated by a network of Cu-binding and -transporting proteins. In an animal model of Wilson disease, a genetic disorder of Cu accumulation, Cu elevation triggers the nucleocytoplasmic redistribution of several RNA binding proteins, including heterogeneous nuclear ribonucleoprotein (hnRNP) A2B1. To better understand the interface between Cu homeostasis and RNA processing and trafficking, we investigated the relationship between Cu and hnRNP A2B1. hnRNP A2B1 has four isoforms generated by the alternative splicing of exons 2 and 9, and these isoforms can be categorized into two groups: the exon 2-containg B isoforms

and the exon 2-lacking a isoforms. We found that small interfering (si)RNA-mediated knockdown of all four hnRNP A2B1 isoforms in HeLa cells resulted in a significant and specific decrease in cellular Cu content. This was associated with an increase in both mRNA and protein levels of the Cu-transporter ATP7A. Knockdown of only the B isoforms was sufficient to increase the abundance of both ATP7A mRNA and protein, suggesting that these isoforms are the ones mainly responsible for the regulation of ATP7A. Furthermore, we observed rapid, concentration-dependent redistribution of hnRNP A2B1 from the nucleus to distinct cytoplasmic puncta that was not reversed by treatment with Cu chelators. These puncta do not stain positive for any markers of classic cytoplasmic granules, suggesting that this redistribution may be a specific response to elevated Cu. Knockdown of the B isoforms resulted in a lack of hnRNP A2B1 redistribution in response to Cu, suggesting that these isoforms are mainly responsible for this effect. These results show that the cellular properties of hnRNP A2B1 are modulated by Cu and suggest that one or more hnRNP A2B1 isoforms play a role in the regulation of ATP7A RNA involved in cellular Cu balance. These findings provide a basis for understanding how Cu homeostasis is regulated on the RNA-level as well as shed light onto a potential role for Cu in RNA metabolism.

Pqbp1 Facilitates the Nuclear Import of Splicing Factor Txnl4a.

X. Liu, Z. Zhang, J. Han; Southeast University, Nanjing, CHINA.

Renpenning syndrome is a group of X-linked intellectual disability (XLID) syndromes which caused by mutations of human polyglutamine-binding protein 1 (PQBP1) gene. Previous studies show that PQBP1 binds to spliceosomal protein TXNL4A through its C-terminal domain, but the biological function of this interaction remains unclear. In this study, we found that TXNL4A was properly imported into the nucleus in the presence of wild-type PQBP1, but it was largely retained in the cytoplasm if its interaction with PQBP1 was disrupted by the mutations in PQBP1 C-terminal domain. PQBP1 is imported by karyopherin β2 through its PY-NLS. When we mutated its PY-NLS, PQBP1 was mislocalized to the cytoplasm as well as TXNL4A. Our data clearly demonstrate that the interaction between PQBP1 C-terminal domain and TXNL4A is critical for TXNL4A nuclear import. Mutations in PQBP1 C-terminal domain impair the import of splicing factor and affect mRNA splicing, which sheds light on the pathogenesis of Renpenning syndrome.

The Novel Nuclear Targeting and BFRF1-interacting Domains of BFLF2 Are Essential for Efficient Ebv Virion Release.

M. Chen; Graduate Institute and Department of Microbiology, College of Medicine, Taiwan University, Taipei, TAIWAN.

Epstein-Barr virus (EBV) genomic DNA is replicated and packaged into procapsids in the nucleus to form nucleocapsids, which are then transported into the cytoplasm for tegumentation and final maturation. The process is facilitated by the coordination of the viral nuclear egress complex (NEC), which consists of BFLF2 and BFRF1. By expression alone, BFLF2 is distributed mainly in the nucleus. However, it co-localizes with BFRF1 at the nuclear rim and in cytoplasmic nuclear envelope-derived vesicles in co-expression cells, suggesting temporal control of the interaction between BFLF2 and BFRF1 are critical for their proper function. The N-terminal sequence of BFLF2 is less conserved to that of alpha- and beta herpesvirus homologs. Here we found BFLF2 a.a. 2-102 is required for both nuclear targeting and its

interaction with BFRF1. Co-immunoprecipitation and confocal analysis indicated that a.a 82-106 of BFLF2 are important for its interaction with BFRF1. Three crucial amino acids (R47, K50, R52) and several non-continuous arginine and histidine residues within a.a. 59-80 function together as a non-canonical NLS, which can be transferred onto YFP-LacZ for nuclear targeting, in an importin β-dependent manner. Virion secretion is defective in 293 cells harboring a BFLF2 knockout EBV bacmid upon lytic induction, and is restored by trans-complementation of wild type BFLF2, but not NLS or BFRF1-interacting defective mutants. In addition, multiple domains of BFRF1 were found to bind BFLF2, suggesting multiple contact regions within BFRF1 and BFLF2 are required for proper nuclear egress of EBV nucleocapsids.

Retromer Retrieves the Wilson Disease Protein, Atp7B from Lysosomes in a Copper-dependent Mode.

A. GUPTA, S. Das, S. Maji, R. Ruturaj, I. Bhattacharya; Indian Institute of Science Education & Research Kolkata, Mohanpur, INDIA.

The Wilson Disease protein, ATP7B utilizes lysosomal exocytosis to export copper out of liver. We investigated, what was the fate of ATP7B, post-copper export. At high copper ATP7B localizes to lysosomes and Rab7 endosome and upon copper chelation, returns to Trans Golgi Network. This retrograde trafficking of ATP7B is mediated by retromer complex. ATP7B co-localizes with Vps35 and Vps26, the core members of retromer. Knocking down of VPS35 or overexpressing the non-functional VPS35-R107A, did not alter TGN exit or vesicularization of ATP7B in response to copper; rather upon subsequent copper depletion ATP7B failed to relocalize to the TGN. Overexpressing the wtVPS35 rescued this non-recycling phenotype. On testing a series of sorting-motif mutants on ATP7B, we found that N-terminal motif NXXY mutant phenocopies retrograde trafficking behavior of ATP7B in VPS35 KD condition. Using Structured Illumination microscopy we demonstrate that VPS35 and ATP7B are juxtaposed on the same lysosomal compartment and possibly their interaction is indirect or transient. We demonstrate that retromer complex regulates lysosome to TGN trafficking of a non-resident lysosomal cargo, viz., ATP7B and that it is dependent upon copper conditions in the cell.

Pleiotropic Role of Drosophila Ph*osphoribosyl Pyrophosphate Synthetase*In Autophagy and Lysosome Homeostasis.

K. Delos Santos[1], M. Kim[1], C. Yergeau[1], S. Jean[2], N. Moon[1]; [1]McGill University, Montreal, QC, CANADA, [2]Université de Sherbrooke, Sherbrooke, QC, CANADA.

Phosphoribosyl pyrophosphate synthetase (PRPS) is a rate-limiting enzyme that plays a crucial role in nucleotide metabolism. The functional importance of PRPS is illustrated by the fact that human *PRPS1* is mutated in neurological disorders such as Arts syndrome, Charcot-Marie-Tooth disease, and nonsyndromic sensorineural deafness. However, it is currently unclear how PRPS deregulation contributes to neuropathogenesis and, as a consequence, no treatment option is available for affected patients. We identified the Drosophila ortholog of *PRPS* (*dPRPS*) as a direct target of RB/E2F in Drosophila, a vital cell cycle regulator, and engineered *dPRPS* alleles carrying patient-derived mutations. Two independent fly models of Arts syndrome-derived mutations established in this study, $dPRPS^{Q165P}$

and *dPRPS*^{R228W}, demonstrate shortened lifespan and locomotive defects, common phenotypes associated with neurodegeneration. While the flies develop normally, they are highly sensitive to nutrient deprivation caused by a failure to mobilize lipid reserves. We also show that *dPRPS* mutant flies have profound defects in macroautophagic induction and lysosome homeostasis, explaining why they fail to properly mobilize lipids upon starvation. Significantly, the nervous system of *dPRPS* mutant flies is affected by these defects and accumulate aberrant lipid droplets and protein aggregates in the brain. Interestingly, S-adenosylmethionine (SAM) supplementation, which is given to patients with Arts syndrome hoping to restore PRPS dysfunction, partially suppresses starvation sensitivity and improves lysosome dysfunction in *dPRPS* mutant flies. This suggests that the *dPRPS* mutants described in this study may be used to identify future therapies for *PRPS1*-associated disorders. Overall, we uncovered an unexpected link between nucleotide metabolism and autophagy/lysosome function and established a *Drosophila* model of PRPS-associated neurological disorder, providing a possible mechanism by which PRPS-dysfunction contributes to PRPS-associated neuropathology.

P2156/B404

HHV-7 U21 Exploits Golgi Quality Control Carriers to Reroute Class I MHC Molecules to Lysosomes.

A. T. Dirck, M. L. Whyte, **A. W. Hudson**; Medical Coll-Wisconsin, Milwaukee, WI.

The human herpesvirus-7 (HHV-7) U21 glycoprotein binds to class I MHC molecules in the ER and reroutes them to lysosomes. How this single viral glycoprotein efficiently redirects the U21/class I MHC complex to the lysosomal compartment is poorly understood. To investigate the trafficking of HHV-7 U21, we followed synchronous release of U21 from the ER as it traffics through the secretory system, using live-imaging confocal and superresolution microscopy. Sorting of integral membrane proteins from the TGN has been shown to occur through tubular carriers that emanate from the TGN or through vesicular carriers that recruit GGA, clathrin adaptors, and clathrin (Chen et al., 2017). Here we present evidence for the existence of a third type of Golgi-derived carrier that is vesicular, yet clathrin-independent. This U21-containing carrier also carries a Golgi membrane protein engineered to form inducible oligomers (Galactosyl Transferase fused to FK506 dimerization domains). We propose that U21 employs the novel mechanism of forming large oligomeric complexes with class I MHC molecules that result in sorting of the oligomeric U21/class I MHC complexes to Golgi-derived quality control (QC) carriers destined for lysosomes.

P2157/B405

Actin-mediated Endosomal Recycling Is Regulated by Endosomal Cargo Load.

B. Savage, E. MacDonald, L. Brown, D. Grimes, H. Liu, T. Waring, S. Urbe, M. Clague, **T. Zech**; University of Liverpool, Liverpool, UNITED KINGDOM.

Transmembrane proteins in the sorting endosome are either recycled to their point of origin or destined for lysosomal degradation. Lysosomal sorting is mediated by the interaction of ubiquitylated transmembrane proteins with the ESCRT machinery. We uncover an alternative role for the ESCRT-0 component HRS in promoting the constitutive recycling of transmembrane proteins. We find that endosomal localisation of the actin-nucleating factor WASH requires HRS, which occupies adjacent endosomal subdomains at steady state. Endosomal localisation of HRS-WASH is responsive to cargo load. Inhibition of receptor recycling leads to an accumulation of WASH on endosomal membranes at steady state. Whereas acute stimulation of cells with EGF lead to a reduction of endosomes associated

with WASH compared to HRS levels. Depletion of HRS results in defective constitutive recycling of epidermal growth factor receptor family (EGFR; ERBB2/Her2) and the matrix metalloproteinase MT1-MMP, leading to their accumulation in internal compartments. We show that direct interactions of receptors with endosomal actin are required for efficient recycling and use a model system of chimeric transferrin receptor trafficking to show that an actin-binding motif can counteract an ubiquitin signal for lysosomal sorting. In order to address how actin sorts cargo on the membrane we took advantage of a previously described actin binding domain in EGFR which is conserved in the ERBB family of proteins. Mutation of this site from EGFR and ERBB2 reduce egress rates of the receptors from the endosome indicating that direct actin binding to receptors facilitates their recycling. ERBB2 positive breast cancer invasion and metastasis is dependent on actin mediated recycling and patients show increased levels of WASH expression. WASH expression is increased in a model of acquired resistance against Trastuzumab based ERBB2 positive breast cancer therapy and inhibition of WASH function overcomes resistance. These findings point towards WASH complex regulation being directly linked to changes in cargo flux.

P2158/B406

pHLARE: a Genetically Encoded Ratiometric Lysosome pH Biosensor.

B. Webb[1], J. Cook[2], T. Wittmann[2], D. Barber[2]; [1]West Virginia University, Morgantown, WV, [2]University of California, San Francisco, San Francisco, CA.

Many lysosome functions are determined by a lumenal pH of ~5.0, including the activity of resident acid-activated hydrolases. Lysosome pH (pHlys) is increased in neurodegenerative disorders and predicted to be decreased in cancers, making it a potential target for therapeutics to limit the progression of these diseases. Accurately measuring pHlys, however, is limited by currently used dyes that accumulate in multiple intracellular compartments and cannot be propagated in cells. To resolve this limitation, we developed a genetically encoded ratiometric pHlys biosensor, pHLARE (pH Lysosomal Activity REporter), with the lysosome transmembrane protein LAMP1 tagged at the lumenal amino-terminus with superfolder GFP and the cytosolic carboxyl-terminus with mCherry. mCherry, with a pKa of 4.5 is insensitive to changes in the cytosolic pH range and allows ratiometric analysis normalized for abundance of the biosensor. We confirmed that pHLARE localizes predominantly in lysosomes, has a dynamic range of pH 4.0 to 6.5, and can be stably expressed in cells for propagation with cell division and for long-term time-lapse imaging. We developed a semi-automated image analysis algorithm to calibrate pHLARE fluorescence ratios, segment lysosomes, and determine the absolute pHlys of approximately a hundred lysosomes per cell. Using this pHLARE analysis, we show that inhibiting mTORC activity significantly decreases pHlys in epithelial cells from 5.22 ± 0.10 in controls to 4.63 ± 0.09. With pHLARE we also find that pHlys is significantly lower in triple negative MDA-MB-157 breast cancer cells (4.56 ± 0.11) and in PANC-1 pancreatic cancer cells (4.39 ± 0.19) compared with tissue-matched untransformed cells (5.36 ± 0.09 and 5.02 ± 0.18, respectively), and expression of oncogenic H-Ras-V12 decreases pHlys to 4.67 ± 0.07. Despite not being previously validated, decreased pHlys in cancers is consistent with increased activity of acid-regulated lumenal hydrolyases for metastasis and to increase biomass to fuel rapid proliferation. pHLARE is a new tool to accurately measure pHlys and for improved understanding of lysosome dynamics that could be a promising therapeutic target.

P2159/B407

Guanine Exchange Factor MADD Regulates Von Willebrand Factor Trafficking in Endothelial Cells Via Activation of Weibel-Palade Body-Associated Rab GTPases.

M. Kat[1], H. Harbiye[1], H. Janssen[2], I. De Cuyper[1], J. Voorberg[1], R. Bierings[3], C. Margadant[1]; [1]Sanquin Research and Landsteiner Laboratory, Amsterdam, NETHERLANDS, [2]Netherlands Cancer Institute, Amsterdam, NETHERLANDS, [3]Erasmus University Medical Center, Rotterdam, NETHERLANDS.

Von Willebrand factor (VWF) is a secreted, multimeric protein that plays a crucial role in hemostasis. Endothelial cells secrete VWF via distinct pathways. Exocytotic vesicles containing small VWF multimers are continuously targeted primarily to the basolateral surface via the constitutive pathway (1), VWF of higher multimeric state is first stored in specialized organelles called Weibel-Palade bodies (WPBs) that steadily release their content through the basal secretion pathway (2) into the vascular lumen to maintain circulating VWF plasma levels. Upon vascular injury rapid stimulus-induced exocytosis of WPBs occurs via the regulated secretion pathway (3) to enable VWF string formation and subsequent platelet activation at the damaged site. Polarized secretion is crucial for the function of VWF at basolateral and apical surfaces, however, the regulation mechanism is unknown. Rab GTPases (Rabs) are a large family of proteins involved in vesicle trafficking. Several Rabs have been implicated in WPB trafficking, including the Rab3 isoforms Rab3B and Rab3D, as well as closely related Rab27A. Whether these WPB-Rabs are redundant or exhibit unique functions is still unknown. Rabs require a guanine nucleotide exchange factor (GEF) for their activation and recruitment to specific membranes. Previously, the Rab-GEF MAP-kinase activating death domain (MADD, also referred to as DENN or Rab3GEP) has been identified as a GEF for Rab27A and Rab3 isoforms in other cell types. Our research aims at elucidating if and how MADD is involved in regulating VWF secretion via these different secretory pathways. To investigate their role in WPB trafficking and secretion, Rab27A, Rab3B, Rab3D, and MADD were each targeted by shRNAs in human umbilical vein endothelial cells (HUVECs). Stable knockdown HUVECs were grown on Transwell membranes and unstimulated (basal) and histamine-evoked (regulated) VWF secretion was measured by ELISA. Unstimulated VWF secretion at the apical surface was decreased upon Rab27A, Rab3B, Rab3D, and MADD knockdown, but release on the basolateral side remained unchanged. Histamine-evoked VWF secretion showed a similar trend. Intracellular VWF content was reduced in Rab3D and MADD depleted cells, and immunofluorescent VWF staining revealed less WPBs. MADD silencing resulted in similar loss of peripheral localization of WPBs as observed in shRab27A treated cells. Based on our findings, we suggest a model in which MADD regulates apical VWF trafficking, through the activation and recruitment of Rab3D and Rab27A to WPBs.

P2160/B408

PQLC2 Signals Lysosomal Cationic Amino Acid Abundance to the C9orf72 Complex.

J. Amick, A. Tharkeshwar, G. Rocha, **S. M. Ferguson**; Yale School of Medicine, New Haven, CT.

The C9orf72 protein is required for normal lysosome function. In support of such functions, C9orf72 forms a heterotrimeric complex with SMCR8 and WDR41 that is recruited to lysosomes when amino acids are scarce. These properties raise questions about the identity of the lysosomal binding partner of the C9orf72 complex and the amino acid sensing mechanism that regulates C9orf72 complex abundance on lysosomes. We now demonstrate that an interaction with the lysosomal cationic amino acid transporter PQLC2 mediates C9orf72 complex recruitment to lysosomes. This is achieved through an interaction between PQLC2 and WDR41. The interaction between PQLC2 and the C9orf72 complex is

negatively regulated by arginine, lysine and histidine, amino acids that PQLC2 transports across the membrane of lysosomes. These results define a new role for PQLC2 in the regulated recruitment of the C9orf72 complex to lysosomes and reveal a novel mechanism that allows cells to sense and respond to changes in the availability of cationic amino acids within lysosomes.

Modulation of Endo-lysosomal System in Mtb Infected Macrophages Mediated by Both Host Heterogeneity and Mycobacterial Lipids.

K. Sachdeva[1], M. Goel[1], M. Sudhakar[2], M. Mehta[3], K. Raman[2], A. Singh[3], V. Sundaramurthy[1]; [1]National Center for Biological Sciences, Bengaluru, INDIA, [2]Department of Biotechnology, Indian Institute of Technology Madras, Chennai, INDIA, [3]Center for Infectious Disease Research, Department of Microbiology and Cell Biology, Indian Institute of Science, Bengaluru, INDIA.

Mycobacterium tuberculosis (Mtb) actively avoids fusion with late endosomes and lysosomes by inhibiting phagosomal maturation. While the mechanisms of phagosome maturation arrest at the level of mycobacterial phagosome are understood to some extent, the global impact of Mtb residence in arrested phagosome on the host cellular processes has not been systematically studied. In this study, we systematically explored the effect of Mtb infection on the host endo-lysosomal system. Our results show higher levels of different endosomal populations, endocytic uptake and lysosomes in Mtb infected cells compared to bystander-uninfected cells. Furthermore, comparison of endocytic profiles with other phagocytic cargos reveal that the observed alterations are not limited to Mtb but constitute a host-mediated effect to phagocytosis. Further dissection of the mechanisms involved identifies the endocytic heterogeneity in the host as a key determinant of the Mtb infection in macrophages. Unlike endosomes, lysosomal alterations are distinctly mediated by Mtb surface lipids in an infected cell. Mtb ΔWhiB3 mutant lacking the lipids elicits weaker lysosomal response suggesting the role of Mtb lipids in inducing lysosomal biogenesis. We find some of these lipids alter the lysosomal state of macrophages by acting upon mTORC1-TFEB axis. Further, abatement of the lysosomal system using pharmacological tools leads to enhanced intracellular Mtb survival, showing that the altered lysosomal state is a crucial determinant of the intracellular Mtb survival. Together, our study demonstrates that the host endocytic heterogeneity determines Mtb phagocytosis and further lysosomal rewiring mediated by Mtb lipids regulates homeostasis of an infected macrophage.

P2162/B410

Irs4 Mediates Egf-dependent Upregulation of Endocytosis through the Recruitment of Ras-pi3k Complex to the Endosome.

M. Amano[1], Y. Fujioka[1], A. O. Satoh[1], K. Horiuchi[1], A. Yoshida[1], H. Sasajima[1], C. Obuse[2], **Y. Ohba**[1]; [1]Department of Cell Physiology, Faculty of Medicine and Graduate School of Medicine, Hokkaido University, Sapporo, JAPAN, [2]Laboratory of Genome Structure and Function, Graduate School of Science and Faculty of Science, Osaka University, Suita, JAPAN.

Molecular dynamics, including changes in the subcellular localization of proteins, play an important role in determining the specificity and strength of intracellular signaling. We have previously reported that the small GTPase Ras, in complex with phosphoinositide 3-kinase (PI3K), translocates to the endosome upon epidermal growth factor (EGF) stimulation, and participates in the regulation of endocytosis and endosomal maturation (Tsutsumi *et al*., ***Cell. Signal.***21: 1672, 2009; Fujioka *et al*., ***PLoS ONE***6: e16324,

2011). More recently, we identified a peptide sequence within the Ras-binding domain of PI3K that dictates the endosomal localization of the Ras-PI3K complex and subsequent regulation of endocytosis (Fujioka *et al*., ***Cell Struct. Funct.***44: 61, 2019). This peptide was named RAPEL after Ras-PI3K endosomal localization. The detailed molecular mechanism through which the complex is recruited to the endosome has yet to be determined, however. Here we report that insulin receptor substrate 4 (IRS4), which had been identified as a RAPEL-binding protein through mass spectrum analysis, translocates to the endosome by EGF stimulation, and recruits the Ras-PI3K complex to this organelle. The knockdown of IRS4 resulted in the inability of the Ras-PI3K complex to localize to the endosome and inhibition of clathrin-independent endocytosis. IRS4 is likely to be recruited to the endosome through two distinct mechanisms: i.e. Through the pleckstrin homology (PH) domain in a quiescent state and through tyrosine phosphorylation by Src in the presence of EGF. Our results might provide novel mechanistic insights into how endocytosis is controlled by the spatiotemporal regulation of signaling molecules.

Type II Phosphatidylinositol 4-Kinases Modulate BLOC-1-Dependent Tubular Transport Carrier Formation from Endosomes during Melanosome Biogenesis.

Y. Zhu[1,2,3,4], C. Delevoye[5], S. Grinstein[6], P. De Camilli[7], T. Balla[8], G. Raposo[5], M. Marks[1,2,3]; [1]Department of Pathology and Laboratory Medicine, Children's Hospital of Philadelphia, Philadelphia, PA, [2]Department of Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA, [3]Department of Physiology, University of Pennsylvania, Philadelphia, PA, [4]Department of Biology, University of Pennsylvania, Philadelphia, PA, [5]Structure et Compartiments Membranaires Institut Curie, Section de Recherche, Paris, FRANCE, [6]Division of Cell Biology, Hospital for Sick Children, Toronto, ON, CANADA, [7]Departments of Neuroscience and Cell Biology, Howard Hughes Medical Institute, Kavli Institute for Neuroscience, Yale University, Medical School, New Haven, CT, [8]Section on Molecular Signal Transduction, Program for Developmental Neuroscience, National Institutes of Child Health and Human Development, National Institutes of Health, Bethesda, MD.

Melanosomes are pigment cell-specific lysosome-related organelles (LROs) in which melanin pigments are synthesized and stored. Melanosome maturation from non-pigmented precursors requires biosynthetic delivery of melanogenic enzymes and transporters from early endosomes (EEs) by two pathways. One essential pathway requires the multisubunit complex, BLOC-1, on EEs to generate tubular transport intermediates through which cargoes such as TYRP1 are delivered to maturing melanosomes. The molecular mechanism by which BLOC-1 facilitates tubule formation is incompletely understood, but recent studies suggest that phosphatidylinositol-4-phosphate (PtdIns4P) and the type II PtdIns 4-kinases (PI4KIIα and PI4KIIβ) might play a role. Moreover, in other cell types PI4KIIα and PI4KIIβ interact respectively with AP-3 and AP-1, which also play roles in BLOC-1-dependent cargo delivery. We hypothesized that PI4KIIα and/or PI4KIIβ regulate EE tubule formation by BLOC-1. By live-cell imaging, both PI4KIIα and PI4KIIβ are detected on melanosome-bound EE tubules. Transient depletion of either PI4KIIα or PI4KIIβ by shRNA impaired melanosome localization of TYRP1 by immunofluorescence microscopy (IFM), as also observed in BLOC-1-depleted cells; however, unlike in BLOC-1-depleted cells, the mislocalized TYRP1 in PI4KII-depleted cells accumulated in late endosomes/ lysosomes and not extensively in EEs. Moreover, depletion of either PI4KIIα or PI4KIIβ in wild-type melanocytes did not affect the association of BLOC-1 with membranes by subcellular fractionation, and in BLOC-1-knockout melanocytes did not prevent TYRP1 accumulation in EEs by IFM. Live imaging showed that deficiency of PI4KIIα, but not of PI4KIIβ, impairs EE tubule length without blocking tubule formation. These results

indicate that PI4KIIα and PI4KIIβ are each required downstream of BLOC-1 for sequential steps in BLOC-1-dependent cargo delivery to melanosomes. They further suggest that PI4KIIα and PI4KIIβ are not required for BLOC-1-mediated tubule initiation but may be required for tubule elongation or stabilization (PI4KIIα) and/or targeting to melanosomes (PI4KIIβ). Our study demonstrates an important role of type II PtdIns 4-kinases in BLOC-1-dependent tubular cargo transport during melanosome biogenesis and extends the cohort of effectors required for LRO biogenesis.

P2164/B412

Ampk Contributes to Autophagosome Maturation and Lysosomal Fusion.

M. Jang[1], Y. Park[1], Y. Cha[1], E. Lee[2], J. Park[1]; [1]Yonsei University, Wonju, KOREA, REPUBLIC OF, [2]Chung-Ang University School of Medicine, Seoul, KOREA, REPUBLIC OF.

AMP-activated protein kinase (AMPK) regulates autophagy initiation when intracellular ATP level decreases. However, the role of AMPK during autophagosome maturation is not fully understood. Here, we report that AMPK contributes to efficient autophagosome maturation and lysosomal fusion. Using CRISPR-Cas9 gene editing, we generated AMPK α1 knockout HEK293T cell lines, in which starvation-induced autophagy is impaired. Compound C, an AMPK-independent autophagy inducer, and trehalose, an mTOR-independent autophagy inducer were used to examine the role of AMPK in autophagosome maturation and lysosomal fusion. While the treatment of control cells with either compound C or trehalose induces activation of autophagosomes as well as autolysosomes, the treatment of AMPK α1 knockout cells with compound C or trehalose induces mainly activation of autophagosomes, but not autolysosomes. We demonstrate that this effect is due to interference with the fusion of autophagosomes with lysosomes in AMPK α1 knockout cells. The transient expression of AMPK α1 can rescue autophagosome maturation. These results indicate that AMPK α1 is required for efficient autophagosome maturation and lysosomal fusion.

Presenilin 1 Functions in Endosomal Recycling to Maintain Lysosomal Clearance.

M. Bretou, R. Sannerud, W. Vermeire, D. Demedts, W. An naert; VIB-KU Leuven Center for Brain & Disease Research, Department of Neurosciences, Leuven, BELGIUM.

Autophagic and endosomal dysfunction observed at preclinical stages of Alzheimer's disease (AD) or in Presenilin (PSEN) 1 -/- mouse neurons are suggested to be related to the non-catalytic role of PSENs in lysosomal homeostasis. The precise molecular mechanism accounting for these alterations remains nonetheless debated, and several hypothesis have emerged over the years, most of them focusing on the alteration of lysosomal function. Previously reported lipidome and proteome analysis of the plasma membrane of PSEN deficient cells have revealed a selective depletion of (i) proteins involved in cell adhesion/migration, transport regulation, signaling and transporters, as well as (ii) a significant depletion of cholesterol. Accordingly endosomal cargoes depleted from the plasma membrane were shown to accumulate intracellularly, highlighting the existence of defects in specific endosomal transport routes to and/or from the cell surface. To re-investigate the role of PSEN1 in endosomal transport regulation, we generated independent clones of PSENdKO mouse embryonic fibroblasts and subsequently rescued those with hPSEN1 and the catalytic inactive mutant variant PSEN1 D257A/D385A, to ensure isogenic backgrounds. These PSENdKO cells present with enlarged late endosomes/lysosomes that (i) display an increased co-localization with early endosomal markers and (ii) also accumulate cargo

such as CI-M6PR and VPS35, a key subunit of the retromer involved in cargo recognition and sorting. These accumulations were relieved upon re-expression of either WT or catalytically inactive PSEN1, indicating that a γ-secretase-independent role of PSEN1 is functionally connected to recycling. Interestingly, similar defects were observed when knocking down ARF6, a small GTPase involved in membrane traffic/clathrin-independent endocytosis and a key regulator of cholesterol trafficking. Conversely, overexpression of ARF6 in PSENdKO cells alleviated partially endolysosomal defects. All together, these results involve PSEN1 in the control of proper endosomal recycling, and this independently from its γ-secretase activity. Age-related alterations in the expression of PSEN1 may therefore potentially affect AD etiology independent from its catalytic function.

P2166/B414

Endolysosome Ferrous Iron Concentrations Are Quantitatively Diverse and Labile.

P. W. Halcrow, N. Khan, G. Datta, N. M. Miller, X. Chen, J. D. Geiger; University of North Dakota School of Medicine and Health Sciences, Grand Forks, ND.

Endosomes and lysosomes (endolysosomes) are acidic organelles that are important both physiologically and pathologically. Implicated in the physiological and pathophysiological processes are readily releasable stores of cations including ferrous iron (Fe^{2+}); an essential cofactor for various enzymes and the generation of reactive oxygen species. To determine the extent to which and mechanisms by which endolysosome Fe^{2+} affects cellular functions, it is important to first determine levels of endolysosome Fe^{2+}. Here, using U87MG astrocytoma cells and primary cultures of rat cerebral cortex neurons we found that FeRhoNox-1 was highly specific for Fe^{2+} and that FeRhoNox-1 positive stores were highly localized in endolysosomes. Control levels of endolysosome Fe^{2+} were 36.6 ± 13.6 µM; endolysosome Fe^{2+} levels increased to 75 ± 15.7 µM when cells were treated with ferric ammonium citrate and decreased to 0.08 ± 0.05 µM when cells were treated with the iron chelator deferoxamine. The Fe^{2+} content in endolysosomes was heterogeneously distributed; findings that suggest subpopulations of endolysosomes. Endolysosomes with higher levels of Fe^{2+} were localized near the nucleus while endolysosomes with lower levels of Fe^{2+} were localized near plasma membranes. Thus, FeRhoNox-1 can be used to label and measure levels of endolysosome Fe^{2+}. In doing so, this will aid in the determination of the importance of Fe^{2+} in subpopulations of endolysosomes, their locations in cells, and the effects of released endolysosome Fe^{2+} on downstream cellular events. Structural Mechanism of Folliculin-mediated Regulation of the Rag Gtpase Activation Cycle.

R. Lawrence, S. From m, Y. Fu, A. Yokom, D. Kim, A. Thelen, L. Young, J. Hurley, R. Zoncu; UC Berkeley, Berkeley, CA.

The decision to allocate resources toward cellular growth or quality control is critical for organismal survival. The mechanistic Target of Rapamycin Complex I (mTORC1) tunes the balance between cellular anabolism and catabolism, and is one of the most frequently mutated pathways in cancer. In response to nutrient stimulation, the Rag GTPases (Rags) recruit mTORC1 from the cytosol to the lysosomal surface, where its kinase function is activated. The Rags are obligate heterodimers (Rag A:RagC), whose nucleotide binding states respond to cellular nutrient status and determine their ability to bind to mTORC1. A key but poorly understood event in mTORC1 activation is conversion of RagC from the GTP-

to the GDP-bound form. A complex of Folliculin (FLCN) and FLCN-interacting protein (FNIP) was proposed to promote mTORC1 activation by functioning as a RagC -specific GTPase Activating Protein (GAP), but how RagC is activated at the right time by FLCN:FNIP, and how it remains in check until needed, is one of the major unanswered questions in the mTORC1 regulation field. To determine the regulatory functions of FLCN:FNIP, we reconstituted a 'lysosomal FLCN complex' (LFC) containing FLCN:FNIP, the starved-state $RagA^{GDP}$:$RagC^{GTP}$ GTPases, and the lysosomal anchor Ragulator and determined its cryo-EM structure to 3.6Å. Surprisingly, this complex inhibits the RagC-GAP activity of FLCN by displacing the catalytic Arg finger of FLCN away from the RagC nucleotide pocket. Conversely, within the LFC, FLCN:FNIP protects starved-state $RagA^{GDP}$, providing a mechanism for stabilization of the inactive state Rag complex. Together, these data identify the LFC as a novel activation checkpoint for mTORC1, whereby FLCN:FNIP may help maintain the Rags in an inactive state under low nutrients, and yet is necessary for conversion to the active state when nutrient levels rise.

Repair of Plasma Membrane Wounds Caused by Bcr-antigen Interaction Is Mediated by Lysosomal Exocytosis and Promotes Antigen Uptake.

W. Song, F. Y. Maeda, J. van Haaren, N. An drews; University of Maryland, College Park, MD.

B lymphocytes survey antigen through the B cell receptor (BCR), which initiates the activation of B cells to mount antibody responses against infectious agents. Polarization of the BCR and lysosomes towards the antigen interaction site are important steps that lead to antigen acquisition and presentation to T cells. Lysosomal enzymes were proposed to participate in extraction of surface-immobilized antigen by B cells (1), but the trigger for lysosomal enzyme secretion at the B cell immunological synapse remained unknown. Plasma membrane (PM) wounding triggers lysosomal exocytosis, a process required for PM repair in several cell types (2). We previously showed the importance of lysosomal exocytosis in the repair of B cell PM wounds caused by pore-forming toxins (3). This study addresses whether PM wounding occurs when B cells engage antigen, and whether PM wounding and repair affect antigen acquisition. We found that pseudo and bona fide antigen but not transferrin, when immobilized to beads or planar lipid bilayers, wound the B cell PM in an antigen dose-dependent manner. The actin motor non-muscle myosin II (NMII) and the BCR polarize towards antigen interaction sites before PM wounding, and NMII inhibition reduces the number of wounded cells. The lysosomal protein Limp2 is exposed at sites of antigen engagement, and inhibition of lysosomal exocytosis or the lysosomal enzyme acid sphingomyelinase increase the number of wounded cells. Thus, antigen-induced PM wounding is followed by lysosome-mediated PM repair. Antigen internalization occurs after polarization of lysosomes towards antigen-binding and PM wounding sites, and is decreased when antigen-induced PM wounding is reduced by the NMII inhibitor. These results suggest that forces generated by NMII within B cells following engagement of immobilized antigen by the BCR can wound the PM, and that lysosome-mediated wound repair can facilitate internalization of antigen from presenting surfaces. Regulation of Cholesterol-dependent Mtorc1 Signaling by Inter-organelle Contacts.

C. Lim[1,2], O. Davis[1,2], H. Shin[1,2], J. Zhang[1,2], C. Berdan[1,3], X. Jiang[4], J. Counihan[1,3], D. Ory[4], D. Nomura[1,3], R. Zoncu[1,2]; [1]Department of Molecular and Cell Biology, University of California at Berkeley, Berkeley, CA, [2]The Paul F. Glenn Center for Aging Research at the University of California, Berkeley, Berkeley, CA, [3]Department of Nutritional Sciences and Toxicology, University of California at Berkeley, Berkeley, CA, [4]Diabetic Cardiovascular Disease Center, Washington University School of Medicine, St Louis, MO.

Organelle communication is key to cellular homeostasis, and its failure is an emerging driver of neurodegenerative and metabolic disease. Cholesterol, an essential building block for membranes and precursor for growth hormones, is exchanged by specialized sterol carriers located at physical contacts between the endoplasmic reticulum (ER) and other organelles. Recently, cholesterol was identified as an essential input that activates the master growth regulator, mTORC1 kinase, by promoting its recruitment to the lysosomal limiting membrane via the Rag guanosine triphosphatases (GTPases). Cholesterol triggers major programs downstream of mTORC1, including upregulation of anabolism and suppression of autophagy, but the mechanisms that regulate lysosomal cholesterol content to enable mTORC1 signaling are unclear. More generally, whether and how inter-organelle contacts govern cell-wide programs for growth and quality control is not understood. Here we show that Oxysterol Binding Protein (OSBP) and its anchors at the ER, VAPA/B, deliver cholesterol across ER-lysosome contacts to activate mTORC1. In cells depleted for OSBP, but not other VAP-interacting cholesterol carriers, mTORC1 recruitment by the Rag GTPases is inhibited due to impaired cholesterol transport to lysosomes. Moreover, in cells lacking the lysosomal cholesterol exporter, Niemann-Pick C1 (NPC1), unopposed ER-to-lysosome transport by OSBP drives aberrant buildup of cholesterol on the lysosomal limiting membrane. Consequently, genetic and small molecule-mediated inhibition of OSBP selectively reverses cholesterol accumulation on the limiting membrane but not in the lumen of NPC1-null lysosomes, suppresses aberrant mTORC1 signaling and restores defective autophagy, a major driver in the pathogenesis of Niemann-Pick type C. Thus, ER-lysosome contacts emerge as signaling hubs that enable cholesterol sensing by mTORC1, and their manipulation via OSBP inhibitors could be beneficial in Niemann-Pick type C and mTORC1-driven diseases.

P2170/B418

A Forward Genetic Screen to Identify Novel Regulators of Vacuole Inheritance.

A. Habib[1], M. Lis-Planells[1], E. Kauffman[1], L. S. Weisman[1,2]; [1]Life Sciences Institute, University of Michigan, an n Arbor, MI, [2]Department of Cell & Developmental Biology, University of Michigan, an n Arbor, MI.

Organelles such as the endoplasmic reticulum, mitochondria, and lysosomes are inherited during eukaryotic cell division. Little is known about the pathways that regulate organelle inheritance or how it is coordinated with the cell cycle. The baker's yeast, Saccharomyces cerevisiae, partitions its vacuole and transports a portion of it into the growing daughter cell during budding. The vacuole is similar to the mammalian lysosome and is responsible for critical metabolic processes such as macromolecule recycling, ion homeostasis, and cell cycle progression. These aspects make budding yeast an ideal organism for studying organelle inheritance. While some of the mechanisms that regulate vacuole inheritance have been uncovered, we hypothesize that there are many components of the pathway that remain to be discovered. To find novel regulators of vacuole inheritance, we are conducting a forward genetic screen to identify mutants in the pathway. We began by treating yeast cells with a red

fluorophore, FM4-64, which specifically labels the vacuole. This labelling allows us to visualize the yeast vacuole either by fluorescence microscopy or flow cytometry. Mutants in vacuole inheritance that are unable to transport the vacuole during budding accumulate vacuoles in the mother cell and lack vacuoles in daughter cells. After labelling the vacuoles, we compared the flow cytometry profiles of known vacuole inheritance mutants with wild-type cells. We assessed both cell size and fluorescence and determined properties that distinguished between mutant and wild-type yeast. We then treated wild-type yeast with the chemical mutagen, ethyl methanesulfonate, and used a fluorescence activated cell sorter along with our predetermined paramaters to enrich for vacuole inheritance mutants. Potential hits were isolated and visualized under the microscope to determine if they have a vacuole inheritance defect. This technique enabled us to identify approximately one mutant colony per fifty colonies screened. We have currently found several mutants that cannot properly inherit the vacuole. After screening we will identify the causative mutations using pooled linkage analysis and whole genome sequencing. Further experiments will include conducting biochemical and genetic assays to determine binding partners of these proteins as well as their catalytic activity. Overall, these studies will identify novel regulators of vacuole inheritance.

P2171/B419

The Lipid Kinase, Vps34, Is a Driver of Selected Membrane Trafficking Pathways.

N. Steinfeld, V. Lahiri, A. Morrison, D. J. Klionsky, L. S. Weisman; University of Michigan, an n Arbor, MI.

Phosphoinositide lipids are low-abundance signaling molecules that control signal transduction pathways and are necessary for cellular homeostasis. The phosphoinositide lipid, phosphatidylinositol 3-phosphate (PI3P), recruits downstream effector proteins to control a wide-range of membrane trafficking events. In the budding yeast, *Saccharomyces cerevisiae*, Vps34, a phosphatidylinositol 3-kinase, is the sole source of PI3P. PI3P is required for several cellular processes including synthesis of $PI3,5P_2$, retromer function, autophagy, and formation of multivesicular bodies via the ESCRT machinery. Moreover, PI3P levels are acutely elevated in response to some stimuli, which suggests that dynamic changes in PI3P drive some downstream pathways. This possibility would not be revealed in most studies, which utilize knock-down or knock-out approaches. Here we seek to extend current knowledge by determining the consequences of increasing PI3P levels. We designed a hyperactive mutant based on a high-resolution structure (Rostislavleva et al., Science 2015) combined with a study that suggested that activation of Vps34 occurs in part via dissociation of the Vps34 kinase domain from its scaffold protein, Vps15 (Stjepanovic et al., Mol. Cell 2017). In addition, we identified Vps34 mutants that increase PI3P levels by screening for mutants that suppress an impaired growth phenotype of a catalytically damaged Vps34 allele. These hyperactive mutants increase cellular PI3P as well as $PI3,5P_2$ levels both at basal conditions and during hyperosmotic shock. Study of these hyperactive mutants has revealed that elevation of PI3P selectively drives certain trafficking pathways while not affecting, or even inhibiting others. Hyperactive Vps34 alleles were found to enhance Snx4-dependent retrograde traffic of Atg27 from the vacuole membrane. In contrast, ESCRT- and membrane fusion-dependent degradation of the plasma membrane methionine transporter, Mup1, following addition of methionine, is unchanged by elevated PI3P. Finally, our data suggests that while autophagy induction is unchanged by excess PI3P, increasing PI3P levels correlates with increasing defects in the degradation of autophagy cargoes. This phenotype may be due to defects in maturation of autophagosomes, their fusion with the vacuole, and/or the proteolytic capacity of the vacuole. Taken together, our data suggests that changes in phosphoinositide lipid levels may provide a way for cells to acutely respond to some stimuli. More

broadly, the approach of using hyperactive mutants can be applied to other lipid kinases and may contribute insights into phosphoinositide lipid signaling.

P2172/B420

Programmable Signaling Endosome Nexus in Regulating Receptor Recycling and Cancer Cell Migration.

P. Chen; IBMB, College of Medicine, National Taiwan University, Taipei, TAIWAN.

Phenotypic plasticity of cancer is modulated by multiple mechanisms including altered receptor trafficking and signaling downstream of gain-of-function (GOF) mutant p53. Reciprocal crosstalk of endocytic trafficking and receptor signaling function as a flexible network to increase the complexity of signaling output to regulate tumor plasticity. We report that neuronal-enriched dynamin-1 isoform (Dyn1) is up-regulated at both the mRNA and protein levels in a manner dependent on expression of GOF mutant p53. Dyn1 is required for the recruitment and accumulation of the signaling scaffold, APPL1, to a spatially localized subpopulation of endosomes at the cell perimeter. The perimeter APPL1 endosomes modulate Akt signaling and activate Dyn1 to create a positive feedback loop required for rapid recycling of EGFR and β1 integrins, increased focal adhesion turnover, and cell migration. Thus, Dyn1- and Akt-dependent perimeter APPL1 endosomes function as a nexus that integrates signaling and receptor trafficking, which can be co-opted and amplified in mutant p53-driven cancer cells to increase migration and invasion. This work exemplifies the signaling endosomes are programmable in response to signaling to create positive and/or negative feedback loops to regulate cancer cell phenotypic plasticity. More work is needed to further disclose the role of programmable signaling endosomes in modulating cancer progression.

Post-Golgi Trafficking

P2173/B421

Dopey1-Mon2 Complex Binds to Dual-lipids and Recruits Kinesin-1 for Centrifugally Biased Bidirectional Trafficking Around the Golgi.

D. Mahajan, H. Tie, B. Chen, **L. Lu**; Nanyang Technological University, Singapore, SINGAPORE.

In the secretory and endocytic pathway, the centripetally positioned Golgi complex exchanges membrane carriers with centrifugally or peripherally positioned organelles such as the ER, endolysosome and plasma membrane (PM). While it is known that microtubule motors can drive organelle positioning and membrane trafficking along microtubule tracks, it is currently unclear how they work at the molecular and cellular level in *vivo*. We found that Dopey1 and Mon2, two poorly characterized Golgi peripheral membrane proteins, can assemble into a novel complex. The Dopey1-Mon2 complex is a heterotetramer comprising a Mon2 homodimer interacting with two copies of Dopey1. Within the complex, three novel domains were identified that can directly interact with KLC2 subunit of kineisn-1 holoenzyme, phosphatidylinositol-4-phosphate (PI4P) and phosphatidic acid (PA). The membrane association of the complex requires both PI4P and PA. We uncovered that the complex functions as a kinesin-1 adaptor by linking PI4P-PA-positive organelles, including the Golgi, ER exit site and endolysosome, and carriers budded from them. Through extensive quantitative imaging, we systematically investigated the complex's function in organelle positioning and membrane trafficking to and from the Golgi. We discovered that it is essential for the peripheral positioning of the ER exit site and endolysosome and the expansion of the Golgi; it promotes the centrifugally directed trafficking

pathways, including the Golgi-to-PM and Golgi-to-ER, and inhibits the centripetally directed ones, including ER-to-Golgi and PM-to-Golgi. In conclusion, Dopey1-Mon2 complex is a dual-lipid-regulated cargo-adaptor that recruits kinesin-1 motor for centrifugally biased bidirectional transport around the Golgi. The identification of Dopey1-Mon2 complex therefore provides an important missing link to coordinate the budding of a membrane carrier and subsequent bidirectional transport along the microtubule network.

P2174/B422

Lack of Rho Activity Contributes to Transcytotic Apical Protein Targeting in Hepatocytes.

F. Lázaro-Diéguez, A. Müsch; Albert Einstein College of Medicine, Bronx, NY.

Protein targeting within cells is crucial for maintaining cell function. In columnar epithelial cells, such as those of the kidney, targeting apical and basolateral proteins to different plasma membrane domains from the *trans*-Golgi network (TGN), requires their segregation into distinct transport carriers. Hepatocytes target apical proteins predominantly by means of a mechanism known as transcytosis in which TGN-derived cargo is targeted first to the basolateral sinuisoidal domain before its arrival at the apical canalicular domain. The molecular mechanisms underlying transcytotic apical targeting in hepatocytes are poorly understood. Specifically it is unknown whether apical and basolateral proteins are segregated during TGN to surface targeting. Here we examined the exit and trafficking of apical (human dipeptidyl peptidase IV) and basolateral (vesicular stomatitis virus glycoprotein) cargo in live hepatocytic epithelial cells by dual-colour confocal and TIRF microscopy. We observed a predominant simultaneous exit of apical and basolateral proteins from the TGN into common tubular carriers that eventually connect and fuse with plasma membrane in hepatocyte-derived WIF-B9 cells and primary cultures of hepatocytes. Rho activation decreases the formation of tubular TGN-derived carriers and promotes the segregation of apical from basolateral proteins into separate vesicles. These findings suggest the lack of a Rho-dependent scission mechanism at TGN-derived tubules in hepatocytic cells, a phenotype that potentially contributes to the hepatocyte transcellular transport function.

Ric1 Regulates Trans-golgi Trafficking of Procollagen and Is Linked to a Complex Human Syndrome.

E. W. Knapik[1], G. Unlu[1], A. Rushing[1], E. Gamazon[1], F. S. Alkuraya[2], N. J. Cox[1]; [1]Vanderbilt University Medical Center, Nashville, TN, [2]Department of Genetics, King Faisal Specialist Hospital and Research Center, Riyadh 11211, SAUDI ARABIA.

Procollagen presents a unique challenge for the secretory pathway because of its bulky rod shape and large secretory volumes during organ morphogenesis. Components of the early secretory pathway machinery transporting extracellular matrix molecules (ECM) were identified, but the distal, post-Golgi components are sparsely known. Using a zebrafish phenotype-driven forward genetic screen and positional cloning of the *round*mutations, we discovered that the *ric1*gene is essential for normal skeletal biology. We show in vivo and in cell culture that activation of Rab6a GTPase by the Ric1-Rgp1 GEF complex is required for procollagen secretion through the Trans-Golgi-Network (TGN) en route to extracellular space. The requirement for the GEF can by bypassed by the constitutively active Rab6a and leads to cell autonomous release of the backlogged collagen. Zebrafish*round*mutations cause chondrocyte dysfunction, musculoskeletal and cranio-dental malformations. Quantitative genetics approaches using gene-based PheWAS by PrediXcan in the BioVU biobank revealed highly significant

associations with skeletal and dental defects in patients with reduced genetically predicted expression of the *RIC1*gene, thereby corroborating the zebrafish phenotypic findings. Furthermore, individuals homozygous-by-descent for a rare variant in *RIC1*were discovered to have many signs of the BioVU associated phenome including cleft lip, cataract, tooth abnormality, intellectual disability, facial dysmorphism and ADHD. Zebrafish and patient skin fibroblasts accumulate intracellular procollagen in TGN, and the human *RIC1*variant fails to rescue the procollagen secretory defects in zebrafish *round*mutants, unlike wild type *RIC1,*establishing the pathogenicity of the variant and evolutionary conservation of this novel procollagen secretory pathway. Taken together, our data indicate that RIC1-RGP1 complex is essential for collagen secretion and normal human development

P2176/B424

Visualization and Molecular Dissection of Collagen IV Secretion in Mouse Epithelial Cells.

S. Wang, K. Matsumoto, K. M. Yamada; National Institute of Dental and Craniofacial Research, NIH, Bethesda, MD.

Collagen IV is a major component of the basement membrane matrix that demarcates epithelial tissues. To facilitate the secretion of 400 nm-long collagen IV protomers, collagen IV mRNAs are known to be basally polarized in follicle epithelial cells of the Drosophila egg chamber. In contrast, we observed unexpected strong apical polarization of collagen IV mRNAs in the outer epithelial cells of mouse embryonic salivary glands using single molecule RNA fluorescence in situ hybridization (smFISH). Moreover, both the endoplasmic reticulum (ER) and the Golgi apparatus were also apically polarized in these cells, indicating the site of collagen IV production was opposite to its site of deposition. To visualize intracellular trafficking, we constructed lentivirus vectors expressing mNeonGreen-tagged collagen IV. The tagged collagen IV could incorporate into the basement membrane of lentivirus-transduced salivary glands, indicating it is at least partially functional. Separately, we used lentiviruses to establish a clonal mouse epithelial cell line stably expressing both mNeonGreen-tagged collagen IV and Cas9. These cells can secrete a dense layer of fluorescent matrix on the ventral (substrate) side. Inside these cells, we observed dynamic collagen IV vesicles with no obvious patterns of movement, presumably because the vesicles were at different stages of secretion. To elucidate the dynamics of secretion, we established a RUSH (retention using selective hooks) assay to synchronize collagen IV secretion by co-expressing an ER-resident streptavidin and a collagen IV subunit tagged with a streptavidin binding peptide (SBP) and mScarlet. We showed that biotin addition quickly released collagen IV from ER retention, and it first became enriched at the Golgi and then secreted from the cells to incorporate into the underlying matrix. Using CRISPR/Cas9, we showed that the amount of collagen IV secretion was reduced or eliminated when Serpinh1 (the collagen-specific chaperone HSP47), Mia3 (mammalian Tango1 homolog required for large COPII vesicle formation), Kif5b (a transport kinesin), or Rab6a were each knocked out. We further demonstrated that the collagen IV secretion eliminated in clonal Rab6a knockout cells could be rescued by expressing mScarlet-Rab6a. On the other hand, Rab10 knockout completely disrupted the polarized distribution of secreted collagen IV matrix without significantly affecting the amount of secretion. In summary, we have established a system for visualizing synchronized collagen IV secretion and demonstrated the importance of several molecular machineries for collagen IV secretion in mouse epithelial cells. We will further pursue the mechanisms underlying polarized collagen IV secretion and evaluate these findings in mouse salivary glands.

A Complex of Conserved Proteins Regulates Ap-1 Functions in Yeast.

C. J. Zysnarski, L. Marmorale, F. T. Javed, J. Y. Martinez-Marquez, J. W. Trowbridge, S. Lahiri, **M. C. Duncan**; University of Michigan, an n Arbor, MI.

The clathrin adaptor protein complex-1 (AP-1) plays a central role in membrane traffic at the *trans*-Golgi network (TGN). It is thought to mediate protein sorting by forming a physical link between clathrin and its membrane embedded cargo. The association of AP-1 with membranes is therefore critical for accurate proteins sorting. Several factors are known to contribute to AP-1 membrane association including phosphatidyl-inositides and Arf-GTPases. In addition, proteins of the conserved HEATR5 family play a conserved but poorly understood role in AP-1 membrane association. Although HEATR5 proteins were identified in AP-1 interactomes, HEATR5 proteins do not contain obvious AP-1 binding sequences, suggesting that their interactions with AP-1 are indirect. Indeed, the mammalian family member HEATR5b is known to interact with two proteins that themselves directly interact with AP-1. However, neither protein is conserved outside of animals suggesting that they may perform activities unique to animal cells. In order to better understand conserved HEATR5 functions, we used a combination of bioinformatics techniques and mass-spectrometry of purified complexes to identify binding partners for the yeast HEATR5 protein Laa1. Combined these approaches identified two conserved co-factors of Laa1 that are essential for the normal association of AP-1 with the TGN. We found that the co-factor Laa2, a likely homolog of mammalian Clba1, binds directly to AP-1. We mapped the interaction of Laa2 with AP-1 to a single canonical AP-1 binding motif in the N-terminus of Laa2. We found that this interaction is essential for the normal association of AP-1 with the TGN in yeast. This approach also identified a poorly characterized GTPase binding protein as a Laa1 binding co-factor. We found that this co-factor is required for Laa1 and AP-1 membrane association. This suggests that Laa1 may integrate signals from multiple GTPases at the TGN. Together these results indicate that Laa1 functions in a complex with other conserved proteins that works in parallel with phosphatidyl-inositides and Arf-GTPases to mediate the stable membrane association of AP-1.

Distinct Roles for Secretory Pathway Acidification during Apical Membrane Biogenesis in Enterocytes.

D. S. Levic[1], S. Ryan[2], L. Marjoram[1], J. Bagwell[1], M. Bagnat[1]; [1]Duke University, Durham, NC, [2]St. Bonaventure University, St. Bonaventure, NY.

Epithelial cell physiology critically depends on the asymmetric distribution of channels, transporters and other membrane proteins. However, little is known of how proteins are targeted to the apical membrane in vivo. Here, we performed a visual forward genetic screen in zebrafish and identified recessive mutants defective in apical targeting of p75, an O-glycosylated membrane protein, in the intestine. One of these mutants, atp6ap1, revealed specific requirements for luminal acidification in apical, but not basolateral, membrane protein transport. Using a visual assay based on the classical low temperature block, we were able to monitor transport of newly synthesized membrane proteins from the trans-Golgi network to the plasma membrane in live zebrafish larvae. Combining this approach with genetic and pharmacologic perturbation of luminal pH, we show that vacuolar H+ ATPase (V-ATPase) activity regulates sorting of O-glycosylated proteins at the TGN as well as Rab8-dependent trafficking of apical membrane proteins. Thus, luminal acidification plays distinct and specific roles in apical membrane biogenesis.

P2179/B427

Unfolded Protein Response Regulates Arf-GAP Gcs1 Phosphorylation to Modulate Arl1 GTPase Activation.

Y. Wu[1], W. Chiu[1], C. Yu[2], F. Lee[1]; [1]Institute of Molecular Medicine, College of Medicine, National Taiwan University, Taipei, TAIWAN, [2]Department of Cell and Molecular Biology, Chang Gung University, Tao-Yuan, TAIWAN.

ADP-ribosylation factor (Arf) and Arf-like (Arl) small GTPases are known to play important roles in membrane trafficking. In *Saccharomyces cerevisiae*, the guanine nucleotide-binding cycle of Arl1 is converted by the guanine nucleotide exchange factor (GEF), Syt1, and the GTPase activating protein (GAP), Gcs1. The induction of ER stress affects many molecular pathways that cause the unfolded protein response (UPR). We previously demonstrated that UPR signaling regulated phosphorylation of Syt1, which is critical for Arl1 activation and recruitment of golgin protein Imh1 to the Golgi. However, the detailed mechanism of how Gcs1 is regulated to access the Golgi membrane and promote GTP-hydrolysis of Arl1 upon UPR induction remains unclear. Based on the prior large-scale screening, Gcs1 harbors numerous putative phosphorylation sites. Here, we showed that Gcs1 was phosphorylated upon treatment of UPR-inducer tunicamycin. By mass spectroscopy, we identified several phosphorylation sites on Gcs1 upon UPR activation. We observed that the phosphorylation decreased the association of Gcs1 to the Golgi membrane. The phosphorylated Gcs1 weakens its ability to access Arl1 that supports an increase of Arl1 and Imh1 puncta under UPR activation. Interestingly, the trigger of Gcs1 phosphorylation upon UPR activation is not dependent on a well-known Ire1-Hac1 signaling pathway, but rather a Slt2-related pathway. Furthermore, Slt2-deletion attenuates an increase of Arl1-mediated golgin Imh1 puncta upon UPR induction. Thus, we infer that the regulation of Gcs1 phosphorylation is critical for modulating the Arl1 function upon ER stress.

Ags3 Transport E-cadherin to Memberane during Embryonic Development in Mice.

Z. Nie, Y. Niu, W. Zhou, D. Zhou, X. Cui; Chungbuk national university, Cheongju, KOREA, REPUBLIC OF.

Activator of G protein signaling 3 (AGS3) alters trans-golgi network structure and function by binding of its GoLoco motif (GPR domain) to Gαi and activating G protein signaling, and therefore regulates transport of proteins to plasma membrane. Compaction of early embryo is based on accumulation of E-cadherin at cell-contect membrane. However, whether and how AGS3 regulates polar transport of E-cadherin to plasma membrane are unknown. To make these clear, AGS3 of mouse early embryo was knocked out by Cas9-sgRNA systerm. In addition, trans-golgi network protein 46 (TGN46) and transmembrane P24 trafficking protein 7 (TMED7) were traced in embryos by fusion to fluorescent protein label. In results, embryos in control group successfully developed to blastocyst stage, E-cadherin was localizated at cell-contect membrane, and trans-golgi network and TMED7-positive vesicle gradually aggregated near to cell-contect membrane; however, most of *AGS3*-edited embryos in knockout group were arrested and fragmented since 4-cell stage with decreased accumulation of E-cadherin at the membrane, trans-golgi network and TMED7-positive vesicle were dispersive and could not be polarized to the membrane. In addition, decreased Gαi3 could rescued these *AGS3*-edited embryos in knockout group. These results indicate that AGS3 reinforces dynamic of trans-golgi network from 4-cell to MO stage by binding and activating Gαi3 at golgi complex. Activated Gαi3 disassociates from Gβγ and it

resulted in activation of G protein signaling at TGN and transport of TMED7-positive cargo containing E-cadherin to cell-contact membrane during mouse early embryo development.

P2181/B429

The Golgin Imh1 Mediates Recycling Transport of SNARE Upon ER Stress.

W. Chiu[1], Y. Chen[1], Y. Wang[1], C. Liu[1], F. S. Lee[1,2]; [1]Institute of Molecular Medicine, National Taiwan University, Taipei, TAIWAN, [2]Department of Medical Research, National Taiwan University Hospital, Taipei, TAIWAN.

Eukaryotic cells have developed conserved pathways to deal with the stress coming from accumulation of unfolded protein in ER. Induction of unfolded protein response (UPR) in yeast has been reported to enhance Arl1 GTPase activation, which promotes the recruitment of additional golgin Imh1 to the trans-Golgi network (TGN). Golgins play important roles in tethering membrane fusion and maintaining the structure of Golgi. However, it is unclear whether induction of additional golgin Imh1 structures associated with amplification of the TGN can alleviate the ER stress. Here, we report that Imh1 is required for transporting exocytic v-SNARE Snc1 from TGN to the plasma membrane upon induction of UPR. Snc1 is a v-SNARE which exocytoses to the plasma membrane and then recycles back to TGN through endosome. We first found that both Arl1 and Imh1 are required for the proper transport of Snc1 under Tunicamycin-induced UPR. Moreover, the N-terminal region of Imh1 is essential for restoring the plasma membrane localization of Snc1 under ER stress. Rab6/Ypt6 GTPase is known to regulate vesicle transport from endosome to the TGN via recruiting Golgi associated retrograde-protein (GARP) complex. We further show that Imh1 cooperates with GARP to assist the exocytosis of Snc1 upon the UPR induction. Thus, we propose a novel action of Arl1-Imh1 on establishing the environment at the TGN upon ER stress that is critical for the recycling of an exocytic SNARE.

Vamp4 Is a New Factors Involved in Membrane Remodeling of Immature Secretory Granules during Maturation.

M. Li, 100101; Instituted of Biophysics ,chinese Academy of science, beijing, CHINA.

Insulin secretory granules (ISGs) named as dense-core vesicles (DCVs), a group of distinguishing organelles in pancreatic β cells, are responsible for storage and secretion of insulin to maintain blood glucose homeostasis. Although the molecular mechanism of ISG exocytosis has been well characterized in the past few decades, the molecular mechanism of ISG maturation is largely unknown because of its high dynamics. In this study, we focused on the vesicle-associated membrane protein 4 (VAMP4) and demonstrated that it participated in the membrane remodeling during ISG maturation.

P2183/B431

Identification of an Arginine Permease Can1 as a Putative Cargo of Arl1 Small GTPase.

C. Wu[1], F. S. Lee[1,2]; [1]Institute of Molecular Medicine, National Taiwan University, Taipei, TAIWAN, [2]Department of Medical Research, National Taiwan University Hospital, National Taiwan University, Taipei, TAIWAN.

Recycling transmembrane nutrient transporters at the cell surface is critical for nutrient uptake and responses to extracellular signals. Nutrient transporters can be internalized from the plasma membrane

and delivered to early endosomes upon stimulation, then selected and sorted for recycling to the Golgi and subsequent delivery back to the cell surface. ADP-ribosylation factor-like protein 1 (Arl1) is an important regulator of intracellular vesicular trafficking in organisms ranging from yeast to mammals. Yeast Arl1 is known to regulate the transport of the GPI-anchored protein Gas1 from the late Golgi to the plasma membrane, however, whether it is involved in recycling vesicle transport remains unclear. Here, we identified an arginine permease Can1 as a putative cargo of Arl1 in recycling from endosome to the late Golgi. It is known that reduced Can1 cell-surface expression levels display resistance to the toxic arginine analog canavanine. Canavanine resistance (*cvr*) would result from reduced canavanine uptake due to defects in cell-surface targeting or recycling of the Can1 permease. We found that Arl1 as well as its upstream regulator Arl3 function in Can1 recycling transport, however Arl1-GEF Syt1 and Arl1-effector golgin Imh1 are not involved in. We observed that in *arl1Δ*, Can1-GFP is mislocalization and co-localized with TGN marker Sec7-mRFP. Using sucrose gradient centrifugation analysis, we demonstrated that the subcellular distribution of Can1 is altered in *arl1Δ* cells. In addition, Arl1-related proteins, Cog8, Ypt6, Vps53, are also involved in Can1 transport, which were also observed in Canavanine resistance plating assay and cell localization analyses. Finally, flippase Drs2, a complex with Arl1, is also able to regulate transportation of Can1. Taken together, our results suggest that Arl1 has a role in regulating Can1 recycling from endosome to the Golgi.

P2184/B432

Action of Arl1 GTPase and Golgin Imh1 in Ypt6-independent Retrograde Transport from Endosomes to the *Trans*-Golgi Network.

Y. Chen, I. Wang, Y. Wang, W. Chiu, J. Hu, W. Chen, F. Lee; Institute of Molecular Medicine, National Taiwan University, Taipei City, TAIWAN.

Action of Arl1 GTPase and golgin Imh1 in Ypt6-independent retrograde transport from endosomes to the trans-Golgi network the Arf and Rab/Ypt GTPases coordinately regulate membrane traffic and organelle structure. Studies and evidences have implied that the two families function in parallel; nevertheless the detailed mechanism between their complementation remained to be clarified. In this study, we found that Golgi-localized Arf, Arl1 and its effector, golgin Imh1, but not flippase Drs2 serve as high-copy suppressors of the defects in retrograde trafficking from endosome to *trans*-Golgi network (TGN) as well as high temperature growth retardation. Moreover, only Arl1 or Imh1, but not Arl3 or Syt1, interdependently restore the defects in ypt6-deleted cells. We further demonstrated that Arl1 and Imh1 reinforce the recruitment of the tethering factor, Golgi associated retrograde-protein (GARP) complex, to the TGN in the absence of Ypt6. To be more specific, the recruitment of GARP complex to TGN is essential for the suppression of the defects in ypt6-deleted cells. Interestingly, we found that the N-terminal domain of Imh1 is critical for restoring GARP complex localization and endosome-to-TGN transport in ypt6-deleted cells. Collectively, our study illustrates the mechanism underlying the suppression of Arl1 and Imh1 in endosome to TGN trafficking defects, revealing the involvement of GARP complex recruitment in the compensation for defects in dysfunctional Ypt6 conditions.

P2185/B433

α-Arrestins Regulation of Kir2.1 Potassium Channel Trafficking Depends on Select Trafficking Machinery in a Yeast Model System.

N. A. Hager[1], C. McAtee[1], M. Bruchez[2], A. V. Kwiatkowski[1], J. L. Brodsky[1], A. F. O'Donnell[1]; [1]University of Pittsburgh, Pittsburgh, PA, [2]Carnegie Mellon University, Pittsburgh, PA.

Protein composition at the plasma membrane is tightly regulated, with rapid protein internalization and selective targeting to the cell surface in response to environmental changes. Ion channels are dynamically relocalized to or from the plasma membrane in response to physiological changes, allowing organisms to maintain osmotic and salt homeostasis. Critical to cardiac function is the localization of Kir2.1, an inward rectifying potassium channel, at the cell surface. Kir2.1 restores the resting membrane potential of heart cells after each contraction and readies the cell for the next action potential. Defective Kir2.1 trafficking and activity is associated with diseases, including Andersen-Tawil syndrome, highlighting the importance of understanding Kir2.1 trafficking. We used a yeast model system where the endogenous potassium channels were deleted and Kir2.1 is expressed; Kir2.1 is able to promote yeast growth on low potassium medium. Using this system, we discovered that specific α-arrestins, an emerging class of protein trafficking adaptors, regulate Kir2.1. Specifically, we found that the Ldb19/Art1, Aly1/Art6, and Aly2/Art3 α-arrestin adaptor proteins promote Kir2.1 trafficking to the cell surface, increasing intracellular potassium levels. To better quantify the intracellular and cell surface populations of Kir2.1, we created fluorescence-activating protein fusions and for the first time used this technique to quantify the cell surface residency of a plasma membrane protein in yeast. We now aim to elucidate the trafficking machinery needed for the α-arrestin-dependent trafficking of Kir2.1. We have identified a number of trafficking factors utilized by the α-arrestins to regulate Kir2.1. α-Arrestin Aly1 requires the AP-1 complex, a clathrin adaptor complex thought to recruit clathrin to vesicles shuttling between the endosomes and the Golgi, to promote Kir2.1-mediated growth on low potassium. Curiously, α-arrestins Aly2 and Ldb19 did not require AP-1 for their role in promoting Kir2.1-mediated growth suggesting that these α-arrestins operate in distinct pathways. Instead, α-arrestin Aly2 is dependent on Vrp1, a protein needed for actin network formation at endocytic sites, and Npr1, a nutrient responsive kinase downstream of TORC1 known to phosphorylate Aly2. Together, our findings show that the α-arrestins function in multiple distinct pathways while trafficking a common cargo in Kir2.1. These multiple inputs on a single cargo may allow for plasticity in the regulation of Kir2.1 trafficking to fine tune Kir2.1 activity at the cell surface.

P2186/B434

Mal2 Function in Basolateral Secretion Is Likely Regulated by Serine Phosphorylation and Actin Binding.

S. S. Davis[1], A. L. Coral[2], P. Tuma[2]; [1]Catholic University, Washington DC, DC, [2]Catholic University of America, Washington DC, DC.

The focus of our laboratory is identifying and defining the mechanisms that regulate polarized sorting of newly synthesized apical and basolateral resident proteins and secreted proteins. For the past 15 years, we have been investigating the role of the tetraspanning integral membrane protein, MAL2 (myelin and lymphocyte protein 2), in these processes. We first confirmed that MAL2 functions in the transcyotic sorting of newly synthesized apical residents. We further determined that MAL2 selectively regulates the TGN to basolateral sorting of newly synthesized polymeric IgA receptor, and more recently, we

determined that MAL2 participates with its known binding partner, serine/threonine kinase 16, in the regulation of constitutive basolateral albumin secretion. To identify the molecular determinants in MAL2 that confer specificity to its function in each of these pathways, we generated a panel of MAL2 mutants. Unlike other MAL family members, only MAL2 encodes the N-terminally-located, cytoplasmically oriented VPPPP and FPAP sequences that resemble the F/L/W/YPPPP recognition sites for EVH1 (enabled, VASP, homology1) motifs present in Ena/VASP proteins. We have changed each of the two motifs to alanines either alone or together. We have also generated mutants in the N-terminally located, cytoplasmically-oriented ser17. In this case the ser was replaced to an ala or asp (a phospho-mimetic). We started our analysis with basolateral secretion assays. Our preliminary results indicate that cells expressing the FPAP (but not VPPPP) mutants displayed decreased albumin release implying a link to the actin cytoskeleton in MAL2 function in secretion. We also determined that expression of the S17A mutant led to impaired secretion implying MAL2 phosphorylation is important for its role in secretion. We are currently testing these mutants in transcytosis and basolateral membrane protein delivery to uncover whether these motifs selectively confer specificity to the different MAL2-mediated trafficking pathways.

P2187/B435

Exocyst Conformational Changes Control Interactions with SNARE and Sec1/Munc18 Proteins.

D. Lepore[1], M. Feyder[1], L. Martinez-Nunez[1], L. Kenner[2], A. Czuchra[1], G. Rossi[3], P. Brennwald[3], A. Frost[2], M. Munson[1]; [1]Department of Biochemistry and Molecular Pharmacology, University of Massachusetts Medical School, Worcester, MA, [2]Department of Biochemistry and Biophysics, University of California, San Francisco, CA, [3]Department of Cell Biology and Physiology, University of North Carolina School of Medicine, Chapel Hill, NC.

Membrane trafficking is an essential eukaryotic process necessary for a variety of cellular functions including, but not limited to, growth, cell division, motility, and signaling. The trafficking and fusion of cargo-containing vesicles with organelles and the plasma membrane is tightly regulated to ensure that proteins and lipids are delivered to their correct cellular destination. SNARE-mediated fusion is regulated by both Sec1/Munc18 (SM) proteins and multi-subunit tethering factors. The exocyst is a conserved, hetero-octameric tethering complex that is essential for exocytosis. Several of the exocyst subunits interact directly with SNAREs and the SM protein Sec1, however it remains unclear how the full complex coordinates these interactions to regulate SNARE complex formation and membrane fusion. Intriguingly, we found that the assembled exocyst octamer interacts only weakly with SNAREs and Sec1, despite previously observed robust SNARE/Sec1 binding to individual recombinant exocyst subunits. We purified exocyst subcomplexes (modules) and showed that a module of exocyst has increased apparent affinities for SNAREs and Sec1, suggesting that SNARE/SM binding sites are occluded within the full exocyst complex. As we cannot detect the presence of this module in wild-type yeast, we propose that the octameric complex undergoes regulated conformational changes to interact with SNAREs/Sec1. We demonstrate that gain-of-function mutations of the exocyst subunit Exo70, previously shown to rescue the *cdc42-6* allele and *rho3Δ*, "activate" the complex by stimulating SNARE binding without disassembling the complex. These activated exocyst complexes have an altered structure, as shown by negative stain electron microscopy, revealing that the SNARE/Sec1 binding subunit Sec6 is more dynamic and accessible than in the wild-type complex. We conclude that conformational changes of the exocyst complex regulate interactions with SNAREs and Sec1 to control SNARE-mediated membrane fusion during exocytosis.

P2188/B436

Tumor Protein D54 Defines a New Class of Intracellular Transport Vesicle.

G. Larocque, **S. J. Royle**, P. J. La-Borde, N. I. Clarke, N. J. Carter; University of Warwick, Coventry, UNITED KINGDOM.

Transport of proteins and lipids from one membrane compartment to another is via intracellular vesicular carriers. Several classes of carrier have been described based on morphology, location and function. For example, clathrin-coated vesicles (50-100 nm diameter) formed at the plasma membrane or trans-Gogi network (TGN), COPII-coated vesicles (60-70 nm) originating at the endoplasmic reticulum (ER), and intra-Golgi transport vesicles (70to90 nm). Whether cell biologists have a complete inventory of all classes of transport vesicle is an interesting open question. We began by investigating the function of Tumor Protein D54 (TPD54/TPD52L2), a member of the TPD52-like family. TPD54 is one of the most abundant proteins in HeLa cells but its function is unclear. We found that TPD54 was involved in multiple membrane trafficking pathways: anterograde membrane traffic, recycling endocytosed proteins back to the cell surface and Golgi integrity. To understand how TPD54 controls these diverse functions, we used an inducible method to reroute TPD54 to mitochondria. Surprisingly, this manipulation resulted in the capture of many small vesicles (30 nm diameter) at the mitochondrial surface. Superresolution imaging confirmed the presence of similarly sized TPD54-positive structures under normal conditions. We demonstrated that INVs meet three criteria for vesicle functionality. They contain specific cargo, they have certain R-SNAREs for fusion, and they are endowed with a variety of Rab GTPases (16 out of 43 tested). We propose that TPD54 defines a new class of transport vesicle, which we term intracellular nanovesicles (INVs). Visible by EM, INVs are small and uncoated; likely escaping previous detection due to their inconspicuousness. The molecular heterogeneity of INVs and the diverse functions of TPD54 suggest that INVs have diverse membrane origins and are likely to have a number of destinations. We conclude that INVs are a generic class of transport vesicle which transfer cargo between these varied locations.

P2189/B437

The Transmembrane Domain of Single-spanning Transmembrane Proteins Contributes to Intra-Golgi Membrane Localization and Export.

P. Lujan Miralles[1], J. van Galen[2,3], V. Malhotra[2,3,4], M. García-Parajo[1,4], F. Campelo[1]; [1]ICFO - the Institute of Photonic Sciences, Castelldefels (Barcelona), SPAIN, [2]CRG - Centre for Genomic Regulation, Barcelona, SPAIN, [3]UPF - Universidad Pompeu Fabra, Barcelona, SPAIN, [4]ICREA - Insitució de Reserca Catalana, Barcelona, SPAIN.

The Golgi complex is the central organelle of the secretory pathway, where secretory proteins are glycosylated and sorted for their export to other parts of the cell. Cargo glycosylation needs to follow a sequential order, achieved thanks to the polarized organization of the Golgi complex, formed by a stack of biochemically-distinct flat cisternae. However, how secretory cargoes visit first the membrane regions enriched in glycosylation enzymes before being exported is still not fully understood. Different protein retention mechanisms have been proposed, such as recognition of cytoplasmic motifs, protein oligomerization, or mechanisms based on the biophysical properties of the membrane. Amongst these, the hydrophobic matching hypothesis suggests that single-spanning transmembrane proteins preferentially partition into membranes with a thickness that matches the hydrophobic length of the

protein transmembrane domain (TMD). According to this hypothesis, Golgi-resident enzymes and secretory cargoes -due to their distinct TMD properties- segregate into membrane domains of different thickness, so-called processing and export domains, respectively. However, this hypothesis has not been fully tested for intra-Golgi protein localization. To test the contribution of the hydrophobic matching mechanism to the sorting of resident and secretory single-spanning transmembrane proteins at the Golgi membranes, we focused on the *trans*-Golgi enzyme sialyltransferase (ST), and TGN46, a protein that cycles between the *trans*-Golgi Network (TGN) and the plasma membrane. We first established by fluorescence confocal and super-resolution microscopy their localization in different regions of the *trans*-Golgi/TGN membranes. Since these proteins' TMD length and amino acid composition are different, we tested their involvement in intra-Golgi differential partitioning. Our results show that neither the length nor the amino acid composition of the TGN46 TMD dictates intra-Golgi localization or glycosylation status. Similarly, increasing the TMD length of ST does not alter its intra-Golgi localization. Moreover, our data suggests that the cytosolic domain of TGN46 is a signal for its intra-Golgi localization. However, adding this domain to ERGIC53, a protein that does not traffic beyond the *cis*-Golgi, is not sufficient to localize it to the TGN, suggesting that the TMD is also required for this purpose. Interestingly, we found that the TMD composition is important for the efficient export of TGN46, as shown by FLIP microscopy. Based on our findings, we suggest that the hydrophobic matching mechanism drives intra-Golgi protein localization together with other stronger signals, and it also contributes to the efficient export of secretory cargoes from the TGN.

P2190/B438

Measuring CD147 and MCT1 Dynamics with an ARE-containing Tetracycline Induction System.

A. R. Lowe, E. N. Robinson, J. Castorino; Hampshire College, Amherst, MA.

The transmembrane glycoprotein CD147 (Emmprin, Basigin, BSG) is highly expressed in many forms of cancer. Shortly after CD147 is synthesized in the endoplasmic reticulum, it interacts with members of the monocarboxylate transporter (MCT) family before being trafficked through the Golgi apparatus and trafficking vesicles on the way to the plasma membrane. It is established that CD147-MCT interaction is required in order for either CD147 or MCTs to be expressed at the plasma membrane. However, whether the complex created between MCTs and CD147 remains intact throughout the dynamics of trafficking, or if the complex is broken and the proteins act on their own remains unknown and is the aim of our study. Using fluorescence microscopy, we show that the steady-state localizations of CD147, MCT1, and a fusion of CD147-MCT1 all differ. CD147 reaches the plasma membrane at a moderate level with some internalized vesicles. MCT1 is predominantly localized to internal vesicles. CD147-MCT1 predominantly localizes to the plasma membrane. This suggests that the composition of the complex impacts its function. These observations were made as constitutively expressed fusion proteins in their steady state. To assess the dynamics of the proteins, it is necessary to quantify protein synthesis and decay. We developed a modified tetracycline-inducible expression system for studying protein decay that avoids high cost (e.g. SNAP tagging) or use of radioactivity. Since the mRNA decay from the tetracycline expression system is too slow to accurately measure protein decay, we modified the expression system to include an Adenylate-Uridylate Rich Element (ARE) from the Insulin-like Growth Factor (IGF) in its 3' untranslated region. By quantitative RT-PCR, we show that the decay of mRNA containing the IGF-ARE is very rapid which allows for a close approximation of protein decay. By western blotting, we show the decay of CD147 protein expressed individually versus a fusion of CD147-MCT1.

This system provides a tool for determining factors that contribute to the increased levels of CD147 found in cancer cells.

P2191/B439

Effects of Oxidative Stress on Expression of Arf Guanine Nucleotide-exchange Factors BIG1 and BIG2.

C. Li[1], C. Lin[1], C. Shen[2]; [1]National Cheng Kung University, Tainan, TAIWAN, [2]National Health Research Institutes, Tainan, TAIWAN.

Brefeldin a (BFA)-inhibited guanine nucleotide-exchange protein BIG1 and BIG2 that are encoded by the ADP-ribosylation factor guanine nucleotide-exchange factor (*Arfgef*)*1* and *Arfgef2* genes, respectively, were initially purified together in a multiprotein complex from bovine brain cytosol. These GEFs are 74% identical in amino acid sequences and with 90% identity in the Sec7 domains that responsible for ADP-ribosylation factor (Arf) activation. BIG1 and BIG2 accelerate the replacement of Arf-bound GDP with GTP to help the formation of intracellular vesicles for cargo transport between the Golgi, endosomal compartments, and the plasma membrane. It has been reported that BIG1 knockdown promotes glioblastoma U251 cell migration and down-regulation of BIG1 by miR-215 inhibited papillary thyroid cancer cell proliferation. The amount of migration-related molecules altered by the increase of HIF-1α expression under hypoxic stress is an essential event in the activation of cell motility. It remains unknown whether BIG1 and BIG2 could be regulated by hypoxia. Here, protein and mRNA levels of BIG1 and BIG2 were assessed in U251 cells treated with the hypoxic mimetic agents, DMOG and $CoCl_2$. We also generated the stably BIG1- or BIG2-knockdown cells by short hairpin RNA (shRNA) to investigate the functional roles of BIG1 or BIG2 in cell morphology, cell motility and cell proliferation. Taken together, our data provide information of effects of hypoxic stress on BIG1 and BIG2 expression and the roles of BIG1 and BIG2 on U251 cell migration and cell proliferation.

Extracellular Vesicles

P2192/B440

Phluo_m153r-cd63, a Bright, Versatile Live Cell Reporter of Exosome Secretion and Uptake, Reveals Pathfinding Behavior of Migrating Cells.

B. Sung[1], A. von Lersner[1], J. Guerrero[2], D. Inman[2], R. Pelletier[1], A. Zijlstra[3], S. M. Ponik[2], A. M. Weaver[1]; [1]Vanderbilt University, Nashville, TN, [2]University of Wisconsin-Madison, Madison, WI, [3]Vanderbilt University Medical Center, Nashville, TN.

Small extracellular vesicles called exosomes affect a variety of autocrine and paracrine cellular phenotypes, including cellular migration, immune activation, and neuronal function. Understanding the function of exosomes requires a variety of tools, including live cell imaging. We previously constructed a live-cell reporter, pHluorin-CD63, that allows dynamic subcellular monitoring of exosome secretion in migrating and spreading cells. However, there were some caveats to its use, including dim fluorescence and the inability to make cell lines that stably express the protein. By incorporating a stabilizing mutation in the pHluorin moiety, M153R, pHluorin-CD63 now exhibits higher and stable expression in cells and superior monitoring of exosome secretion. Using this improved construct, we demonstrate visualization of secreted exosomes in 3D culture and in *vivo* and identify a role for exosomes in promoting leader-follower behavior in 2D and 3D migration. By incorporating a further non-pH-sensitive

red fluorescent tag, this reporter allows visualization of the exosome lifecycle, including multivesicular body (MVB) trafficking, MVB fusion, exosome uptake and endosome acidification. This new reporter will be a useful tool for understanding both autocrine and paracrine roles of exosomes.

P2193/B441

A Genetically Encoded Nanobody Reveals the Mechanism of Extracellular Vesicle Cargo Release in Cells.

B. S. Joshi, M. A. d. Beer, B. N. G. Giepmans, I. S. Zuhorn; University Medical Center Groningen, Groningen, NETHERLANDS.

Cell to cell communication takes place through direct contact between cells and via secreted factors such as small molecular messengers and extracellular vesicles (EVs). EVs contain biomolecules such as proteins, lipids, and nucleic acids and mediate a myriad of cellular processes including regeneration, development, immune response and disease pathogenesis. They also show promise as drug delivery vehicles owing to their low immunogenicity, cell specificity, and efficient biomolecule delivery. In order to induce functional changes in recipient cells, EVs need to unload their contents. Currently, the mechanism of cytosolic delivery of EV cargo remains largely unknown. Using a cytosolic probe, i.e., a genetically encoded nanobody that specifically binds to EV cargo, combined with correlative light and electron microscopy (CLEM), we show that EV cargo is released from endosomes through EV-endosome membrane fusion. Specifically, cytosolic exposure of EV cargo was detected by nanobodies, resulting in the formation of nanobody punctae. Subsequent CLEM of the nanobody punctae revealed late endosomes/multivesicular bodies as the underlying cellular compartments from where cargo release takes place. Neutralization of endosomal pH and accumulation of endosomal cholesterol blocked cargo release, showing that EV cargo release is dependent on endosomal pH and cholesterol level. Furthermore, the absence of endosome permeabilization in EV-treated cells showed that membrane fusion is the mechanism behind cargo release. We show that genetically encoded nanobodies that recognize EV content offer an excellent approach to study both the mechanism and efficiency of EV cargo release in cells. Our findings provide a foundation for EV-mediated drug delivery improvement and EV-mediated disease transmission prevention by stimulating and inhibiting EV-endosome membrane fusion, respectively.

Extracellular Vesicles from Differentiated Neuronal Cells Promote Neural Induction of Mesc through Cyclind1.

L. Song, R. Schekman; Department of Molecular and Cell Biology,University of California at Berkeley, Berkeley, CA.

Exosomes may contribute to a range of important biological processes by mediating the transfer of protein and RNA cargoes between cells. However, how exosomes function in developmental events such as in the differentiation and organization of nerve cells remains unclear. Here, we show dynamic changes in a physical property, the buoyant density, of extracellular vesicles secreted by PC12 cells stimulated with nerve growth factor (NGF) leading to neuronal differentiation. Exosomes secreted from differentiated PC12 cells and Neural 2A cells promote neural induction of mouse embryonic stem cells (mESCs). One protein that contributes to this induction is the cell cycle-related factor cyclinD1, which we find enriched within exosomes derived from differentiated neuronal cells. Exosomes purified from cells

overexpressing cyclinD1 were more potent in neural induction of mESC cells. Depletion of cyclinD1 from the exosomes reduced the neural induction effect. Our results suggest that extracellular vesicles regulate neural development through sorting of cyclinD1.

Anisotropic Cues Promote Symmetry Breaking to Initiate Migration of Adherent Cells.

D. Li, Y. Wang; Carnegie Mellon University, Pittsburgh, PA.

Symmetry breaking is the transition of cells from a symmetric to an asymmetric state. After symmetric spreading of adherent cells, symmetry breaking generates regions of protrusion and retraction, enabling cells to develop polarity and initiate migration. It is unclear if the timing of symmetry breaking is predominantly controlled by an internal timing mechanism, or whether it is responsive to external anisotropic cues such as confinement, substrate adhesiveness, and cell-cell contact. While these cues are known to affect the behaviors of post-symmetry breaking cells such as migration, their effects on symmetry breaking are less explored. By manipulating culture conditions or micropatterning the substrate, we show that NRK-52E epithelial cells and NIH 3T3 fibroblasts break symmetry at faster rates in response to anisotropic cues including cell-cell contacts, cell-substrate adhesions, and substrate stiffness. These cues may be located tens of microns away from the cell border. Furthermore, symmetry breaking may be promoted by asymmetric stimulation of either protrusion or retraction, with the former being more stimulative than the latter. Using pharmacological agents, we show that the promotion of symmetry breaking by anisotropic cues is dependent on the formin pathway, suggesting involvement of formin-dependent filopodia in probing the environment. While it is difficult to rule out an internal timing mechanism for symmetry breaking, our results suggest that mechanotransductive cues that regulate directed cell migration also provide effective stimulations for symmetry breaking, and that filopodia may play a central role of sensing for regulating both initial polarization and steady state migration.

Competing Forces Redistribute Surface Macromolecules during EF-directed Cell Migration.

A. Sarkar, M. A. Messerli; South Dakota State University, Brookings, SD.

DC electric fields (EFs) polarize cells, directing their migration and elongation. Cells sense and respond to EFs as weak as 10mV/mm, much weaker than EFs required to depolarize excitable cells. We propose that applied EFs polarize cells by redistributing plasma membrane macromolecules. Two competing forces in the plane of the plasma membrane control electromigration. Electrophoresis of surface macromolecules with net negative charge is toward the anode and electro-osmosis (electrically driven water flow) next to the negatively charged cell surface promotes water flow in the cellular boundary layer toward the cathode. We present a molecular flux model that predicts electromigration of membrane surface macromolecules based on the size and charge of the macromolecule, and the average surface charge of the cell. We have compared predictions of the flux model with the measured electromigration for the surface protein, tdTomato-GPI, under different EF strength and pH. We show that reduction of electro-osmosis with neutral, viscous polymers reverses the direction of migration

from cathode to the anode. We also describe a method for identifying the physical properties of plasma membrane proteins to predict the asymmetric redistribution of other surface macromolecules. These results are consistent with the model that applied EFs promote an asymmetric distribution of cell surface macromolecules while polarizing and directing cell migration during healing of chronic epidermal wounds and induction of cellular polarity during tissue engineering.

BRCA1 Haploinsufficiency Results in Aberrant Mammary Epithelial Cell Polarity.

V. V. Botchkarev, Jr., M. Gibson-Williams, D. M. Livingston; Dana-Farber Cancer Institute/Harvard Medical School, Boston, MA.

BRCA1 mutation-bearing (B1+/-) women are more likely to develop breast and/or ovarian cancer than their B1+/+ counterparts. Many such cancers have lost all intact B1 function implying that a full loss of B1 function in these particular cancers is a pivotal step in B1 breast cancer development. But how B1 loss translates into breast cancer development remains incompletely understood. In particular, the early events that occur following loss of B1 function, which lead to BrCa development, remain unclear. We have found that human mammary epithelial cells (HMECs) obtained from B1 mutation carriers (B1 wt/mut genotype), which are competent for multiple B1 functions, show aberrant polarity when grown in 3D cell culture unlike HMECs taken from healthy women. These cells are also defective in 2D migration. The polarity defects of primary B1 wt/mut HMECs were reproducibly detected when the cells from patients carrying different clinically-relevant B1 mutations were analyzed. This suggests that these phenotypic abnormalities represent a novel B1 haploinsufficiency phenotype in human mammary cells. Our data also suggest the existence of a new cell biological link between BRCA1 and the cytoskeletal cell motility machinery. Collectively, our work reveals a new haploinsufficient role for BRCA1 in maintaining normal mammary epithelial cell biology. A relevant question is whether this function is of clinical importance.

P2198/B447

Nuclear and Cytoskeleton Polarization in Differentiating Ipsc Derived Retinalpigmentepithelium.

R. Sharma, 20814[1,2], D. Ortolan[1,2], M. Nimmagadda[1,2], G. Liang[1], D. Bose[1], R. Dejene[1], K. Bharti[3]; [1]NEI/NIH, bethesda, MD, [2]National Eye Institute, Bethesda, MD, [3]NEI/NIH, BETHESDA, MD.

The inherent capacity of Pluripotent Stem Cells (PSCs) to differentiate into any cell type combined with the reporter Induced Pluripotent Stem Cell (iPSC) technology to tag endogenous proteins linked to the cytoskeleton, nuclear lamina or any other organelle with GFP allows visualization of cellular architecture remodeling during the differentiation process. We developed a protocol to differentiate iPSCs into fully polarized and functional retinal Pigment Epithelium (RPE) cells. This developmentally guided differentiation of iPSCs into RPE recapitulates the embryonic stages of RPE development from a proliferating neuroectoderm cell into post-mitotic RPE cell. Differentiation of RPE from reporter iPSCs with GFP-tagged nucleus and cytoskeleton proteins have allowed us to discover how RPE cells acquire polarization. Embryonically, RPE is of neuroectoderm origin. We used dual SMAD inhibition to generate neuroectoderm, directed the differentiation of neuroectoderm cells into RPE progenitors by inhibiting the FGF and TGF pathways, and addition of Activin-A induced the fate of RPE progenitors into the committed RPE cells. Cytoskeleton organization in a specific order is needed to attain complete polarization and hexagonal morphology of RPE cell in a monolayer. We used GFP tagged TUBA1B and

LAMINB iPSC lines from Allen Institute to determine changes in the arrangement of the cytoskeleton (tubulin filaments) and nuclear lamina during differentiation into RPE. iPSC cells were seeded on iBidi chamber slides for differentiation, fixed after the end of the early neuro-ectoderm phase, progenitor middle phase, and final RPE committed phase, stained for the early and late RPE specific markers and imaged using an LSM700 microscope. The expression levels of PAX6 and MITF, the RPE specific transcription factors determine the differentiation of neurectoderm to RPE progenitor cells. This work has provided an improved understanding of RPE polarization during differentiation from iPSCs.

P2199/B448

Shear Stress Modulation of Bmp/alk1 Signaling and Flow-polarization in Endothelial Cells Revealed by an All-in-one Multi-shear Stress Microfluidic Device.

Y. Cheng[1], U. Sonmez[2], W. Okech[1], B. L. Roman[1], L. A. Davidson[1]; [1]University of Pittsburgh, Pittsburgh, PA, [2]Carnegie Mellon University, Pittsburgh, PA.

Vascular morphogenesis is driven by proliferation and collective movement of endothelial cells (ECs). A hierarchically organized vascular network emerges during angiogenesis, and matures as blood vessels remodel. Defects in angiogenesis and remodeling, via overgrowth or inadequate network elaboration, lead to various diseases. To understand the origin of these defects we seek to understand how ECs respond to biomechanical and biochemical cues in their microenvironment. We focus on the effect of bone morphogenetic protein 9 (BMP9) since it has been shown to interact with the cellular receptor ALK1 to polarize EC cells, modulate EC migration, and direct vascular morphogenesis. To understand how flow and BMP9 interact we developed a microfluidic device together with a custom image analysis pipeline to quantify end-point immunofluorescence staining. Our device and flow protocols bracket physiological wall shear stress (SS) conditions in the artery environment to expose how ECs respond to both SS and growth factor stimulation. We named our microfluidic system "All-in-One" since it is capable of delivering multiple levels of laminar and gradient SS in different regions of the same device, so responses to biomechanical cues could be evaluated easily. To modulate biochemical cues we cultured confluent HUVECs in BMP-depleted serum for 4 hours, and then either added 2% FBS or kept ECs in BMP-depleted serum for 1 hour. After 1 hour of flow we observed pSMAD1/5/9 nuclear translocation and by 24 hours we found ECs aligned to the direction of the flow. When SS and ligands stimulated ALK1 signaling together, pSMAD translocation increased synergistically. Under conditions of reduced BMP9, nuclear translocation of pSMAD is strongly reduced. By comparing pSMAD translocation across many flow conditions, we find flow increased translocation but that the level of translocation was independent of the flow magnitude. All-in-One also allows quantification of cell polarity, defined as the vector from the center of the nucleus to the center of the Golgi apparatus. SS stimulation decreased the percentage of downstream-polarized ECs dependent on SS-magnitude (24±9% to 15±11%, $p < 0.05$ with t-test) while ligands increased the portion of upstream-polarized ECs (22±10% to 29±15%, $p < 0.05$ with t-test). Both high SS and serum stimulation reduced downstream-polarization and expanded the population of upstream-polarized ECs. Interestingly, the magnitude of SS has differing impact on ALK1 signaling and flow-aligned EC polarity; while flow-alignment depends on SS-magnitude, ALK1 signaling did not. To better understand the role ALK1 signaling play in EC migration, we plan to extend our microfluidic study to include high-resolution imaging of live ECs under spatially varying SS and BMP9 cues.

P2200/B449

Apico-basolateral Symmetry Breaking in the *C. Elegans* Intestinal Epithelium.

V. Naturale, J. L. Feldman; Stanford University, Stanford, CA.

Cells polarize by adopting spatially distinct structures and is an important process for cell and tissue function. One type of polarized cells is the epithelial cells that line tissues, which have an apical surface facing exteriorly or into a lumen and basolateral surfaces oriented into the body. During development, non-polarized precursors reproducibly define the location of this apico-basolateral axis in a process called symmetry breaking. Despite its requirement for polarization, epithelial symmetry breaking remains poorly understood, especially in *vivo*. To elucidate symmetry breaking mechanisms we are studying the *C. elegans* embryonic intestine, a simple epithelial tube composed of 20 'E' cells that orient their apical surfaces toward a common midline surrounded by basolateral surfaces facing each other and non-E cells. In this tissue, apical surfaces form at homotypic contacts and basal surfaces form at heterotypic contacts, thus we hypothesize that these differences in cell contact inform symmetry breaking. To test this hypothesis, we are using *pop-1* mutant embryos which produce twice as many E cells to characterize the distribution of polarity markers when there are ectopic E contacts. The intestines in these embryos are often arranged into multiple layers such that some E cells participate in homotypic contacts at all surfaces. The apical marker PAR-6 localizes to these exogenous homotypic contacts, consistent with a role for cell contact in symmetry breaking. While the molecular cues underlying this contact recognition remain unknown, likely candidates include adhesion proteins which could bind homophilically between E cells. For example, the two adhesion proteins HMR-1/E-cadherin and SAX-7/L1CAM are expressed in E cells and localize to cell membranes prior to polarization. Either protein alone is dispensable for polarity establishment, however the depletion of HMR-1/E-cadherin and SAX-7/L1CAM together results in a polarity defect, consistent with an early role for adhesion proteins in polarization. This work will highlight the role of cell/cell adhesion in *C. elegans* intestinal symmetry breaking, a mechanism likely conserved in other polarization contexts.

P2201/B450

A High-Content and Computational Approach to Study Cell Shape and Polarity in Epithelia.

D. Ortolan[1,2], R. Sharma[1], N. Hotaling[3], D. Bose[1], J. Ferraris[1], N. Lin[1], G. Pegoraro[1], S. Di Marco[2], S. Bisti[2], K. Bharti[1]; [1]National Institutes of Health, Bethesda, MD, [2]Universita' dell'Aquila, L'Aquila, ITALY, [3]NIH/NCATS, Bethesda, MD.

Epithelial cells have specialized structural features that are strictly linked to their functions. The Retinal Pigment Epithelium (RPE) is a monolayer of epithelial cells located in the back of the eye that constitutes part of the outer blood-retina barrier and plays a crucial role in photoreceptor survival. The integrity of this barrier is achieved by RPE cells through the establishment of epithelial phenotype - formation of tight junctions between neighboring cells allowing the cells to acquire apical-basal polarity. Failure in acquiring or maintaining the epithelial phenotype leads to retinal diseases, such as age-related macular degeneration (AMD). The aim of this study is to understand how the epithelial phenotype is established in RPE cells using high-resolution and high-content imaging. This is achieved using several CRISPR-modified induced pluripotent stem cell (iPSC) reporter lines generated by the Allen Institute (Seattle, WA), each expressing fluorescently tagged proteins to label intracellular organelles and structures. Among these are: cell membrane, nuclear envelope, Golgi apparatus, endoplasmic reticulum, mitochondria, lysosomes, endosomes, peroxisomes, tubulin and actin cytoskeleton, cell junctions and

focal adhesions. All these iPSC lines have been successfully differentiated into fully polarized RPE and imaged with high-resolution and high-content confocal microscopy. As a control, RPE has been treated with HPI-4, a drug known to disrupt the polarization process. A machine learning algorithm is used to automatically segment each labelled structure. More than 10,000 images of RPE cells are taken at every time point for each sample during the six weeks of RPE polarization. The location of organelles is precisely calculated by computationally averaging the data. A virtual 3D map of RPE representing the precise subcellular location of every organelle is being generated for each time point, showing how cellular structures rearrange themselves during maturation to establish the epithelial phenotype. In conclusion, these results shed light on the mechanisms responsible for impairment of polarity in RPE and, in general, other epithelia. Moreover, the method of investigation proposed here represents an innovative approach to describe morphology of intracellular structures and can be broadly applied.

P2202/B451

Asymmetric Localization of Dishevelled Protein Assemblies Via Lysosome Association during Oocyte Meiosis.

S. Swartz[1], M. Perillo[2], G. M. Wessel[2], I. M. Cheeseman[1], A. H. Wikramanayake[3]; [1]Whitehead Institute for Biomedical Research, Cambridge, MA, [2]Brown University, Providence, RI, [3]University of Miami, Coral Gables, FL.

Cellular asymmetries in the oocyte are intimately linked to the body axes formed during embryogenesis. Our goal is to understand how symmetry is broken in the oocyte to establish polarity. Here, we report an essential symmetry-breaking event that occurs during meiosis in oocytes of the sea star *Patiria miniata*. Using 4D time-lapse imaging and functional approaches, we find that the Wnt signaling component Dishevelled is uniformly distributed in the mature oocyte, but becomes specifically enriched at the vegetal cortex during meiosis. Localized Dishevelled is required to direct specification of the an terior-Posterior axis during early embryogenesis. Vegetal localization requires intrinsic cues from the oocyte cortex, as well as conserved domains within the Dishevelled protein that confer specific and separable granule forming and localization behaviors. We find that Dishevelled forms distinct populations of both dynamic and static granular assemblies that are locally concentrated on the cytoplasmic surface of lysosomes and at the cortex. Our results suggest a paradigm that bridges previous models for Dishevelled localization that invoke lipid binding versus accumulation in biomolecular condensates through phase separation.

P2203/B452

Tuba Regulates Cdc42 Functions in Neuronal Polarization Coupling Membrane and Actin Dynamics.

C. Gonzalez-Billault[1], M. Fukuda[2], P. Urrutia[1]; [1]Universidad de Chile, Santiago, CHILE, [2]Tohoku University, Sendai, JAPAN.

Neurons are highly polarized cells, in which the sprouting and elongation of neurites, and its subsequent development in axons and dendrites, are key events during early neuronal differentiation. These processes depend mainly on changes in cytoskeletal dynamics and directed membrane traffic and are controlled by the Rho and Rab families of small GTPases respectively. The small Rho GTPase, Cdc42, has emerged as a critical regulator of neuronal polarity, however, to date, the GEF responsible of Cdc42 activation during polarity acquisition is unknown. In this work we proposed that Tuba is the GEF that activates Cdc42 during axon specification. Using primary cultures of rodent neurons, we observed a

sustained increase in Tuba expression during the initial stages of culture, concurring with polarity development. In addition, the overexpression of Tuba induces the formation of neurons with multiple axons, similarly to the phenotype observed with the expression of Cdc42 fast cycling. On the other hand, the loss-of- function of Tuba (mediated by the expression of an shRNA or a GEF-deficient form) impaired axon formation. Moreover, Tuba co-localizes with Rab8, a Rab GTPase involved in exocytic traffic from the trans Golgi network to the plasma membrane during neuronal polarization. In neurons, Rab8a dramatically alters normal neuronal polarization, because a dominant-negative form of Rab8a impaired axon formation, while a constitutively active form of Rab8a induces the formation of multiple axons. Accordingly, the overexpression of Rab8 induces an increase in the total activity of Cdc42 and this effects is mediated by Tuba. These findings suggest that Tuba acts as linker between the regulation of cytoskeleton dynamics and the directed vesicular traffic during neuronal polarization.

P2204/B453

Cdc42 GEFs Gef1 and Scd1 Crosstalk to Promote Transition from Monopolar to Bipolar Growth in Fission Yeast.

B. Hercyk, J. Rich-Robinson, A. Mitoubsi, M. Harrell, **M. Das**; University of Tennessee, Knoxville, Knoxville, TN.

The GTPase Cdc42 is a major regulator of cell polarity in most eukaryotes. Cells polarize when they break symmetry by establishing a Cdc42-activating positive feedback loop. This leads to accumulation of Cdc42 regulators at one site at the expense of other sites, resulting in a single growing pole. How, then, do cells activate growth at additional sites in the presence of an established growing pole? to address this, we used fission yeast, which grow in a monopolar manner after cell division and eventually transition to bipolar growth. A previous model proposes that bipolar growth occurs once cells reach a threshold size at which they synthesize sufficient activators for two growth sites. However, cell cycle mutants (*cdc10*) that remain monopolar can achieve a large cell size, indicating that a size threshold alone does not lead to bipolarity. In fission yeast, positive feedback is established first at the pre-existing, dominant old-end. Bipolar growth occurs when a new-end can compete with the old-end to establish a second site of Cdc42-activating positive feedback by an unknown mechanism. Cdc42 is activated by the GEFs Gef1 and Scd1. We find that in *gef1Δ* mutants, cells fail to establish a second site of growth since they cannot overcome the dominance at the old-end. Moreover, in these mutants Scd1 is monopolar, suggesting that Gef1 regulates Scd1 localization. Investigating the relationship between Gef1 and Scd1 is difficult due to the dynamicity of the GEFs at the cell ends. We took advantage of our previous finding that Gef1 and Scd1 sequentially localize to the cell division site during cytokinesis. Using cytokinesis as a paradigm, we find that Gef1 promotes Scd1 localization via Cdc42 activation. Our data show that Gef1-mediated active Cdc42 recruits the scaffold protein Scd2 which then recruits Scd1. This regulation also occurs during interphase at the new-end where Gef1 activates Cdc42 to provide a seed for Scd1/Scd2-mediated positive feedback to overcome old-end dominance. Furthermore, we find that Gef1 localization itself is tightly regulated, with Scd1 restricting Gef1 to sites of polarized growth to maintain cell shape and prevent ectopic growth sites. Our data reveal an elegant regulatory pattern in which Gef1 enables a new site to overcome old-end dominance by establishing a second site of Scd1-mediated Cdc42 activity to promote bipolar growth.

P2205/B454

Cell-Cycle-Dependent Cues Temporally Regulate Cdc42 Activity at Growth Sites in Fission Yeast.

J. Rich-Robinson, A. Russell, E. Mancini, M. Das; University of Tennessee, Knoxville, TN.

Cdc42 is the master regulator of polarized cell growth in most eukaryotes. In fission yeast, Cdc42 activity, and thus growth, gradually stops at the cell ends upon mitotic entry and resumes after the G1/S transition once cytokinesis completes and cells abscise. It is unknown how Cdc42 is inactivated at the cell ends during mitosis and whether resumption of Cdc42 activity requires completion of cytokinesis. To investigate the cell-cycle-dependency of Cdc42 activity at the cell ends, we have developed a system whereby we can delay cytokinesis while mitosis progresses via a temporary Latrunculin a (LatA) treatment. In these cells, Cdc42 activation resumes at the ends even before the completion of cytokinesis. We call this the PrESS phenotype - polar elongation sans cell separation. This indicates that Cdc42 activation at the cell ends is independent of completion of cytokinesis. Mitotic exit requires degradation of the G2/M cyclin Cdc13. In cells arrested in mitosis due to expression of a non-degradable *cdc13*, the frequency of the PrESS phenotype decreases. Moreover, G1/S-cyclin mutants, which have a lengthened G1 cell cycle phase, display an enhanced PrESS phenotype. This suggests that Cdc42 activity at the cell ends is inhibited by an active Cdk1/Cdc2-Cdc13 complex and can resume only after entry into G1. Next, to identify how Cdc42 is regulated at the cell ends during mitosis, we analyzed the PrESS phenotype in mutants of different Cdc42 regulators. Cdc42 is inactivated by the GTPase activating proteins (GAPs) Rga4 and Rga6. We find that loss of *rga4* or *rga6* increases the frequency of the PrESS phenotype. Furthermore, Rga4 and Rga6 show enhanced localization at the cell ends during mitosis. We also find that the scaffold Scd2, which is required for polarized Cdc42 activation, remains at the cell ends even during mitosis. This suggests that loss of Cdc42 activity at the cell ends during mitosis is likely not due to the inability to recruit Cdc42 activators, but rather due to enhanced Rga4 and Rga6 localization. Based on these data, we propose that the cell cycle temporally modulates Cdc42 activity at the cell ends via regulation of the GAPs such that growth does not occur during mitosis.

P2206/B455

Proteomic an alysis Uncovers Distinct Segregation Patterns of Yeast Cell-peripheral Proteins.

S. Sugiyama[1,2,3], M. Tanaka[2,3]; [1]OIST, Okinawa, JAPAN, [2]RIKEN Center for Brain Science, Saitama, JAPAN, [3]Tokyo Institute of Technology, Kanagawa, JAPAN.

Protein segregation contributes to various cellular processes such as polarization, differentiation, and aging. However, the difficulty in global determination of protein segregation hampers our understanding of its mechanisms and physiological roles. To overcome this, we globally monitored segregation of preexisting proteins during cell division of budding yeast, and identified crucial domains that determine the segregation of cell-peripheral proteins. Remarkably, the proteomic and subsequent microscopic analyses demonstrated that the flow through the bud neck of the proteins that harbor both endoplasmic reticulum (ER) membrane-spanning and plasma membrane (PM)-binding domains is not restricted by the previously suggested ER membrane or PM diffusion barriers but by septin-mediated partitioning of the PM-associated ER (pmaER). Furthermore, the proteomic analysis revealed that although the PM-spanning t-SNARE Sso2 was retained in mother cells, its paralog Sso1 unexpectedly showed symmetric localization. We found that the transport of Sso1 to buds enhances cell elongation during pseudohyphal growth. Taken together, these data resolve long-standing questions about septin-

mediated compartmentalization of the cell periphery, and provide new mechanistic insights into the segregation of cell-periphery proteins and their cellular functions.

P2207/B456

Patterning of Membrane-associated Proteins through Membrane Flows.

V. Gerganova[1], I. Lamas[1], D. Rutkowski[2], A. Vjestica[1], D. Vavylonis[2], S. G. Martin[1]; [1]University of Lausanne, Lausanne, SWITZERLAND, [2]Lehigh University, Bethlehem, PA.

How cells pattern and polarize in response to internal and external cues is a fundamental biological problem. In the rod-shaped fission yeast cell, the polar and lateral plasma membranes are distinct in lipid and protein composition. Polar zones are defined by local Cdc42 GTPase activity, which directs polarized secretion. By contrast, how the lateral membrane is patterned and how membrane-associated proteins, such as the Cdc42 GAP Rga4, accumulate laterally is less well understood. We have recently developed a light-inducible tool based on the CRY2PHR-CIBN system to acutely recruit proteins to the plasma membrane upon blue light photo-stimulation. Blue light activation triggers the formation of large CRY2PHR-CIBN complexes at the cell cortex, which are initially homogeneously distributed. Remarkably, after photo-activation, CRY2PHR-CIBN complexes are rapidly cleared from the growing pole(s). We hypothesize that exocytosis at the center of a broader zone of endocytosis at sites of growth acts as a driver of membrane flows causing this cell patterning. Mathematical simulations indeed show that the density of plasma membrane-associated proteins at the pole decreases according to membrane affinity (Koff). Experiments confirm a concentrated zone of exocytosis within a broader zone of endocytosis at zones of future CRY2PHR-CIBN clearance and disruption of the phenomenon by blocking polarized secretion. Empirical modulation of membrane binding affinity using both synthetic probes and the endogenous Rga4 further demonstrate that this parameter defines their cortical distribution. These results suggest that membrane flows created by the specific location of polarized secretion and endocytosis pattern the lateral distribution of membrane-associated proteins.

Optogenetics Reveals Cdc42 Local Activation by Scaffold-mediated Positive Feedback and Ras GTPase.

S. G. Martin, I. Lamas, L. Merlini, A. Vjestica, V. Vincenzetti; University of Lausanne, Lausanne, SWITZERLAND.

The small GTPase Cdc42 is critical for cell polarization. Scaffold-mediated positive feedback regulation was proposed to mediate symmetry-breaking to a single active zone in budding yeast cells. In rod-shaped fission yeast *S. pombe* cells, active Cdc42-GTP localizes to both cell poles, where it promotes bipolar growth. Here, we implement the CRY2-CIBN optogenetic system for acute light-dependent protein recruitment to the plasma membrane, which allowed to directly demonstrate positive feedback. Indeed, optogenetic recruitment of constitutively active Cdc42 leads to co-recruitment of the guanine nucleotide exchange factor (GEF) activator Scd1, in a manner dependent on the scaffold protein Scd2. We show that Scd2 scaffold function is completely bypassed and positive feedback restored by an engineered interaction between the GEF and a Cdc42 effector, the Pak1 kinase. Remarkably, such re-wired cells are viable and grow in a bipolar manner even when lacking otherwise essential Cdc42 activators. These cells also reveal that Ras1 GTPase plays a dual role in localizing and activating the GEF, thus potentiating the feedback. We conclude that scaffold-mediated positive feedback, gated by Ras activity, is minimally required for rod-shape formation.

P2209/B458

Role of Cdc42 GTPase-activating Proteins in Asymmetric Cell Division and Cdc42 Oscillatory Dynamics.

F. Verde; University of Miami, Miami, FL.

The highly conserved small GTPase Cdc42 regulates polarized cell growth and morphogenesis from yeast to humans. We previously reported that Cdc42 activation exhibits oscillatory dynamics in *Schizosaccharomyces pombe* cells. Mathematical modeling suggests that this dynamic behavior enables a variety of symmetric and asymmetric Cdc42 distributions to coexist in cell populations. Individual growing wild type cells, however, follow a stereotypical pattern, where Cdc42 distribution is initially asymmetrical in young daughter cells, and becomes more symmetrical, enabling bipolar growth activation, as cell volume increases. To further explore whether different states of Cdc42 activation are possible in a biological context, we examined *S. pombe rga4Δ* mutant cells, lacking the Cdc42 GTPase activating protein (GAP) Rga4. We find experimentally that monopolar *rga4Δ* mother cells divide asymmetrically, leading to the emergence of both symmetric and asymmetric Cdc42 distributions in *rga4Δ* daughter cells. By genetic screening approaches to identify mutants that alter the *rga4Δ* phenotype, we tested the predictions of different computational models that reproduce the unequal fate of daughter cells. We find experimentally that the unequal distribution of active Cdc42 GTPase in daughter cells is consistent with an unequal inheritance of another Cdc42 GAP, Rga6, in the two daughter cells. Our findings highlight the crucial role of Cdc42 GAP protein localization in determining the morphological fate of cell progeny and ensuring consistent Cdc42 activation and growth patterns across generations.

P2210/B459

A Minimal System to Reconstitute Pom1 Gradient.

R. Maan, N. Taberner, K. Vendel, E. vd Sluis, M. Dogterom; Technical University Delft, Delft, NETHERLANDS.

A number of protein concentration patters have been reported to influence various process in Biology. One such pattern is Pom1 gradient found in fission yeast cells, S. Pombe., with maximum at the cellular poles. Pom1 gradient has been suggested to correlate cell size with cell division by regulating the activity of Cdr2 nodes at the cortex in the middle of the cell. SAD kinase Cdr2 has inhibitory effect on cyclin dependent kinase Cdk1 via Wee1 and hence can control mitotic entry of the cell. When the Pombe cells reach their characteristic length the gradient profiles from the two cellular poles do not overlap with the Cdr2 nodes and the fission yeast cell can undergo mitosis. Using the bottom up approach, we are trying to reconstitute Pom1 gradient in cell size confinements. Microfluidics is used to make cell size confinements and microtubule based transport is used to transfer proteins to the two poles in the confinement. Here we show how shape of the emulsion droplets influence the microtubule growth and forces them to grow along the longer axis in elongated droplets. We also establish microtubule plus end tracking inside the elongated droplets to enable protein transport. Combining the two results together, we aim to develop minimal system to reconstitute Pom1 gradient inside the emulsion droplets of cellular dimensions.

P2211/B460

Courtship Is a Two-way Conversation: Yeast Mating as a Model of Cell-cell Communication.

R. Clark-Cotton, N. Henderson, D. J. Lew; Duke University, Durham, NC.

Many cells track chemical signals during feeding, fertilization, development, and immune responses, but the mechanisms of target location are elusive. The budding yeast, an established model of such cell-cell communication, tracks a pheromone signal to locate a mating partner. Pheromone binding to cell surface receptors triggers the concentration of polarity proteins at a small zone of the cell cortex (the "polarity patch"). The polarity patch is oriented toward the partner, and through its effectors, directs polarized growth toward that mate. In classical models of polarization, a cell first decodes the pheromone gradient and then polarizes toward the region of highest signal. However, studies of yeast in artificial gradients found that cells that polarize in the wrong direction can move the patch to align with the partner. As receptors and G proteins concentrate at the patch, local pheromone sensing and secretion may mediate communication between partners. A fundamentally different "exploratory polarization" paradigm for orientation in a gradient posits that polarity sites move around the cortex in a search process, and that when the patches of two partner cells are aligned, each cell senses a high pheromone signal, causing the patches to stop moving. Unlike the artificial gradient studies, cells in mating mixes first assemble weak and transient polarity clusters that move erratically around the cell cortex, often engaging different partners before stably polarizing. It is unclear whether such polarity clusters are functionally important for partner identification. Here we ask whether the weak early clusters are engaged in exploratory polarization, only stabilizing when two clusters co-oriented, or if the cells perform a more classical global survey of the pheromone landscape, without need for the weak polarity clusters. To distinguish between these models, we performed live-cell fluorescence microscopy of mating mixes in which wildtype cells were paired with partners that either failed to make polarity clusters, or that made but could not stabilize clusters. Strikingly, we found that the wildtype cells displayed extended indecisive behavior and did not commit to such partners. Stabilizing the patches of polarity mutants with exogenous pheromone allowed wildtype cells to commit to them. We also confirmed that both sensing, signaling, and secretion markers were enriched at indecisive phase polarity clusters, thereby providing direct experimental evidence that local pheromone secretion promotes commitment to a partner, in support of the exploratory polarization model. We conclude that reciprocal communication between two partners' polarity sites is essential for successful commitment to a mating partner.

Mechanical Feedback Maintains Polarization in Budding Yeast Mating Projection Growth.

S. P. Banavar[1], M. Trogdon[2], B. Drawert[3], L. R. Petzold[1], O. Campas[1]; [1]University of California Santa Barbara, Santa Barbara, CA, [2]Salk Institute, San Diego, CA, [3]University of North Carolina, Asheville, Asheville, NC.

Cell Polarization is one of the commonly studied cases of spontaneous symmetry breaking in cells and controls many cellular processes, including morphogenesis, in budding yeast. However, the mechanisms that coordinate continued polarization to the growth region during mating projection formation, and the subsequent change in geometry from a spherical cell, remain unknown. We theoretically show that a genetically-encoded mechanical feedback relaying information about cell's geometry is sufficient to

maintain key polarity molecules and growth machinery remain localized to the site of growth. We have demonstrated that this same feedback mechanism also results in cell wall stability.

P2213/B462

Kar9 Symmetry Breaking Alone Is Insufficient for Spindle Positioning in Budding Yeast.

M. Meziane, R. Genthial, J. Vogel; McGill University, Montreal, QC, CANADA.

Asymmetric cell division requires the alignment of the spindle along the polarity axis of the cell. The interactions of astral microtubule +ends with the cortex are needed for spindle positioning. Budding yeast has an asymmetric cell morphology, and the spindle must be correctly positioned at the bud neck and aligned to the polarity axis for a successful mitosis. Prior to anaphase, the spindle is positioned at the bud neck by Kar9 - a microtubule +end binding protein that binds the type V myosin Myo2. The interaction between Kar9 and Myo2 couples microtubule +ends to cortical actin in the bud, effectively aligning the entire spindle along the polarity axis. The asymmetric localization of Kar9 to one spindle pole is thought to be sufficient for spindle positioning. However, the temporal correlation between Kar9 symmetry breaking in relation to the alignment of the spindle has not been investigated. In this study, we develop an algorithm to quantitatively and reliably determine Kar9 symmetry breaking in a dynamic state and correlate it with stable spindle alignment (“perfect alignment”). Using confocal microscopy, we examine wild type cells, as well as cells expressing a Kar9 mutation (Kar9-AA) that inhibits its phosphorylation by Cdk1 and thus increases Kar9 association with both spindle poles. Strikingly, we find that Kar9 asymmetry is insufficient for perfect alignment, as the majority of asymmetric cells failed to display perfect alignment. Additionally, a subset of symmetric cells displayed perfect alignment, despite persistent attachment of Kar9 to both poles. Furthermore, we show that perfect alignment is correlated with Kar9 bud entry and persistence in the bud. We speculate that the binding of Kar9 to Myo2 is regulated in the bud. Based on these findings, we propose a revised model of spindle alignment, for which both Kar9 symmetry breaking and Kar9-Myo2 interactions are independently acting to align the spindle.

P2214/B463

The Role of Rna Structure in the Physical State and Maturation of Phase Separated Droplets.

C. Roden; the University of North Carolina at Chapel Hill, Chapel Hill, NC.

Analogous to the separation of oil from water, a process called liquid-liquid phase separation (LLPS) partitions cellular contents. LLPS is dictated by intrinsic biophysical/biochemical properties of component molecules. Many phase-separated droplets form from RNA-binding proteins in complex with target RNAs (RNPs). In pathological contexts, the dynamics of these molecules are disrupted and it is hypothesized this influences disease pathology. It is now appreciated that RNA sequence/structure, can dictate assembly and physical state of droplets. This provides a new role for RNA sequence, which is encoding mesoscale biophysical properties of cellular bodies. Although there is a link between RNA sequence and droplet behaviors, the details are still a mystery. We hypothesize that RNA serves as a scaffold for RNA-based condensates and that depending on the RNA sequences engaged in LLPS, droplets emerge with distinct biophysical properties and cellular functions. Specifically, we predict that sequence-directed RNA structures control inter-molecular RNA-RNA interactions and how RNA-binding proteins bind to RNAs in condensates. We previously found that the mRNA encoding the cyclin *CLN3* and the RNA-binding protein Whi3 condense to localize cyclin transcripts near nuclei in multinucleate fungal

cells. The structure of Whi3's target RNA, *CLN3,* is known to regulate features of droplet formation. In order to identify *CLN3* RNA sequences and structures important for Whi3 phase separation behaviors, we first employed a computational approach, which combines RNA structure predictions, RNA structure chemical probing data, and analysis of sequence/structural conservation across fungal species. This led to the identification of a number of RNA sequences/structures which regulate RNP droplet formation. Mutants were generated based on these predictions and these mutant *CLN3* RNAs were analyzed using an in *vitro* phase separation assay. Interestingly, one mutant which includes disruption of a potential site of intramolecular RNA/RNA pairing, an RNA structure that regulates protein binding site clustering, and protein binding site occupancy showed dramatic differences in droplet formation. Droplets made from mutant RNAs had altered biophysical properties (size, viscosity, diffusivity) suggesting that RNA-RNA and RNA-protein interactions are critical for the physical parameters of droplets. Current work is focused on testing the impact of these mutations in cells. These studies highlight the critical importance of specific RNA structures in determining key features of biomolecular condensates.

Neuronal Sphk1 Acetylates Cox2 and Contributes to Pathogenesis in a Model of Alzheimer'S Disease.

H. Jin, J. Lee, K. Park, W. Han, J. Bae; Kyungpook Natl University, Daegu, KOREA, REPUBLIC OF.

Although many reports have revealed the importance of defective microglia-mediated amyloid β phagocytosis in Alzheimer's disease (AD), the underlying mechanism remains to be explored. Here we demonstrate that neurons in the brains of patients with AD and AD mice show reduction of sphingosine kinase1 (SphK1), leading to defective microglial phagocytosis and dysfunction of inflammation resolution due to decreased secretion of specialized proresolving mediators (SPMs). Elevation of SphK1 increased SPMs secretion, especially 15-R-Lipoxin A4, by promoting acetylation of serine residue 565 (S565) of cyclooxygenase2 (COX2) using acetyl-CoA, resulting in improvement of AD-like pathology in APP/PS1 mice. In contrast, conditional SphK1 deficiency in neurons led to reduction of SPMs secretion and abnormal phagocytosis similar to AD. Overall, these results reveal a novel mechanism of SphK1 pathogenesis in AD that leads to defective microglial phagocytosis due to impaired SPMs secretion, and suggests that SphK1 in neurons has acetyl-CoA dependent cytoplasmic acetyltransferase activity towards COX2.

Genetic Ablation of Neuronal Mitochondrial Calcium Uptake Prevents Alzheimer'S Disease Progression.

P. Jadiya[1], D. W. Kolmetzky[1], D. Tomar[1], D. Praticò[2], J. W. Elrod[1]; [1]Temple University, Center for Translational Medicine, Philadelphia, PA, [2]Temple University, Alzheimer's Center at Temple, Philadelphia, PA.

Background. Alzheimer's disease (AD) is characterized by extracellular deposition of amyloid beta, intracellular neurofibrillary tangles, synaptic dysfunction and neuronal cell death. These phenotypes correlate and are linked with elevated neuronal intracellular calcium ($_{i}Ca^{2+}$) levels. Recently, our group reported that $_{m}Ca^{2+}$ overload due to loss of $_{m}Ca^{2+}$ efflux contributes to AD progression. In this report we also noted proteomic remodeling of the mitochondrial calcium uniporter channel (mtCU). The mtCU is

the primary mechanism for Ca^{2+} uptake into the mitochondrial matrix, therefore, inhibition of the mtCU has the potential to reduce or prevent $_mCa^{2+}$ overload in AD. **Methods. To** define the role of $_mCa^{2+}$ uptake in AD we generated 3xTg-AD mutant mice with neuronal-specific deletion (Camk2a-Cre) of the mtCU pore-forming subunit, *Mcu*, and evaluated age-associated changes in cognitive function, and neuropathology. Neuroblastoma (N2a) and AD-mutant (APPswe) cell lines transduced with lentivirus encoding shRNA targeting MCU were used to examine mitochondrial calcium signaling, cell death and oxidative stress. **Results.** We observed that neuronal-specific loss of $_mCa^{2+}$ uptake in 3xTg-AD mice reduced Aβ and tau-pathology, synaptic dysfunction and cognitive decline. Knockdown of MCU in APPswe cell lines significantly decreased matrix Ca^{2+} content, oxidative stress and cell death. **Conclusions.** Inhibition of neuronal $_mCa^{2+}$ uptake represents a novel therapeutic target to reduce AD progression and associated mitochondrial dysfunction.

Preventive Ex Vivo Gene Therapy for Stroke in Rat Model.

V. A. Markosyan[1], Z. Z. Safiullov[1], F. O. Fadeev[1], A. A. Izmailov[1], M. E. Sokolov[1], M. S. Kuznetsov[1], A. N. Lisyukov[1], D. A. Trofimov[1], A. M. Gibadullin[1], G. G. Kundakchyan[2], I. I. Sallafutdinov[2], F. V. Bashirov[1], R. R. Islamov[1]; [1]Kazan State Medical University, Kazan, RUSSIAN FEDERATION, [2]Kazan (Volga Region) Federal University, Kazan, RUSSIAN FEDERATION.

Contemporary gene and cell technologies are widely employed in pre-clinical trials for treatment of different pathological conditions in appropriate animal models. The discovery of such new approaches for stroke therapy is under intensive investigation as well. Recently we have shown that intrathecal injection of genetically engineered human umbilical cord blood mononuclear cells (UCB-MC) transduced with adenoviral vectors (Ad5) which carried genes encoding vascular endothelial growth factor (VEGF), glial cell line-derived neurotrophic factor (GDNF) and neural cell adhesion molecule (NCAM) successfully rescued neurons following cerebral blood vessel occlusion. In the present study we employed the same gene-cell construct for preventive ex vivo gene therapy. Rats were anesthetized and intrathecally infused with 2×10^6 UCB-MC+Ad5-VEGF+Ad5-GDNF+Ad5-NCAM in 20 µl of saline. An imals in the control group (n=5) were subjected to intrathecal administration of 2×10^6 UCB-MC transduced with Ad5 carrying reporter green fluorescent protein gene. Three days after ex vivo gene delivery brain ischemia was induced in animals from both groups by permanent occlusion of the middle cerebral artery (MCA). Three weeks after the surgery histological study of rat brain revealed a local infarct in parietal cortex. Morphometric analysis demonstrated that in rats receiving preventive ex vivo gene therapy the infarct area was significantly smaller 2.47 (1.39, 4.51) mm^3 in comparison with the control animals 17.12 (7.26, 72.17) mm^3($p<0.05$). These results demonstrate that intrathecal injection of genetically engineered UCB-MC over-expressing therapeutic molecules (VEGF, GDNF and NCAM) at risk of a stroke may enhance the survivability of neural cells with the onset of a stroke. This study was supported by the grant of Russian Science Foundation No 19-75-10030.

Pyridoxine Deficiency Affects to Expression of V-type Proton Atpase and Guanine Nucleotide-binding Protein in the Hippocampus.

I. Hwang[1], H. Jung[1], W. Kim[2], D. Kim[3], D. Yoo[4], Y. Yoon[1]; [1]Seoul National University College of Veterinary Medicine, Seoul, KOREA, REPUBLIC OF, [2]Research Institute for Bioscience and Biotechnology, Hallym University, Chuncheon, KOREA, REPUBLIC OF, [3]Research Institute of Oral Sciences, College of Dentistry, Gangneung-Wonju National University, Gangneung, KOREA, REPUBLIC OF, [4]College of Medicine, Soonchunhyang University, Cheonan, KOREA, REPUBLIC OF.

In the previous studies, pyridoxine supplementation significantly increased the hippocampal functions by upregulating phosphorylation of CREB signaling. In the present study, we investigated the effects of pyridoxine deficiency on hippocampal neurogenesis and proteins based on immunohistochemistry and proteomic approach, respectively. Eight-week-old mice received control diet (7 mg/kg) or pyridoxine deficient diet (4.4 ug/kg) for 4 weeks and sacrifice the animals for immunohistochemistry and 2D gel electrophoresis and subsequently for matrix-assisted laser desorption/ionization. Mice fed with pyridoxine deficient diet significantly decreased the cell proliferation and differentiated neuroblasts in the dentate gyrus based on Ki67 and doublecortin immunohistochemistry. In the proteomic study, among 378 paired proteins, 16 proteins were identified as significantly changed (2 folds or more) proteins. Especially, V-type proton ATPase and guanine nucleotide-binding protein was prominently decreased in pyridoxine deficient diet treated groups compared to that in the control group. These results suggest that pyridoxine has an essential role for hippocampal neurogenesis by modulating V-type proton ATPase and guanine nucleotide-binding protein in the hippocampus.

Analysis of the expression profile of mRNAs in brain of hyperglycemic rats.

J. L. Rojas, L. M. Arratia, A. V. Vega; Carrera de médico cirujano, Facultad de Estudios Superiores Iztacala, UNAM, Estado de México, MEXICO.

Diabetes mellitus (DM) is a metabolic disease characterized by a failure in the secretion of insulin or by the ineffectiveness of this hormone on its target tissues, which leads to the development of hyperglycemia. This condition is harmful to many tissues, which leads to the development of comorbidities such as neuropathies, retinopathies and nephropathies, which in turn have been related to changes in the vasculature and systemic blood pressure, however it is unclear whether hyperglycemia promotes the appearance of these changes. Using the microarray technique, we analyzed the expression of ~ 5000 genes from the messenger ribonucleic acid (mRNA) of brain from normal and hyperglycemic rats (*Rattus Norvergicus*) (>250 mg / dL). Thus, we found that sustained hyperglycemia (72h) modifies the expression of genes encoding proteins important for the regulation of vascular function. Although we found a total of 18 positively regulated genes, only 3 of these genes encode proteins important for vascular function. 1) arginine succinate synthase (ASS), an enzyme involved in the synthesis of citrulline and nitric oxide. 2) Dysadherin (FXYD5), a transmembrane protein that positively regulates the activity of Na + -K + -ATPase and E-cadherin. The overexpression of this gene could be a mechanism of vascular protection, since it has been reported that the expression of Dysadherin is suppressed in spontaneously hypertensive rats. An d 3) the beta subunit of the epithelial sodium channel, which is expressed in hypothalamic neurons that secrete vasopressin, a potent vasoconstrictor

hormone that plays an essential role in water balance and regulation of blood pressure. None of the 26 genes negatively regulated seems to be related to the control of vascular function.

P2220/B470

Molecular Characterization of the Parkinsonian Brain After Long-term Stem Cell Transplantation.

B. Song; Catholic Kwandong University, Gangneung, KOREA, REPUBLIC OF.

To improve Parkinson's disease (PD) belonging to neurodegenerative disease, stem cell therapy is known to functionally enhance nigrostriatal dopaminergic neurons. Despite these functional recoveries, the long-term state of stem cells in vivo and their relationship with surrounding cells have not been clearly studied. In previous study, we examined a three dimensional structure of intact brain tissue after bone marrow mesenchymal stem cell (MSC) treatment at short-term induction in PD. In this study, we investigated in vivo proof-of-concept and their microenvironment of MSCs 1-year after transplantation into 6-hydroxydopamine hydrobromide-induced rat PD model at the medial forebrain. One year after surgery, amphetamine-induced rotation test was performed to evaluate the degree of the dopaminergic lesion. For transplantation, MSCs were injected into the femoral vein. One day after the final behavior test, the rats were anaesthetized, and perfused with a mixture of 4% paraformaldehyde, 4% acrylamaide, 0.05% bis-acrylamide, 0.25 VA044 in PBS. Isolated brains were incubated in 4°C for 2 days, and then temperature was increased to 37°C to induce polymerization for 2.5 hours. Hydrogel-embedded brains were plated in 10~60V organ-electrophoresis system, circulating 200 mM sodium borate buffer with 4% SDS. For three dimensional interface of graft-host axis, it was visualized by immunofluorescence to MSC-positive cells (PKH26-labelled), polysialylated neural cell adhesion molecule, and/or neuron-specific class III beta-tubulin or NeuN marker. At this site, we analyzed RNA-Sequencing to confirm the change of gene expression between PD and PD transplanted with MSC group. Using Excel-based Differentially Expressed Gene an alysis tool, we analyzed the categories related to cell migration and neurogenesis between the two groups. Furthermore, GO & Pathway and Network an alysis was mainly performed on the specifically changed genes. Taken together, our results demonstrate distinct pathophysiological and molecular patterns of in vivo responses between PD and PD transplanted with MSCs suggest structural and molecular-based differential features as candidate tool for the evaluation of stem cell during long-term therapy. This study was funded by NRF-2019R1H1A1035608.

P2221/B471

Cuprizone Affects Hypothermia-induced Neuroprotection and Enhanced Neuroblast Differentiation in the Gerbil Hippocampus After Ischemia.

Y. Yoon[1], W. Kim[2], K. Hahn[1], H. Jung[1], J. Kim[1], I. Hwang[1]; [1]Seoul National University College of Veterinary Medicine, Seoul, KOREA, REPUBLIC OF, [2]Research Institute for Bioscience and Biotechnology, Hallym University, Chuncheon, KOREA, REPUBLIC OF.

Cuprizone causes demyelination in the pyramidal cells of the hippocampal CA1 region and activates the microglia and astrocytes in the hippocampus. In contrast, hypothermia protects neurons from ischemic damage in the gerbil hippocampus. Herein, we investigated the effects of cuprizone on neuronal death and activation of astrocytes and microglia in the normothermic and hypothermic hippocampus of gerbils. Cuprizone was supplemented by food at 0.2% *ad libitum* for six weeks; thereafter, gerbils received transient forebrain ischemia with or without hypothermic preconditioning. Two weeks after ischemic surgery, animals were sacrificed, and cresyl violet staining and immunohistochemistry by glial

fibrillary acidic protein (GFAP), ionized calcium-binding adapter molecule 1 (Iba-1), Ki67 and doublecortin (DCX) were conducted to reveal the effect of cuprizone on brain ischemia. Brain ischemia decreased cell survival (cresyl violet staining) and increased reactive microglia (Iba-1-positive), and astrocytes (GFAP-positive) in the hippocampal CA1 region. Ischemia also increased proliferating (Ki67-positive) cells and differentiating (DCX-positive) neuroblasts in the dentate gyrus. In contrast, hypothermic conditioning ameliorated these changes in the gerbil hippocampal CA1 region and dentate gyrus. However, cuprizone treatment decreased cell survival induced by hypothermic preconditioning and increased reactive microglia and astrocytes in the hippocampal CA1 region. Cuprizone also decreased the ischemia-induced increases in proliferating cells and differentiated neuroblasts in the dentate gyrus. These changes occur because the protective effect of hypothermia in ischemic damage is disrupted by cuprizone administration. In addition, cuprizone decreases cell proliferation and neuroblast differentiation in the dentate gyrus, induced by transient forebrain ischemia. Myelinated nerve fibers in the hippocampus may be associated with cell survival in the gerbil hippocampal CA1 region and neuroblast differentiation, induced by hypothermic therapy, during transient forebrain ischemia.

P2222/B472

Chaperonin Containing Tcp-1 (cct) Complex Negatively Regulates Tau Accumulation and Toxicity in a Drosophila Model of Tau Toxicity.

S. Aizawa[1], T. Saito[1,2], A. Asada[1,2], K. An do[1,2]; [1]Laboratory of Molecular Neuroscience, Department of Biological Sciences, Graduate School of Science, Tokyo Metropolitan University, hachioji-shi, Tokyo, JAPAN, [2]Division of Biological Sciences, School of Science, Tokyo Metropolitan University, Hachioji-shi, Tokyo, JAPAN.

Abnormal accumulation of microtubule-associated protein tau is associated with a number of neurodegenerative diseases including Alzheimer's disease. In disease brains, tau is hyperphosphorylated and misfolded, and accumulation of those tau species is believed to cause neuronal death. Chaperonin containing TCP-1 (CCT) is a complex that assists folding of the proteins, including cytoskeletal components, and has been reported to control protein aggregation and degradation. However, the role of chaperones in tau toxicity is not fully understood. Here we show that CCT negatively regulates tau accumulation and toxicity in a Drosophila model of tau toxicity. In this model, expression of human tau in the fly retina causes neurodegenerationl. CCT is a large double-ring complex composed of eight paralogous subunits (CCT1-CCT8). We found that RNAi-mediated knockdown of CCT1 reduces tau levels. CCT1 knockdown did not affect mRNA levels of tau, suggesting that CCT regulates the turnover of tau protein. We also found that overexpression of CCT2 increased tau levels and enhanced tau-induced neurodegeneration. Next, we investigated if CCT specifically affects pathological tau species. Tau is highly phosphorylated in the disease brains, and among the disease-associated phosphorylation sites, its phosphorylation at Ser262/356 is reported to promote tau accumulation and enhance its toxicity. We tested whether tau phosphorylation at these sites affects the effect of CCT on tau levels by using transgenic flies expressing tau carrying alanine substitutions at Ser262/356. We found that CCT1 knockdown does not reduce the levels of tau, suggesting that CCT interacts with tau species phosphorylated at these sites. Our results suggest that CCT can enhance the accumulation of abnormal tau species. Since dysregulation of molecular chaperone network has been suggested in brain tissues from human aging and neurodegenerative diseases, further studies of the mechanisms by which CCT regulates tau levels will enhance our understanding of disease pathogenesis.

P2223/B473

Identification of *Poe* as a Novel Modifier of Par-1 Activity in *Drosophila* and Its Role in Neurodegeneration in an Alzheimer'S Disease Model.

J. Ono[1], A. Asada[1,2], T. Saito[1,2], K. An do[1,2]; [1]Department of Biological Sciences, School of Science, Tokyo Metropolitan University, Tokyo, JAPAN, [2]Graduate School of Science, Tokyo Metropolitan University, Tokyo, JAPAN.

partition-defective kinase 1 (Par-1) is an evolutionary conserved serine-threonine protein kinase and play critical roles in cell polarity, neuronal differentiation, and microtubule stability. Mammalian homologs of Par-1, microtubule affinity regulating kinase (MARK) 1-4, have been linked to neurological diseases. MARKs phosphorylate microtubule-associated protein tau, which is hyperphosphorylated and accumulated in neurodegenerative diseases, including Alzheimer's disease. Elevated MARK activity is found with tau lesions in Alzheimer's disease brains, and a mutation in MARK4 increases the risk of Alzheimer's disease. Elevated levels of MARK1 have been linked to autism spectrum disorder. These reports suggest that disruption of MARK/Par-1 contribute to the pathogenesis of neurodegenerative diseases. However, the regulatory mechanisms of MARK/Par-1 activity in neurons are not fully understood. Here we report that *purity of essence* (*poe*) is a negative regulator of Par-1. From a genetic screen, we identified *poe* as a modifier of Par-1 protein levels in the fly retina. Western blotting revealed that RNAi-mediated knockdown of *poe* reduces the protein levels of Par-1. mRNA levels of Par-1 was not affected, suggesting that *poe* affects the turnover of Par-1 protein. *poe* knockdown did not reduce firefly luciferase expressed in the retina, indicating that the reduction in Par-1 by *poe* knckdown is not due to the enhancement of general protein degradation. We also found that *poe* overexpression increased Par-1 protein levels. To test *poe* affects Par-1 activity, we used a fly model of human tau toxicity. In this model, human tau is overexpressed in the eye, and it is phosphorylation at Ser262 by endogenous Par-1. We found that *poe* knockdown reduces tau phosphorylation at Ser262, indicating that *poe* negatively regulates Par-1 activity. *poe* is suggested to act as an E3 ubiquitin-protein ligase. Par-1 is ubiquitinated and degraded by Skp, Cullin, F-box containing complex (SCF), and this process is triggered by phosphorylation of Par-1 at Thr408. To ask whether *poe* is involved in this process, we tested the effect of *poe* knockdown on a mutant form of Par-1 with substitution of Thr408 to unphosphorylatable Alanine (Par-1^{T408A}). *poe* knockdown significantly reduced the levels of Par-1^{T408A}, suggesting that poe regulates Par-1 metabolism in a different mechanism. In summary, our results indicate that *poe* negatively regulates the degradation of Par-1 protein. Further studies will reveal a novel mechanism that regulates Par-1/MARK activity and may shed light on its dysregulation in disease pathogenesis.

P2224/B474

New Directions in Neurodegenerative Disease: Delineating the Histone Modification Landscape of ALS.

M. P. Torrente; Brooklyn College - City University of New York, BROOKLYN, NY.

Amyotrophic lateral sclerosis (ALS) is a fatal and incurable neurodegenerative disease that affects cells in the brain and the spinal cord. ALS has been linked to mutations in many genes including SOD1, FUS, TDP- 43 and C9orf72. Interestingly, the protein products of these genes accumulate in inclusions within affected neurons. Eukaryotic DNA is packaged into chromatin, a highly organized protein-DNA complex. Changes in the structure of chromatin are sufficient to cause heritable phenotypic changes termed epigenetic. Epigenetic mechanisms include the methylation of DNA and the covalent post-translational

modification of histone proteins. Up until now, the majority of investigations into ALS epigenetics have focused on DNA methylation. Comprehensive characterization of the histone modification landscape in ALS is still lacking. We hypothesize that post-translational modification (PTM) of histones plays a role in the cellular demise observed in ALS. We have discovered distinct histone modification profiles associated with FUS, TDP-43 and C9orf72 proteinopathies in yeast and human models. Remarkably, we discovered distinct changes in histone modification profiles for each proteinopathy model evidencing that histone PTM changes are not associated with general protein aggregation toxicity pathways. Furthermore, we have identified small molecules that diminish the toxicity of FUS overexpression. Our data corroborates previous findings in different model systems, while significantly broadening our knowledge of the epigenetic landscape of neurodegenerative disease. Our findings highlight novel epigenetic mechanisms at play in ALS. Epigenetic processes are highly accessible targets for pharmaceutical treatments and thus they can lead to novel, alternative approaches in the treatment of ALS and other neurodegenerative diseases.

Cortical Synaptic and Mitochondrial Dysfunction in Mouse Models of Huntington'S Disease.

Y. GU, 92122, A. Pope, C. Christopher, W. Mobley, C. Wu; UCSD/SDSC, NIST, san diego, CA.

Cortical synaptic and mitochondrial dysfunction in mouse models of Huntington's disease

Huntington's disease (HD) is a fatal movement disorder. Due to the CAG repeats expansion (>36) of exon 1 in the Huntingtin (HTT) gene, HD is likely resulted from accumulation of mutant HTT (mHTT) protein with increased polyglutamine (polyQ) tract near the N terminus. Despite of intensive research, the underlying mechanisms of mHTT eliciting HD is still not clear. We used two related HD mouse models to explore the cellular mechanisms of the pathogenesis in HD. One is the BACHD mouse that expresses a moderate level of the full-length human mHTT transgene (polyQ97) using a bacterial artificial chromosome (BAC). The second model is based on BACHD except the N-terminal 17-residues were removed (ΔN17-BACHD). We first examined the formation of synapses by IF using anti-synapsin I for pre-synapses and anti-post synaptic density 95 (PSD95) for post-synapses. Our findings are: a) the synaptic formation began to form at DIV14; b) No difference between WT and BACHD cortical neurons was observed at DIV14; c) Starting at DIV21, BACHD neurons showed a progressive reduction in synapses up till DIV35. By contrast, the synapses in ΔN17 BACHD cortical neurons were significantly increased at DIV28 and DIV35. We then used JC-9 to measure mitochondrial activity. Our results demonstrated: a) BACHD primary cortical neurons showed accumulation of multiple mitochondria accumulated locally and formed inclusion-body like structures in the processes at DIV8. Mitochondrial membrane potentials were also significantly reduced at DIV13 in these neurons. Again, the data for ΔN17 BACHD cortical neurons were contrary to BACHD i.e an increase in mitochondrial membrane potential. We thus conclude that both of BACHD and ΔN17 BACHD neurons showed abnormal synaptic formation and mitochondrial activity, albeit the two models displayed opposite effects. Understanding the molecular and cellular mechanisms underlying the difference between the two HD models will yield important insights into HD pathogenesis.

P2226/B476

Effects of Distressed SH-SY5Y Cells on the Migration and Aggregation of Activated Bv2 Cells.

M. Roberts-McDonald, T. Stein, E. Nolan, R. Caffrey, N. Raffensberger, B. Fenner; King's College, Wilkes-Barre, PA.

Parkinson's disease (PD) is a debilitating disorder that affects dopaminergic neurons of the Substantia Nigra. The degeneration of dopaminergic neurons begins decades before symptoms are first seen. One possible contributor to PD may be systemic activation of inflammation or over-activation of microglia in the brain. While microglia are necessary for brain health, there is evidence that over-activated microglia, as seen in the LRRK2 mutation associated with PD, can lead to increased susceptibility of dopaminergic neurons to injury. We hypothesize that activated microglia can be pushed from a physiological to pathological state in the presence of distressed neurons. Therefore, we developed an in *vitro* model of PD where we co-culture distressed SH-SY5Y cells with lipopolysaccharide (LPS)-activated BV2 cells. We used bright-field and fluorescence microscopy to quantitate the effects of distressed SH-SY5Y cells on BV2 migration and aggregation. In our model, increased LPS concentrations had a direct relationship with increase microglia aggregation and migration. These effects were not evident when activated BV2 cells were co-cultured with healthy SH-SY5Y cells. Ongoing studies are investigating the effects of other pro-inflammatory factors on BV2 activation states.

P2227/B477

2-carba Cyclic Phosphatidic Acid Contributes to the Neuroprotection in Stab-wounded Cerebral Cortex *Via* Regulation of Astrocytes.

M. Nakashima; Ochanomizu University, Tokyo, JAPAN.

Traumatic brain injury (TBI) is caused by physical damage, and the brain structure is disrupted due to the biomechanical insult to the cranium. We previously revealed that 2-carba cyclic phosphatidic acid (2ccPA) significantly suppresses the hemorrhage level and inflammation *via* the regulation of microglial activation in the stab-wounded cerebral cortex as a TBI mouse model. 2ccPA is a metabolically stabilized derivative of cyclic phosphatidic acid (cPA), and with phosphate oxygen is replaced with a methylene group at the *sn*-2 position of cPA. Furthermore, we have already reported that the suppression of hemorrhage level by 2ccPA is related to the recovering from blood-brain barrier (BBB) breakdown caused by the TBI. Astrocytes, one of the major components of BBB, take a critical role in neuroprotection. However, the mechanism how astrocytes are involved in the promotion of the neuroprotection by 2ccPA in the stab-wounded cortex remains unknown. In addition, it is known that the expression of tenascin-C (TN-C), one of extracellular matrix proteins, is upregulated in the reactive astrocytes after experimental subarachnoid hemorrhage and suggests that delay of the recovery from BBB breakdown. In this study, to investigate the effect of 2ccPA on the neuroprotective function through astrocytes after the brain injury, we analyzed the glial fibrillary acidic protein (GFAP), an astrocyte marker and upregulated when it became reactivated and TN-C, expression levels and neuronal survival in the stab-wounded mouse cortex. We found that the administration of 2ccPA to brain injured mice decreased the *Gfap* mRNA and protein expression levels. Not only that, 2ccPA reduced the number of GFAP- and Sox9 (an activated astrocyte marker)- double positive astrocytes, suggesting that 2ccPA attenuates the activation of astrocytes after the stab wound. Moreover, to analyze the effect of 2ccPA on the neuro survival in the wounded regions. We revealed that 2ccPA reduced the number of the activated caspase-3 positive cells, indicating that 2ccPA suppresses the neuronal cell death. Therefore,

these results suggest that 2ccPA is involved in neuroprotection *via* the regulation of astrocyte activity in the stab-wounded cortex.

Secretion of Tau by Vamp8: a Novel Pathway for Tau Clearance.

J. Pilliod, A. Desjardins, M. Gelinas-Faucher, **N. Leclerc**; University of Montreal, Montreal, QC, CANADA.

In Alzheimer's disease (AD), tau, a neuronal microtubule-associated protein becomes hyperphosphorylated, aggregates and accumulates in the somato-dendritic compartment. In parallel to its intracellular accumulation, tau was also shown to accumulate in the extracellular space in AD. Indeed, tau was detected in the cerebrospinal fluid during the progression of the disease, which was believed to correlate with neuronal cell death. However, recent studies including ours have reported that neurons can secrete tau. Based on the fact that both intracellular and extracellular accumulations of tau were shown to be detrimental to neurons, we have investigated tau secretory pathway. Tau secretion occurs through unconventional secretory pathways, which were known to involve structures such as late endosomes, autophagosomes and lysosomes, membranous organelles that can fuse with the plasma membrane to release their content. Previously, we reported that Rab7A associated with late endosomes was implicated in tau secretion. In this study, we explored whether vesicle-associated membrane protein 8 (VAMP8), a SNARE involved in endosomal fusion and exocytosis of several secretory cells was involved in tau secretion. The effects of VAMP8 on tau secretion were examined in the neuroblastoma cell line N2A using immunoblot, dot blot and TIRF microscopy. The overexpression of VAMP8 significantly increased tau secretion resulting in a decrease of its intracellular accumulation in N2A. The same effects of VAMP8 overexpression was observed with tau mutants linked to Fronto-Temporal Dementia with Parkinsonism, P301L and R406W, and with alpha-synuclein, indicating that VAMP8 could be used for clearance of multiple proteins involved in neurodegenerative diseases. Using TIRF microscopy, it was possible to observe the fusion of VAMP8-positive vesicles with the plasma membrane, which was associated with the depletion of tau signal in the cytoplasm. We previously demonstrated that cleavage of tau by caspase-3 increased its secretion. This was also observed when tau secretion was increased by VAMP8 overexpression. Extracellular tau was shown to be responsible for the propagation of tau pathology in the brain. In this context, extracellular tau is presently a therapeutic target in several clinical trials where it is neutralized by an anti-tau antibody. From the above observations, one can speculate that the increase of tau secretion combined with the capture of extracellular tau by an antibody could be an efficient approach to prevent tau intracellular accumulation as well as the propagation of tau pathology in AD brain.

The Role of Lamin a and Progerin in Brain Aging and Neurodegenerative Diseases.

H. Xue, S. J. Gates, III, K. Cao; University of Maryland, College Park, College Park, MD.

Neurodegenerative diseases, which are featured by progressive neuronal impairment, are one of the most severe public health problems over the world. Alzheimer's disease (AD) is the most common neurodegenerative disease, characterized by amyloid plaques and tau fibrils. The nuclear lamina, consisting of a and B type lamins, plays a structural supporting role for most cell types including brain cells, and it is associated with brain development and neuronal survival. While B type lamins are universally expressed in brain cells, the expression of a type lamins in the brain is generally repressed.

Interestingly, a recent study showed an up-regulation of a type lamins in the hippocampus in the late-stage AD. Here, we aim to study the potential role of a type lamins and a lamin a mutant form, progerin in brain aging and neurodegenerative diseases. Using a neural progenitor cell (NPC) line which can be differentiated into neurons, we first examined the regulation of type a and B lamin expression during differentiation. We found differential regulations, at transcriptional and translational levels, of lamins A, B and C. We also used lentiviral constructs to overexpress lamin a and progerin in NPCs and evaluated their impacts on neuronal function. Our results suggest that overexpression of lamin a and progerin could induce nuclear blebbing, increase apoptosis events and cell cycle re-entry. We further postulate that induced lamin a and progerin with age may contribute to neurodegeneration.

***Drosophila* Models of ALS Identified the Context Impact on the Toxicity of Expanded GGGGCC Repeats.**

F. He[1,2], B. N. Flores[2], A. Krans[2], S. Niraula[1], M. Frazer[2], O. Adefioye[1], S. Natla[2], S. Barmada[2], P. K. Todd[2,3]; [1]Texas A&M University, Kingsville, TX, [2]University of Michigan, an n Arbor, MI, [3]Ann Arbor VA Medical Center, an n Arbor, MI.

An intronic hexanucleotide repeat expansion in *C9ORF72* causes familial and sporadic Amyotrophic Lateral Sclerosis (ALS) and frontotemporal dementia (FTD). This repeat is thought to elicit toxicity through RNA mediated protein sequestration and repeat-associated non-ATG (RAN) translation. We generated transgenic flies expressing an artificial intron containing interrupted GGGGCC repeats within a GFP reporter. 484 intronic repeats elicited minimal alterations in eye morphology, viability, longevity, or larval crawling but did trigger RNA foci formation. In contrast, insertion of 28 GGGGCC repeats into the 5' leader upstream of GFP was toxic in some reading frames. To investigate whether the GGGGCC repeat toxicity is also modified by the surrounding context of human *C9ORF72* gene, phenotype analyses were performed on several transgenic fly lines either expressing expanded GGGGCC repeat alone or expressing the GGGGCC repeats along with the 3' downstream sequence encoding hypothetical C-terminal fragments. It was found that the 3' downstream sequence in these expanded repeats partially attenuated the repeat toxicity. Similar findings of the 3'-downstream sequence attenuations was also confirmed in cell culture transfected with similar constructs. In summary, the toxicity of expanded GGGGCC repeats in *Drosophila* ALS models is highly dependent on the context: while intronic expanded repeats are largely nontoxic in *Drosophila*, exonic repeat toxicity is further modified by the intrinsic 3' downstream sequence. These findings are meaningful for better understanding C9ALS disease pathogenesis.

P2231/B481

Phenotypic Screening and Functional Genetics in Ftd/als.

S. W. Humble[1,2], B. J. Ryan[2], R. Wade-Martins[2], M. E. Ward[1]; [1]National Institute of Neurological Disorders and Stroke, NIH, Washington, DC, [2]Department of Physiology, an atomy and Genetics, Oxford, UNITED KINGDOM.

Frontotemporal Dementia (FTD) and Amyotrophic Lateral Sclerosis (ALS) are adult-onset neurodegenerative diseases that are closely related clinically, pathologically, and genetically. Therefore, it is likely that converging disease pathways exist and can be used both to enhance our understanding of basic FTD/ALS biology and as leads for therapeutic intervention. FTD/ALS is often inherited and causal mutations are highly penetrant, indicating that these mutations have large effects on critical cellular

pathways. Approximately half of the genes known to cause FTD/ALS encode proteins that regulate endolysosomal biology or play a crucial role in regulating proteostasis. Our own unpublished data implicates lysosomal dysfunction as a central pathophysiological consequence of mutations in *GRN*due to defects in endolysosomal acidification and/or maturation, building upon previously established work from my mentor demonstrating that lysosomes are a key player in FTD/ALS-related neurodegeneration. Here, we propose to use our modified i^{3}Neuron platform to facilitate systematic knockdown of large panels of FTD/ALS-associated genes through CRISPR interference (CRISPRi) to interrogate Gene-Drug and Gene-Gene interactions. From this, we will generate genetic interaction maps of pairs of FTD/ALS genes in iPSC-derived neurons, identifying common pathogenic changes elicited by disease genes related to several key cellular processes, including endolysosomal acidification and maturation, lysosomal ion homeostasis, selective autophagy, organelle quality control, and neuronal survival. We will also use drug libraries with well-characterized molecular targets in combination with CRISPRi knockdowns to more precisely define sensitized pathways in FTD/ALS. Through these efforts, we hope to lay the groundwork for improved molecular understanding and therapeutic discovery.

P2232/B482

Identification of Cell Receptors Involved in the Propagation of Tau Aggregates.

P. Wang, Y. Ye; NIH, Bethesda, MD.

Prion-like propagation of aberrant protein aggregates in the brains of neurodegenerative disease (ND) patients involves the release of misfolded proteins from neurons, their uptake by nearby cells, and induction of endogenous protein aggregation and proteotoxic stress in recipient cells. Inflammation response is another insult that has been linked to the interaction of misfolded proteins with cells in ND. Little is known about how misfolded proteins either in a monomeric state or as aggregates interact with the plasma membrane and the resulting pathophysiological impact. To understand how misfolded proteins interact with the plasma membrane to initiate prion-like propagation and potential signaling pathway, we used Tau as a model because it is misfolding prone protein and the transmission of Tau aggregates between cells impacts the progression of Alzheimer's disease. We employed spatially-restricted proteomic mapping using APEX2-tagged Tau. APEX2 is an engineered peroxidase that can covalently tag proximal proteins with a biotin molecule in the presence of biotin-phenoxyl radicals. Following the binding of Tau-APEX2 to the cell surface, biotinylation labeling was initiated by addition of biotin-phenoxyl, and biotinylated plasma membrane proteins were then enriched by streptavidin-affinity purification and identified by mass spectrometry. Using this approach, we identified a member of the integrin family as the potential Tau binding receptor. Integrins are a major cell adhesion molecule that binds extracellular matrix proteins and are involved in maintenance of neuronal functions. Using in-vitro and cell-based pull-down assay, we confirmed the interaction between integrins and both monomeric and oligomerized Tau. We also found that over-expression of integrin family members in 293T cells can increase Tau binding, and conversely, knockout of endogenous integrins in SH-SY5Y cells by CRISPR/Cas9 decreases Tau-plasma membrane interaction. In order to reveal the physiological consequence of Tau-plasma membrane interaction, RNAseq was employed to identify gene expression differences between primary astrocyte treated with Tau monomers or fibrils. Partial overlapping but distinct sets of induced genes were identified. Typically, we found that cytokine and chemokine induced neuro-inflammation was significantly increased in Tau-fibril treated astrocytes, which also upregulate reactive astrocyte marker genes, compared to those treated with Tau monomers. Interestingly, knockdown of integrin can significantly reduce the activation of inflammation. In summary, we have

identified a receptor for misfolded Tau, which not only mediates the uptake and propagation of Tau fibrils, but also regulates the inflammation in response to misfolded proteins.

P2233/B483

Bait RNA Oligonucleotides to an tagonize Pathological Protein Aggregation in ALS/FTD.

J. Mann[1], L. Guo[2], A. Gleixner[1], J. Mauna[1], E. Gomes[3], J. Shorter[3], C. Donnelly[1]; [1]University of Pittsburgh, Pittsburgh, PA, [2]Thomas Jefferson University, Philadelphia, PA, [3]University of Pennsylvania, Philadelphia, PA.

Aberrant aggregation of RNA-binding proteins, such as TDP-43 and FUS, is a common neuropathological hallmark of neurodegenerative disorders such as amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). Current cellular models of these neurodegenerative proteinopathies often rely on the overexpression of disease-linked mutant proteins to induce pathological protein aggregation. However, mutations in the TARDBP and FUS genes each only account for ~5% of familial ALS (fALS) cases. The vast majority of patients do not harbor mutations in these genes, yet still experience aggregation of these proteins. Similarly, rodent models of ALS produced from the overexpression of these mutant proteins have been historically unreliable and often fail to produce pathologically-relevant inclusions. Here we present a novel optogenetic-based technique to induce pathological aggregation of TDP-43 and FUS with a previously unachievable level of spatial and temporal control (optoTDP43/optoFUS). Using this approach, we discovered that the RNA-binding status of TDP-43 and FUS dictate their propensity to undergo liquid-liquid phase separation (LLPS) and form pathological inclusions. We also show that these aberrant intracellular phase transitions are toxic to human neuronal cultures and that bait RNA oligonucleotides (bONs) mimicking known TDP-43 or FUS binding sequences can prevent light-induced phase transitions and rescue resulting neurotoxicity. In order to work towards a more therapeutically-relevant paradigm, we also investigate the ability of bONs to disaggregate existing TDP-43 and FUS inclusions and examine resulting effects on neuronal survival. This optogenetic strategy can be further applied to a number of different disorders and will aid in the identification of negative regulators of pathological protein aggregation, as well as in-depth investigations into the effects of these pathological aggregates on various cellular pathways and downstream pathological processes.

P2234/B484

Myosin-7B Facilitates Heparan Sulfate Proteoglycan-mediated Endocytosis of α-Synuclein Fibrils**.**

Q. ZHANG; NIH, Bethesda, MD.

Cell-to-cell transmission of misfolding-prone α-synuclein (α-Syn) has emerged as a key pathological event in Parkinson's disease. This process comprises two poorly characterized cellular pathways: release of α-Syn by unconventional protein secretion and uptake of α-Syn-bearing fibrils via clathrin-mediated endocytosis (CME). Using a CRISPR-mediated knockout screen, we identify SLC35B2 and Myosin-7B (MYO7B) as critical regulators for endocytosis of α-Syn preformed fibrils (α-Syn PFF). SLC35B2 is a membrane transporter involved in the synthesis of cell surface heparan sulfate proteoglycan (HSPG), whose sugar moieties bearing linearized negative charges can insert into a groove formed by two K-X-K motifs clustered in α-Syn PFF. MYO7B, an unconventional myosin acts with actin filaments to maintain membrane dynamics at plasma membrane domains enriched in clathrin. Without MYO7B, a fraction of clathrin-coated pits fail to be severed from the plasma membrane, causing accumulation of large clathrin-containing scars on the cell surface. Intriguingly, the functions of MYO7B and SLC35B2 are only

restricted to the uptake of α-Syn PFF and other polycation-bearing cargos that enter cells via HSPG. We propose that the maturation and optimal function of clathrin-coated pits (CCP) in HSPG-dependent endocytosis requires additional force generated by MYO7B and the actin network.

P2235/B485
A Robust Double Mutant Mouse Model of Hereditary Spastic Paraplegia Reveals Expanded Endoplasmic Reticulum in Axons.
P. Zhu, C. Blackstone; National Institute of Neurological Disorders and Stroke, NIH, Bethesda, MD.

Hereditary spastic paraplegias (HSPs) are neurologic disorders affecting the longest corticospinal axons, resulting in lower extremity spasticity. The most common autosomal dominant forms are caused by mutations in genes that encode spastin (SPG4), atlastin-1 (SPG3A) and REEP1 (SPG31). These proteins harbor hydrophobic hairpin domains, bind one another, and play an important role in shaping the tubular ER network. To date, most studies on atlastin-1 and REEP1 have been performed in cultured cells, although they are highly enriched in the central nervous system. Here, we report a robust double mutant mouse model of HSP in which a GTPase-defective atlastin-1 has been generated with a K80A missense change and the *Reep1* gene has been disrupted. These double mutant mice show significant behavioral changes in hindlimb function tests. The hindlimb weakness appears as early as 4 weeks and continues to progress, with euthanasia typically performed around 6-8 months due to severe motor impairment. Interestingly, ER within corticospinal tract axons in spinal cord is expanded dramatically in the double mutant mice as compared to wild-type and single mutant mice. This robust mouse model will prove useful for studying the roles of impairments in atlastin-1 and REEP1 function that result in ER morphology changes that underlie the most common forms of HSP, and it also may help to identify potential molecular targets for the development of therapeutics.

Neuronal Morphogenesis and Axo-Dendritic Organization

P2236/B486
A Pair of E3 Ubiquitin Ligases Compete to Regulate Filopodial Dynamics and Axon Guidance.
N. P. Boyer, **S. Gupton**, L. McCormick, S. Menon, F. Urbina; University of North Carolina-Chapel Hill, Chapel Hill, NC.

Appropriate axon guidance is necessary to form accurate neuronal connections. The cytoskeletal rich growth cone at the tip of an extending axon senses and responds to extracellular guidance cues in order to navigate axon growth toward appropriate targets. Filopodia at the periphery of the growth cone have long been considered sensors for axon guidance cues, yet how they perceive and respond to extracellular cues remains ill-defined. Our work has found that in embryonic murine cortical neurons, the filopodial actin polymerase VASP is regulated via TRIM9-dependent non-degradative ubiquitination, and that appropriate VASP ubiquitination and deubiquitination are required for axon turning in response to the guidance cue netrin-1. Here we show that the TRIM9-related E3 ubiquitin ligase TRIM67 antagonizes TRIM9-dependent VASP ubiquitination. Ubiquitination alters the dynamics of VASP at filopodia tips and the stability of growth cone filopodia. TRIM67 ligase activity is surprisingly required for antagonizing VASP ubiquitination, as well as its strong interaction with VASP, which outcomes TRIM9. By antagonizing VASP ubiquitination, TRIM67 increases filopodia stability and promotes responses to netrin. This antagonistic role in VASP ubiquitination is required for netrin-1 dependent filopodial and

growth cone responses and netrin-dependent axon branching. Using a compartmentalized axon guidance microfluidic device, which exposes only axons to a stable gradient of netrin, we find that TRIM67 is required for netrin-dependent axon turning responses in vitro. In vivo, netrin is required for the formation of the corpus callosum, a major midline axon projection in the cortex. We find that deletion of *Trim67* delays the formation of this fiber tract, and the resultant commissure is thinner than in wildtype littermates. This phenotype is the opposite phenotype of mice in which *Trim9* is deleted. We suggest a novel yin yang model: coordinated regulation of non-degradative VASP ubiquitination by a pair of ligases is a critical element of netrin-dependent filopodial stability, growth cone response, and axon guidance.

P2237/B487

Transcriptomic an alysis of CAD Cell Differentiation.

C. Cevallos[1], **A. White**[1], J. Feng[1], D. Posfai[2], O. A. Quintero[1], A. L. Hill[3], J. M. Warrick[1]; [1]University of Richmond, RIchmond, VA, [2]Duke University, Durham, NC, [3]Bates College, Lewiston, ME.

CAD cells are a model neuron-like cell line derived from Cath.A cells a mouse central nervous system catecholaminergic cell line. Serum-starvation of CAD cells induces the production of long neurite extensions over the course of 5 days. These cells have been used in multiple published studies of neuronal function, and in other work from our lab CAD cells are serving as the base cell type for characterization of proteins involved in mitochondrial traffic and neuronal development via stable shRNA expression. CAD cells bear a morphological resemblance to isolated neurons when observed by either light microscopy or electron microscopy. We hypothesized that they would also bear a similar pattern of gene expression changes compared to developing neurons. We approached this hypothesis by carrying out comparative transcriptomic RNAseq analysis comparing undifferentiated and differentiated wild type CAD cells. We identified approximately 1900 mRNA transcripts that changed expression levels between undifferentiated and differentiated cells (-1>logbase2>1, padj<0.1). Using immunofluorescence microscopy, we demonstrated that protein level changes for a select number of these genes mirrors the changes in mRNA levels. Using Pathview, we identified pathways as a starting point where gene expression within the pathway changed. We examined a subset of the 80 identified pathways that were related to neuronal function. We also compared the changes in gene expression observed in CAD cells to changes in gene expression observed in cortical embryonic stem cells differentiated in vitro (http://cortecon.neuralsci.org/) and were able to identify a set of genes and pathways whose expression changes in CAD cells mirror those observed in developing cortical neurons. These data provide a more detailed understanding of the neuron-like character of differentiated CAD cells.

P2238/B488

Kansl1 Haploinsufficiency Suppresses Postnatal Neurogenesis and Normal Neural Behavior in Mice.

B. Jeon, H. Lee, W. Kim; Kent State University, Kent, OH.

Koolen-de Vries syndrome is a neurodevelopmental disorder characterized by developmental delay and intellectual disability. The syndrome is caused by either mutations in the *KAT8 regulatory NSL complex complex subunit 1* (*KANSL1*) gene or microdeletions in the 17q21.31 chromosomal region that includes *KANSL1*, leading to *KANSL1* haploinsufficiency. However, the pathogenic mechanism of how *KANSL1* haploinsufficiency disrupts intellectual function is unknown. Here, we report that *Kansl1*

haploinsufficient mice show learning and memory impairments, which recapitulates intellectual dysfunction in human Koolen-de Vries syndrome. The Morris water maze test revealed that *Kansl1* haploinsufficient mice spent more time in finding the platform than wild type controls. The novel object test confirmed the disrupted intellectual function of identifying novel object in *Kansl1* haploinsufficient mice. The social novelty test using the three-chamber paradigm also showed abnormal recognition in the mutant mice. Interestingly, *Kansl1* haploinsufficient mice exhibited the reduced size of the olfactory bulb, indicating disrupted neurogenesis and migration of subventricular zone neural progenitors. Additionally, neural progenitor proliferation in another neurogenic niche, the hippocampal dentate gyrus, was decreased in *Kansl1* haploinsufficient mice. The number of proliferative progenitors identified by short-pulse BrdU tracing and phospho-histone H3 (Ser 10) immunostaining was reduced in the mutant mice, compared to control mice. These results demonstrate that both copies of *Kansl1* is required for postnatal neurogenesis. Combined with behavioral phenotypes of *Kansl1* haploinsufficient mice, our data suggest that impaired genesis and integration of newborn neurons in neurogenic niches may contribute to the development of intellectual dysfunction in Koolen-de Vries syndrome.

P2239/B489

Motor Neuron Morphogenesis Is Controlled by Transcriptional Activation of Phospholipid Signaling to the Actin Cytoskeleton.

D. Buttigieg[1], Z. Tian[2], A. Jacquier[1], S. Blanchard[3], M. Barad[4], I. Medina[5], D. Gentien[6], P. De La Grange[7], D. Bohl[3], D. Cleveland[2], J. Santini[2], M. Erb[2], **G. Haase**[2,1]; [1]INSERM, Marseille, FRANCE, [2]UCSD, La Jolla, CA, [3]Institut Pasteur, Paris, FRANCE, [4]CIML, Marseille, FRANCE, [5]INMED, Marseille, FRANCE, [6]Institut Curie, Paris, FRANCE, [7]Genosplice, Paris, FRANCE.

Neurons display the greatest morphological diversity among all cell types in the adult organism but the developmental pathways controlling the morphogenesis of their axons, dendrites and cell bodies remain ill understood. The objective of this study was to analyze the molecular programs controlling the morphogenesis of motor neurons innervating skeletal muscle. To this end, we analyzed the morphogenesis of two subsets of spinal motor neuron both in *vivo in* developing mouse embryos - using light sheet and dive-in microscopy - and *ex vivo* - using novel techniques of motor neuron FACS and flow cytometry (Schaller et al PNAS 2017), patch clamp recording, gene expression profiling and genetic modification. Our results show that motor neurons innervating hindlimb muscles exhibit higher rates of axon and cell body growth than motor neurons innervating axial muscles. We demonstrate that these morphogenic differences are cell-intrinsic (cell autonomous) and associated with the differential regulation of a phospholipid signaling pathway leading from activation of SGMS2, DGKb, CDS1, PI5P-4K and PLCE to actin polymerization. DGKb (diacylglycerol kinase beta) is identified as the key enzyme in this pathway since its gene knockdown or over expression is sufficient to switch the morphogenic path of hindlimb and axial motor neurons. The transcription factors FoxP1 and Hb9 act as upstream regulators of this pathway since their cross repressive actions mimic the effects of DGKb on actin polymerization as well as axon and cell body growth. In conclusion, these data unravel how transcriptional codes fine tune the morphogenesis of motor neurons through differential phospholipid signaling to the actin cytoskeleton.

P2240/B490

Snap47 and Trim67 Alter Mode of Vamp2-mediated Exocytic Fusion in Developing Cortical Neurons.

F. Urbina, S. Menon, S. Gupton; University of North Carolina: Chapel Hill, Chapel Hill, NC.

Exocytosis is required in developing neurons to supply material for plasma membrane expansion during morphogenesis. Classically, two modes of fusion have been reported. During full-vesicle-fusion (FVF), the fusion pore dilates and the vesicle collapses into the membrane. During kiss-and-run fusion (KNR) the fusion pore opens transiently for secretion, without adding plasma membrane material. We hypothesized that during neuronal morphogenesis, FVF-like exocytosis predominates to supply membrane material. To test this, we exploited VAMP2-pHluorin as a fluorescent readout of fusion pore opening. Images were analyzed using our automated analysis platform. Here we introduce a novel machine-learning method using multiple classifiers, including hierarchical agglomerative clustering, dynamic time warping, and feature selection with dimensionality reduction for unsupervised categorization of exocytosis. A majority-rule committee of 28 indices selected four discrete classes. This surprising result suggests classes diverging from FVF and KNR exist. All four classes were tetanus sensitive, indicating bona fide VAMP2-mediated fusion. HEPES addition increased the half-life of fluorescence decay in two classes, indicating decay resulting from re-acidification, consistent with KNR fusion. The HEPES insensitive classes displayed diffusion of fluorescence away from the fusion site, consistent with FVF-like behavior. One KNR and one FVF class exhibited immediate fluorescence decay after fusion pore opening, whereas the others demonstrated a delay in decay onset, consistent with the pore remaining open prior to diffusion or resealing. We named the four classes instantaneous FVF (FVFi), delayed FVF (FVFd), instantaneous KNR (KNRi), and delayed KNR (KNRd). Modes were confirmed by following the fate of VAMP2 using VAMP2-TagRFP and VAMP2-pHluorin and by expressing a VAMP2 peptide that inhibits FVF. Mathematical modeling suggests FVF supplies sufficient plasma membrane material for morphogenesis in developing neurons. Deleting the E3 ubiquitin ligaseTrim67 significantly shifted the mode of exocytosis toward KNR fusion, without altering the frequency of exocytosis. We identified SNAP47 as a t-SNARE that interacts and colocalizes with TRIM67. SNAP47 levels increased upon deletion of Trim67. SNAP47 co-localized with a subset of VAMP2-mediated fusion events. Overexpression of SNAP47 in wildtype neurons partially phenocopied loss of Trim67, increasing KNRd exocytosis, whereas SNAP47 knockdown in Trim67-/- neurons rescued exocytic mode phenotypes. Together these results suggest that TRIM67 alters exocytic mode via SNAP47. This study provides novel quantitative and mechanistic insights into the modes of exocytosis and how they alter neuronal morphogenesis.

P2241/B491

Activity-dependent Neuroprotective Protein (adnp) Functions Via Multiple Distinct Mechanisms to Drive Cortical Neuronal Morphogenesis.

S. A. Bennison, S. M. Blazejewski, X. Liu, T. Smith; Drexel University College of Medicine, Philadelphia, PA.

Activity-dependent neuroprotective protein (Adnp) is a master regulator of ~400 genes and various signaling pathways essential to embryonic and postnatal development, and mutations in Adnp are some of the most frequent underlying Autism Spectrum Disorder and lead to a distinctive combination of clinical features. Adnp also functions in the cytoplasm during neuronal maturation to promote dendritic spine/synapse formation via microtubule interactions. Adnp's activities in earlier neuronal development

remain elusive but are important to understand how Adnp mutations result in pathology. Previous research has suggested that Adnp may play a role in promoting neurite formation. Defective neuritogenesis is currently gaining notoriety as a contributing pathogenic mechanism behind a variety of neurodevelopmental diseases, prompting us to investigate Adnp's suggested role in more detail. Our RNA-Sequencing (RNA-Seq) data suggest increased Adnp expression throughout neuritogenesis, and our cortical neuritogenesis analyses implicate a much more complex role for Adnp in neuronal morphogenesis than previously reported. Overexpression of Adnp in *vitro* leads to premature spine-like formation on all neurites, including the neurite most likely to become the axon suggesting that Adnp may function in neuronal polarization and timing of dendritic spine emergence. Knockdown of Adnp in *vitro* and in *vivo* leads to increased neurite initiation and increased elongation of the axon only. In *vivo* analysis using in *utero* electroporation revealed Adnp knockdown leads to an additional morphological deficit, disrupting the angle of the apical dendrite at P3. This may reflect altered connectivity and response to guidance cues, which is ultimately based on microtubule dynamics. Adnp is known to promote microtubule polymerization and we conclude that this defect at P3 as a result of Adnp knockdown is due to altered microtubule dynamics. *Ex vivo* time-lapse live imaging of neuritogenesis in living brain slices revealed further severe defects in neurite formation and dynamics including dilations and swellings on growing neurites from Adnp deficient cells, potentially as a result of cytoskeletal bundling and/or defective cellular transport. Further notable defects include increased neurite length but decreased growth throughout imaging, decreased growth and shrinking velocity, and increased neurite stabilization. We conclude that Adnp works via multiple distinct mechanisms to establish proper neuronal morphogenesis, which is crucial for cortical development, and that both overexpression and deficiencies in Adnp result in severe morphological defects in cortical neurons which have implications for overall cortical function.

P2242/B492

***Arid1b* Haploinsufficiency Suppresses Neurite Development and Mitochondria Function.**

H. Lee, E. Jung, B. Jeon, W. Kim; KENT STATE UNIVERSITY, KENT, OH.

Haploinsufficiency of the *AT-rich interactive domain 1B (ARID1B)* gene, a chromatin remodeling gene, causes autism spectrum disorder and intellectual disability. Despite *ARID1B*'s critical status in neurodevelopmental pathogenesis, the consequences of *ARID1B* haploinsufficiency at the molecular and cellular level remain poorly understood. Here using *Arid1b* heterozygous knockout mice, we show that *Arid1b* haploinsufficiency suppresses outgrowth and branching of axons and dendrites in the cerebral cortex. The number and length of primary cortical dendrites were decreased in *Arid1b* haploinsufficient mice, compared with wide-type controls. Secondary, tertiary and quaternary branches as arborization indicators showed a reduction in the mutant condition. Elongation of callosal axons was also impaired in *Arid1b* haploinsufficient mice. Dendritic spines appeared abnormal as they revealed thin and short protrusions on dendrites in the mutant mice. The abnormal spines accompanied an increase in the synaptic cleft width and a decrease in the length of post-synaptic density, compared with controls mice. Intriguingly, there were reductions in the mitochondrial membrane potential and cytochrome c oxidase activity in *Arid1b* haploinsufficient neurons. Furthermore, *Arid1b* haploinsufficient neurons revealed decreased *Ntrk2* (*TrkB*) mRNA expression as well as reduced binding of acetylated histone H3 (H3K9ac) on the *Ntrk2* promoter. Together, our findings suggest that *Arid1b* haploinsufficiency leads to abnormal histone modification at K9 via energy deficiency, which is likely caused by mitochondrial dysfunction. This disrupted epigenetic status may suppress the energy-demanding process of chromatin remodeling

on the *Ntrk2* gene, thereby inhibiting *Ntrk2* expression and neurite development in *Arid1b* haploinsufficient neurons.

P2243/B493

Extracellular ATP Promotes Spiral Ganglion Neuron Maturation Via P2rx3 Receptors.

Z. Wang[1], T. Babola[2], J. Jung[1], K. Rangoussis[1], T. Inbar[1], C. Faaborg-Andersen[1], D. E. Bergles[2], T. M. Coate[1]; [1]Georgetown University, Washington, DC, [2]Johns Hopkins University, Baltimore, MD.

The mammalian cochlea undergoes a highly dynamic process of growth during development. This process includes the extension of the cochlear duct along with spiral ganglion neuron (SGN) migration, followed by their maturation and synaptic contact with hair cells (HCs). In mouse, this process commences around embryonic day 12 (E12) and continues through early postnatal stages. Understanding the molecular mechanisms of precise cochlear wiring reveals principles of developmental biology and will be crucial for developing molecular-based treatments for hearing loss. Extracellular ATP is known to act as a neurotransmitter for mature neurons by activating either ionotropic or metabotropic purinergic receptors. However, little is known about their roles in development. We have found that one of the ionotropic receptor family members, P2X3, is expressed at high levels in SGNs from E12.5 to P6. We show here this developmental period includes a phase of dramatic branch pruning and hypothesized that P2X3 was involved in this process. To examine the function of P2X3 in SGN development, we examined individual SGNs from *P2x3*$^{-/-}$ cochleae after genetic labeling using *Sox2*^{CreERT2} and *R26R*^{tdTomato}. Using this approach, we found that loss of P2X*3* results in more complex branching patterns at axonal terminals and dysregulated branch refinement near SGN cell bodies around P0. These data suggest that P2X3 normally mediates a pruning process to eliminate excessive branches during early SGN development. Given that P2X3 predominantly permeates calcium and such spontaneous calcium transients coincide with the critical period of branch pruning, we further tested if P2X3 underlies spontaneous neuronal activity. Using Flou4-AM and calcium imaging, we found that a,ß,me-ATP, a P2X3 agonist, potentiates SGN calcium events and that NF110, a P2X3 antagonist, alters activity patterns. We also found that SGN activity patterns are dysregulated in the absence of P2X3. These data show that calcium transients in embryonic SGNs are mediated by P2X3 receptors. Previously, extracellular ATP and purinergic receptors have been implicated in spontaneous calcium action potentials to organize neural circuits. Taken together, we conclude that SGN maturation requires P2X3-mediated extracellular ATP and intracellular calcium signaling.

Cyclic AMP-dependent Co-stabilization of Axonal Arbors from Adjacent Developing Neurons.

A. Louail[1], M. Sierksma[1], A. Chaffiol[2], A. Assali[3], S. Couvet[1], M. Nedjam[1], F. Roche[1], Y. Zagar[1], J. Duebel[2], **X. Nicol**[2]; [1]Sorbonne University - Institut de la Vision, Paris, FRANCE, [2]CNRS - Institut de la Vision, Paris, FRANCE, [3]Inserm - Institut du Fer à Mouliln, Paris, FRANCE.

The connectivity of many neuronal networks is exuberant early during development, before axonal arbors are refined by activity-dependent competitive mechanisms. Competition is generally considered to entail synapse destabilization and pruning mechanisms resulting from asynchronous activity between pre- and post-synaptic partners. In addition, theoretical predictions include non-competitive interactions between co-active neighboring axons to co-stabilize their connections. The demonstration of such interactions in a physiological context has been limited by the complexity of the experimental paradigms

needed. We provide direct evidence that axonal arbors from neighboring retinal ganglion cells in the retina co-stabilize their branches. This co-stabilization influences axon pruning in the thalamus *via* a cAMP-dependent mechanism that does not affect spontaneous activity in the retina.

P2245/B495

Mechanistic Insights into the Interactions of Ndel1 with Neuronal Specific an kyrins and Implications in Axonal Polarity Maintenance through Selective Cargo Transport.

J. Ye[1], J. Li[2], C. Wang[1], M. Zhang[2]; [1]University of Science and Technology of China, Hefei, CHINA, [2]Hong Kong University of Science and Technology, Hong Kong, CHINA.

Ankyrin-G (AnkG), a highly enriched scaffold protein in the axon initial segment (AIS) of neurons, plays crucial roles for the maintenance of axonal polarity and integrity of the AIS organization. In the AIS, an kG regulates selective intracellular cargo trafficking between the soma and axon through interaction with a dynein regulator Ndel1. However, the molecular mechanism governing the interaction of an kG with Ndel1 remains elusive. Here, we report that Ndel1 C-terminal coiled-coil (CT-CC) binds to both an kG and an kB (the homology of an kG) on the neuronal specific domains with a 2:1 molar stoichiometry. Furthermore, we solved high-resolution crystal structure of an kB in complex with Ndel1 CT-CC, revealing the detailed molecular basis for the complex assembly. Mechanistically, an kB binds with Ndel1 through forming a stable four-helix bundle majorly mediated by extensive hydrophobic interactions at six different layers. Moreover, we demonstrated that AIS cluster of Ndel1 required the specific interaction between an kG and Ndel1. Finally, we evaluated the effect of cargo sorting through the AIS by disrupting the an kG/Ndel1 complex. Collectively, our findings provide mechanistic insights into complex formation of an kG with Ndel1 and maintenance of axonal polarity and are valuable for further understanding of the functional roles of an kB/Ndel1 complex in cargo transport at the distal axon.

Development of Corticospinal Tract Connections: a Light Sheet an alysis.

Z. Tian[1], M. Erb[1], O. Gozutok[2], B. Genc[2], H. Özdinler[2], J. Santini[1], G. Haase[1,3]; [1]UCSD, La Jolla, CA, [2]Department of Neurology, Northwestern University, Feinberg School of Medicine, Chicago, IL, [3]INSERM, Marseille, FRANCE.

The correct development of the nervous system depends on the establishment of precise functional connections between neurons and their targets. The corticospinal tract (CST) is a major descending motor pathway which originates in the cerebral cortex, projects through the internal capsule, cerebral peduncle and medulla, crosses at the level of the pyramids and terminates at different levels of the spinal cord. The molecular mechanisms underlying the functional development of the CST remain ill understood, partly due to difficulties in its retrograde tracing and 2D microscopic imaging. Our objective is to understand the mechanisms of CST development in mice at increased temporal and spatial resolution. To this end, we here combined novel techniques for tissue clearing, light sheet imaging and 3D reconstruction. We first optimized tissue clearing techniques for mouse brain and spinal cord of embryonic, early postnatal and mature adult stages. We then used UCHLl1:GFP reporter mice to visualize the CST and fluorescent Hb9 and Chat reporter mice to visualize brainstem and spinal motor neuron cell bodies and axons. Light sheet imaging was done with a Zeiss Z.1 microscope using 2.5 or 5x imaging objectives (EC Plan-Neofluar NA 0.16), a 5x LightSheet objective (LSFM 5x NA 0.1), a Clarity-

specific chamber (RI 1.45) and single-view acquisition mode. Image analysis and nerve desegmentation were performed using Imaris software. Our data show that CST, brainstem and spinal neurons can be monitored over time at single cell resolution allowing refined analysis of their growth, pathfinding, branching and connection. We conclude that this approach offers new perspectives to better understand the development of the motor nervous system and potentially also to apprehend its degeneration in ALS, primary lateral sclerosis and other diseases.

P2247/B497

Identification of Novel Downstream Targets and Function in Neurite Formation for Plxdc1.

S. Blazejewski, S. Bennison, X. Liu, K. Toyooka; Drexel University College of Medicine, Philadelphia, PA.

Neural circuits undergo neurite outgrowth in response to seizures, leading to aberrant axonal sprouting and changes to the morphology and connectivity of mature neurons. Thus, neurite growth inhibitory factors could have clinical applications. Identification of new therapeutic targets for epilepsy patients is crucial, as only about one third of patients can control seizures using current antiepileptic drugs. Previously, microRNA targeting Plxdc1 (Plexin domain containing 1) has been shown to be inversely correlated with epileptogenesis. Plxdc1 serves as a receptor for nidogen-1 and PEDF. Disruption of nidogen-1 leads to seizure-like symptoms, while deletion of PEDF may contribute to the etiology of Miller-Dieker Syndrome which is strongly associated with epilepsy. Interestingly, we observed that Plxdc1 overexpression (OE) drives the formation of neurite-like extensions in N2a cells. Plxdc1 OE in primary cortical neurons led to increased dendrite length, while Plxdc1 knockdown led to fewer and shorter dendrites. We confirmed these phenotypes in *vivo* by using in *utero* electroporation. To elucidate the Plxdc1 signaling pathway and identify potential therapeutic targets, we conducted a high-throughput kinase inhibitor screen in which N2a cells undergoing Plxdc1-OE-driven neurite formation were treated with 493 kinase inhibitors. The screening implicated Akt and its downstream target GSK3β in Plxdc1-OE-driven neurite formation, which we confirmed using primary cortical neurons. To identify a target of Plxdc1 that may directly interact with the cytoskeleton, we performed sub-cellular fractionation in N2a cells undergoing Plxdc1-OE-driven neurite formation. Proteomic analysis of the cytoskeletal fraction revealed a 3.43 fold increase in activity-dependent neuroprotector homeobox protein (Adnp) expression following Plxdc1 OE. Adnp interacts with microtubules and promotes microtubule assembly and polymerization. Plxdc1 signaling including Akt and GSK3β may influence neuronal morphology by regulating microtubules via Adnp; however, the precise mechanism should be investigated. We have identified a novel function for Plxdc1 in regulating neurite formation and propose several downstream targets for Plxdc1, which may have therapeutic roles in treating epilepsy. Further work is necessary to determine how changes in Plxdc1 expression impact neuronal connectivity and networks.

Gq-mediated Calcium Dynamics and Membrane Tension Modulate Neurite Plasticity.

K. M. Pearce[1], M. Bell[2], W. H. Linthicum[1], Q. Wen[1], J. Srinivasan[1], P. Rangamani[2], S. Scarlata[1]; [1]Worcester Polytechnic Institute, Worcester, MA, [2]University of California San Diego, La Jolla, CA.

The formation and disruption of synaptic connections during development is a fundamental step in neural circuit formation. Subneuronal structures such as neurites are known to be sensitive to the level of spontaneous neuronal activity but the specifics of how neurotransmitter-induced calcium activity

regulates neurite homeostasis are not yet fully understood. In response to stimulation by neurotransmitters such as acetylcholine, calcium responses in cells are mediated the Gαq/phospholipase Cβ (PLCβ)/ phosphatidylinositol 4,5 bisphosphate ($PI(4,5)P_2$) signaling pathway. Here, we show that prolonged Gαq stimulation results in the retraction of neurites in PC12 cells and rupture of neuronal synapses by modulating membrane tension. To understand the underlying cause, we dissected the behavior of individual components of the Gαq/PLCβ /$PI(4,5)P_2$ pathway during retraction, and correlated these to the retraction of the membrane and cytoskeletal elements impacted by calcium signaling. We developed a mathematical model that combines biochemical signaling with membrane tension and cytoskeletal mechanics, to show how signaling events are coupled to retraction velocity, membrane tension and actin dynamics. The coupling between calcium and neurite retraction is shown to be operative in the C. *elegans* nervous system. This study uncovers a novel mechanochemical connection between the Gαq/PLCβ /$PI(4,5)P_2$ pathway that couples calcium responses with neural plasticity.

Uridine Promotes Neurite Outgrowth in Neuro2a Cells.

J. Spathies; Eastern Illinois University, Charleston, IL.

Neurodegenerative diseases such as Alzheimer's disease and Parkinson's disease are the main causes of age-related dementia. These diseases can be due to neuronal cell death and impairment of neurite outgrowth. Giant oyster mushroom (GOM), *Pleurotus giganteus*, is used as a nootropic that can prevent the onset of dementia. The underline mechanism behind the medicinal property of GOM is unclear. Previous studies have shown that GOM has a high concentration of uridine. In this study, we examined the effects of uridine on neurite outgrowth in Neuro-2a (N2a) neuroblastoma cell line. In preliminary studies, we examined the effects of various concentrations of uridine on neurite outgrowth in N2a cells. When exposed to uridine N2a cells produced significantly longer neurite extensions ($P<0.001$) and exhibited a significant increase in neurite bearing cells ($P<0.001$) with an ideal concentration of 100M. Our preliminary results suggest that uridine significantly promoted neurite outgrowth in N2a cells. ($P<0.001$) Future studies are required to identify the mechanism behind uridine therapeutic potential on neurodegenerative diseases.

Regulation of the Retromer Complex by Mtor Kinase.

M. Blazejczyk[1], K. Kisielewska[1], O. Tkaczyk[1], K. Kuchcinska[1], A. Brzozowska[1], J. Zmorzynska[1], J. Weslawski[1], M. Macias[1], M. Bakun[2], K. Misztal[1], M. Dadlez[2], L. Johannes[3], J. Jaworski[1]; [1]IIMCB, Warsaw, POLAND, [2]IBB, Warsaw, POLAND, [3]Institut Curie, Paris, FRANCE.

Introduction: mTOR kinase is an important regulator of neuronal cell development and neuronal plasticity. Among stages of neurogenesis regulated by mTOR is dendritogenesis. Primarily mTOR was believed to affect neurogenesis almost exclusively by controlling translation but now it is known that there are many other cellular processes downstream of mTOR involved in this process. Our preliminary data revealed that among mTOR targets is TBC1D5, a Rab7 GAP that regulates retromer activity. The retromer sets up the transport of proteins, including several membrane receptors, from the endosomes to the Golgi, known as retrograde transport. Retromer was shown to participate in dendritogenesis. Thus, we tested a hypothesis that mTOR regulates dendritogenesis at least partly via control of retromer

function.Materials and Methods. TBC1D5 phosphorylation was assessed by mass spectrometry and kinase assays in HEK293T cells. An alysis of TBC1D5 phosphorylation via mTOR was shown using stable HeLa cell lines - GFP versus TBC1D5-GFP WT or its mutants. Retromer function was tested with STxB uptake assay and immunofluorescence analysis of cellular VPS35 distribution in HeLa cells. Effect of mTOR-dependent TBC1D5 and VPS35 function on neuronal dendritic arborization and dendritic trafficking was tested in cultured hippocampal neurons.Results. We show that blocking mTOR activity with rapamycin influences retromer function. Upon treatment with rapamycin, fluorescently labeled STxB reached the Golgi at a decreased rate, suggesting an interplay between mTOR and the retromer. Our subsequent search for possible mTOR targets has found TBC1D5, a negative regulator of the retromer, to be phosphorylated by mTOR. The overexpression of unphosphorytable mutants of TBC1D5 or silenced VPS35 impaired attachment of retromer complex to the endosomal membrane as well as resulted in a significant simplification of dendritic arbors of developing neurons (observed effects are reversed by upstream mTOR regulator - PI3 kinase or an agonist of TrkB receptor - BDNF) and TrkB receptor transport along dendrite is changed.Discussion.The results of this study have revealed the mTOR kinase as a potential regulator of the retromer complex and contribution of the mTOR-retromer pathway in neuronal development. Moreover results point to intracelluar transport of TrkB receptor as key retromer-dependent processcritical for dendritogenesis.This work has been supported by Polish National Science Centre OPUS grant 2017/27/B/NZ3/01358.

P2251/B501

Retrograde Ret Signaling Controls Sensory Pioneer Axon Outgrowth.

A. Tuttle, C. Drerup, M. Marra, H. McGraw, **A. Nechiporuk**; Oregon Health & Science University, Portland, OR.

The trafficking mechanisms and transcriptional targets downstream of long-range neurotrophic factor ligand/receptor signaling that promote axon growth are incompletely understood. Zebrafish carrying a null mutation in a neurotrophic factor receptor, Ret, displayed defects in peripheral sensory axon growth cone morphology and dynamics. Ret receptor was highly enriched in sensory pioneer neurons and Ret51 isoform was required for pioneer axon outgrowth. Loss-of-function of a cargo adaptor, Jip3, partially phenocopied Ret axonal defects, led to an accumulation of activated Ret in pioneer growth cones, and reduced retrograde Ret51 transport. Jip3 and Ret51 were also retrogradely co-transported, ultimately suggesting Jip3 is a retrograde adapter of active Ret51. Finally, loss of Ret reduced transcription and growth cone localization of Myosin-X, an initiator of filopodial formation. These results show a specific role for Ret51 in pioneer axon growth, and suggest a critical role for long-range retrograde Ret signaling in regulating growth cone dynamics through downstream transcriptional changes.

TRIM9 and TRIM67: Master Regulators of Developing and Adult-born Neurons.

S. Menon[1], D. Goldfarb[1], C. Hardie[1], E. Johnson[1], M. B. Major[2], **S. Gupton**[1]; [1]University of North Carolina-Chapel Hill, Chapel Hill, NC, [2]Washington University in St. Louis, St. Louis, MO.

We have identified TRIMs 9 and 67 as two critical neuronally-enriched E3 ubiquitin ligases that regulate membrane remodeling & cytoskeletal dynamics during neuronal morphogenesis. They are essential for appropriate morphogenesis of murine embryonic cortical neurons at steady state & for appropriate

responses to the extracellular guidance cue netrin-1. TRIM9 is required for appropriate morphogenesis, migration, & synaptogenesis in adult-born neurons of the dentate gyrus. Deletion of either *Trims* results in subtle neuroanatomical defects, yet striking behavioral deficits, including spatial learning & memory deficits. These results indicate that TRIMs 9 & 67 are master regulators of form & function of developing embryonic & adult-born neurons. Our longterm goal is to understand how these ligases are uniquely positioned to temporally & spatially modulate neuronal morphogenesis via regulation of cytoskeletal dynamics & membrane trafficking. Based on previous studies from our lab we hypothesized that TRIMs 9 & 67 modulate neuronal morphogenesis via their ligase activity & by protein interactions. To identify additional interacting partners and/or ubiquitinated substrates, we performed a two-pronged unbiased proteomic study to identify additional putative interaction partners & ubiquitination targets of TRIM9 and TRIM67 from murine embryonic cortical neurons - the proximity-dependent biotin identification (BioID) approach & a ubiquitinated peptide enrichment approach. The two approaches identified numerous candidate interaction partners and/or substrates. Using immunoprecipitation & ubiquitination assays we validated some of the high priority candidates such as Myo16, Coronin-1A, Doublecortin, SNAP47, PRG-1, Tmod3, & Kinesin 3 family members KIF1a & b. Additionally, for a subset of these validated candidates, we used time-lapse TIRF microscopy & showed that they colocalize with the TRIM proteins.

Early Development and Polarity Establishment in a Sensory Neuron Follow Pre-established Epithelial Apicobasal Polarity.

J. Lee, K. Shen; Stanford University, Stanford, CA.

Neurons are highly polarized cells with distinctive dendritic and axonal processes as well as their underlying microtubule polarity. A fundamental question is how axon-dendrite polarities are established in developing neurons during the development of nervous system. Here, we describe stereotyped development of a ciliated mechanosensory neuron, PDE, in *C. elegans*. PDE neuron is generated postembryonically from an epithelial lineage. Consistent with its epithelial origin, PDE neuron is born with apicobasal polarity, forming apical junctions with surrounding epithelial and sister neural cells. Using 4-D microscopy, we show that PDE neuron goes through apical constriction and its apical attachment remains anchored to the epithelia, marking the future site of ciliogenesis. Moreover, we find that an apical microtubule-organizing center (MTOC) is established following the apical constriction. Consistent with the nascent apical MTOC, γ-TuRC components translocate from centrosome to the site of apical attachment in PDE neuron. These results suggest that minus-end out microtubule polarity in the dendrite is likely laid out by the apical MTOC, which in turn may be established by PDE apical constriction. Based on these observations, we hypothesize that axon-dendrite polarity in PDE neuron may be derived from pre-existing apicobasal polarity from its epithelial lineage. Future investigation on the function of apicobasal polarity regulators during PDE development should reveal whether apicobasal polarity indeed instructs axon-dendrite polarity.

Establishing and Maintaining an Organelle 3

Local Regulation of Lipid Synthesis Controls ER Sheet Insertion into Nuclear Envelope Holes to Complete Nuclear Closure.

L. Penfield[1], R. Shankar[2], E. Szentgyörgyi[3], M. Mauro[1], A. Laffitte[1], A. Audhya[2], T. Müller-Reichert[3], S. Bahmanyar[1]; [1]Yale University, New Haven, CT, [2]University of Wisconsin-Madison, Madison, WI, [3]Technische Universität Dresden, Dresden, GERMANY.

The metazoan nuclear envelope (NE) forms from bilayer glycerophospholipids synthesized in the ER that wrap around segregated chromosomes. To complete NE formation, ESCRT-III machinery transiently accumulates at NE holes that intersect with spindle microtubules and coordinates spindle disassembly with membrane fission. Here, we demonstrate that local control of glycerophospholipid synthesis serves as an additional mechanism to ESCRT-mediated NE closure by regulating ER sheet biogenesis. After meiosis II in C. elegans oocytes, ESCRTs accumulate into a plaque at the nascent NE adjacent to the dissipating meiotic spindle. However, nuclei are not detectably leaky in the absence of the NE-specific adaptors for ESCRT-III, LEM2 and CHMP7, suggesting that additional mechanisms contribute to NE closure. 3D electron tomography of meiotic oocytes revealed ER sheets that contact the outer nuclear membrane and feed into ~100 nm holes occluded by persisting spindle microtubules. Because the abundance of ER sheets proximal to the NE is controlled by CNEP-1 - the NE-enriched phosphatase that activates the key lipid metabolizing enzyme, lipin, to locally regulate glycerophospholipid synthesis - we tested the ability of cnep-1 mutant embryos to form sealed NEs. cnep-1 mutant embryos contain excess ER sheets that extend into the nuclear interior during NE formation and are leaky after both meiosis and mitosis. Nuclear morphology and sealing defects are also present in embryos depleted of lipin and are exacerbated upon deletion of LEM2 or CHMP7 indicating that local conversion of glycerophospholipids by lipin provides a partially overlapping mechanism with ESCRT-III activity to seal the NE. Preventing the formation of ectopic ER sheets by restoring glycerophospholipid synthesis in cnep-1 mutants rescues nuclear sealing defects. We conclude that ER sheets, limited by local control of glycerophospholipid synthesis, feed into NE gaps that intersect with spindle microtubules, and thus serve as a partially redundant mechanism to ESCRT-mediated membrane fission to ensure the closure of NE holes after open mitosis and meiosis.

P2255/B506

A Futile Cycle Initiated by ER-PM Tethering Drives Energy Expenditure.

X. Chen, 100871; Peking University, Beijing, CHINA.

Spatial and temporal organization of signaling platforms generate biological signals encoded in amplitude or frequency. One such scenario involves calcium oscillations initiated from the ER-PM contacts. Here we show that the evolutionarily conserved Ral pathway balances energy metabolism and couples oscillatory calcium signaling via modulating ER-PM tethering. The RalGAP complex controls the activity of the G protein RalA, which in turn mobilizes the exocyst complex, a molecular tether. Liver-specific deletion of RalGAP, resulting in RalA activation, reduces circulating nutrients including lipids and glucose. Genetic and imaging analysis reveals that RalGAP inhibition accelerates the rhythmic frequency of calcium oscillations via increased PM-ER tethering. The increased phasic calcium signal promotes mitochondrial oxidative metabolism and fuel consumption, constructing a “futile cycle” of energy

expenditure. Hepatic RalGAP inactivation accordingly leads to an overall improvement in glucose and lipid metabolism during energy overload, alleviating pathologies including liver steatosis, obesity and insulin resistance. Collectively, our work reveals metabolic function resulted from modulating the ER-PM contacts, uncovering RalGAP as a molecular brake in energy metabolism via fine-tuning digitized cell signaling.

P2256/B507

Highspeed GI-TIRF-SIM Microscopy Reveals Extensive Co-assembly of Vimentin Intermediate Filaments with Peripheral ER-matrices.

A. S. Moore[1], M. Kittisopikul[2,3], A. Vahabikashi[2], R. D. Goldman[2], J. Lippincott-Schwartz[1]; [1]Howard Hughes Medical Institute, Ashburn, VA, [2]Northwestern University, Chicago, IL, [3]UT Southwestern Medical Center, Dallas, TX.

Vimentin intermediate filaments (VIFs) form an extensive intracellular network that coordinates a diverse list of cellular functions including the regulation of cell shape, force transmission, cytoplasmic mechanics and organelle positioning. Previous work has shown that VIFs surround and tether multiple organelles, including mitochondria, Golgi, lipid droplets, pigment granules and the nuclear envelope. However, if and how vimentin associates with the endoplasmic reticulum (ER), one of the largest and most morphologically complex organelles in the cell, is unknown. Here, using STED, 3D SIM, and grazing incidence TIRF-SIM (GI-TIRF-SIM) microscopy, we find that VIFs form extensive contacts with the ER. In COS-7, U2-OS, and mouse embryonic fibroblasts (MEFs), we observe VIF densities, or “knots,” that co-assemble with and stabilize highly concentrated matrices of ER tubules. Using an adaptive resolution multi-orientation segmentation algorithm, we find that VIF knots remain stably associated with ER matrices as both structures undergo persistent retrograde flow toward the perinuclear region. In peripheral regions devoid of assembled VIFs, we note a clear absence of ER matrices. Thus, we find that VIF knots represent a stable molecular marker for dynamic ER matrices, structures that were previously characterized only by their morphological complexity. Though vimentin frequently co-localizes with other cytoskeletal filaments, we do not observe enhanced F-actin or microtubule density at ER matrices. These results suggest one of three models: that VIFs pattern the morphology and distribution of ER, that ER matrices template VIFs, or both.

Dual Role of Orp5 in Regulating Lipid Transport and Calcium Import to Mitochondria at Endoplasmic Reticulum (er)- Mitochondria Membrane Contact Sites.

L. Rochin[1], **F. Giordano**[1], C. Sauvanet[1], E. Jääskeläinen[2], A. Houcine[3], A. Kivela[2], X. MA[4], E. Marien[5], J. Dehairs[5], J. Neveu[1], R. Le Bars[1], J. Swinnen[5], D. Bernard[4], D. Tareste[6], V. Olkkonen[7]; [1]Institut de Biologie Integrative de la Cellule (I2BC)-UMR9198/CNRS, Gif-sur-Yvette, FRANCE, [2]Minerva Foundation Institute for Medical Research, Biomedicum 2U, Helsinki, FINLAND, [3]Institut Jacques Monod, CNRS, UMR7592, Paris, FRANCE, [4]Centre de Recherche en Cancérologie de Lyon, UMR INSERM U1052/CNRS 5286, Lyon, FRANCE, [5]Laboratory of lipid metabolism and cancer, Department of Oncology, KU Leuven, Leuven, BELGIUM, [6]Institute of Psychiatry and Neuroscience of Paris (IPNP), UMR-S1266 INSERM, Paris, FRANCE, [7]Department of an atomy, Faculty of Medicine, FI-00014 University of Helsinki, Helsinki, FINLAND.

Mitochondria are dynamic organelles essential for cell survival whose structural and functional integrity rely on selective and regulated transport of lipids from/to the endoplasmic reticulum (ER) and across the

two mitochondrial membranes. As they are not connected by vesicle transport, the exchange of lipids between ER and mitochondria occurs at sites of close organelle apposition called membrane contact sites. However, the mechanisms and proteins involved in these processes are only beginning to emerge. We have found that ORP5/8 mediate non-vesicular transport of Phosphatidylserine (PS) from the ER to mitochondria in mammalian cells. We have also found that ER-mitochondria contacts where ORP5/8 reside are physically and functionally linked to the Mitochondrial Intermembrane space Bridging (MIB) complex, that anchors the outer and inner mitochondrial membranes, to facilitate PS transfer from the ER to the mitochondria. Finally, we show that ORP5 but not ORP8, additionally regulates import of calcium to mitochondria and consequently cell senescence.

P2258/B509

Loss of Mitochondria-Plasma Membrane Tethering Adversely Impacts Organelle Function and Cellular Fitness.

A. J. White[1], J. V. Dietz[2], O. Khalimonchuk[2], L. L. Lackner[1]; [1]Northwestern University, Evanston, IL, [2]University of Nebraska, Lincoln, NE.

The specific shape and positioning of mitochondria are intimately tied to the ability of this organelle to engage in its essential functions within the cell. The proper distribution of mitochondria contributes to the formation of a dynamic, interconnected network that is required for overall cellular fitness. Central to maintaining this network is the ability of mitochondria to associate with other organelles through membrane contact sites (MCSs), where tether proteins bring membranes into close proximity without fusion. Despite the importance of MCSs for the maintenance of cellular function, little is known about the mechanisms by which these MCSs contribute to organelle function and cellular fitness. Using *Saccharomyces cerevisiae* as a model system to investigate MCS function, we focus on Num1, the core component of the Mitochondria-ER-Cortex an chor, which has dual anchoring functions: tethering mitochondria at the plasma membrane (PM) for proper distribution of the organelle and anchoring the motor protein, dynein, to the PM, which is critical for nuclear inheritance during cell division. In addition to Num1's role as a physical anchor, our research suggests that Num1 plays a more direct role in maintaining mitochondrial function. Specifically, in the absence of Num1, cells have a growth defect when forced to respire, and preliminary data suggest Δ*num1* cells exhibit a decreased rate of oxygen consumption. The growth defect is distinct from other mutants which impact mitochondrial morphology and from Num1's role in dynein-mediated nuclear inheritance. Interestingly, this defect can be rescued by artificially clustering the mitochondrial interacting domain of Num1 at the PM, but not by tethering mitochondria to the PM with synthetic tethers that lack domains of Num1. These data suggest that there are Num1-dependent functions of mitochondria-PM contacts, beyond physically tethering the two membranes, that impact mitochondrial and cellular functions. These studies highlight the idea that MCSs are not simply sites of physical tethering between membranes, but functional hubs that are critical for overall cellular fitness.

P2259/B510

A Mitochondrial Translocon Subunit Promotes Assembly of the Cristae Organizing MICOS Complex in Proximity to ER Contact Sites.

P. Tirrell, **J. Friedman**, R. Lohray, K. Nguyen; UT Southwestern, Dallas, TX.

Mitochondrial cristae organization is regulated by the highly conserved MICOS complex. MICOS, an approximately megadalton complex comprised of six conserved subunits, localizes to cristae junctions, sites of membrane invagination on the mitochondrial inner membrane. The principal MICOS component, Mic60, assembles into structures that persist in the absence of other complex members and in mitochondria devoid of cristae, suggesting it marks sites of MICOS assembly and cristae biogenesis. However, there are no known upstream determinants of Mic60 assembly and positioning. Using an unbiased visual screen, we find that a subunit of the translocase of the outer mitochondrial membrane (TOM) complex regulates Mic60 assembly into structures that predominantly localize in proximity to endoplasmic reticulum (ER) membrane contact sites. Mic60 assemblies are more generally linked to inter-organelle contact sites as they reposition in proximity to mitochondrial-vacuole contacts in a yeast strain where the ER-mitochondrial tether is deleted and bypassed. These data reveal that positioning of the MICOS complex is contingent on extra-mitochondrial spatial cues and are consistent with a model that a phospholipid micro-environment on the inner mitochondrial membrane generated by inter-organelle contact sites regulates MICOS assembly and dictates cristae biogenesis sites.

P2260/B511

ER Membrane Contact Sites Are a Platform for Regulating Mitochondrial Dynamics and Bioenergetics.

R. G. Abrisch[1], S. C. Gumbin[2,3], G. K. Voeltz[2,3]; [1]Biochemistry, University of Colorado Boulder, Boulder, CO, [2]Molecular, Cellular, and Developmental Biology, University of Colorado Boulder, Boulder, CO, [3]Howard Hughes Medical Institute, Boulder, CO.

Mitochondria are organelles derived from ancient endosymbiotic organisms and are present in the cytoplasm of all eukaryotes. Despite the fact that they are rapidly fusing and dividing, they are somehow able to maintain a characteristic morphology. Disruption of this steady-state morphology results in either a fragmented or elongated network, both of which are associated with altered metabolic states and disease. How cells spatially organize division and fusion machineries to produce mitochondria of appropriate size is a fundamental question that is still unresolved. We now know that different organelles form membrane contact sites with each other to coordinate their function in the cellular context and mitochondria form conspicuous contact sites with the endoplasmic reticulum (ER MCS). These ER MCS regulate calcium buffering, lipid transfer, and mark the position of division along the length of the mitochondrion. Here we show that ER MCS also mark the position of mitochondrial fusion using a photoconvertible fluorescent protein targeted to mitochondrial compartments allowing the detection of content exchange upon a *bona fide* fusion event. Surprisingly, we found that both division and fusion machinery (Drp1 and Mitofusins) accumulate together in nodes at ER MCS where mitochondria can perform either process. Additionally, depolarization of individual mitochondria revealed that fusion at ER MCS nodes rescues the polarization state of the large majority of depolarized mitochondria. Thus, we propose that division and fusion are spatially coordinated at ER MCS where mitochondria are poised to alter their morphology in response to metabolic needs.

P2261/B512

Single Molecule Characterization of Protein Dynamics at Endoplasmic Reticulum-Organelle Contact Sites.

J. Nixon-Abell[1], C. J. Obara[1], F. Riccio[2], J. Lippincott-Schwartz[1], C. Blackstone[3]; [1]Janelia Research Campus, Ashburn, VA, [2]Kings College London, London, UNITED KINGDOM, [3]National Institutes of Health (NINDS), Bethesda, MD.

The endoplasmic reticulum (ER), present in all eukaryotic cells, consists of a complex membranous network stretching from the nuclear envelope to the plasma membrane. This remarkably versatile organelle plays crucial roles in numerous cellular functions, from calcium signaling to protein and lipid synthesis. Recent work has also highlighted an emerging role for the ER as a key regulator of the morphology and function of other subcellular organelles, with ER-organelle contact sites mediating the exchange of crucial signaling components and biomolecules. Several candidate proteins have been proposed to act as molecular tethers to facilitate specific ER-organelle interactions. However, the dynamics and spatial regulation of these tethering proteins within the ER membrane remains unclear. Here, we introduce a high-speed, correlative single molecule imaging approach to study molecular behavior at ER-organelle contact sites. With this approach, we track the motion of several ER-organelle tethering proteins in live cells, including VAP-A, VAP-B, Mfn1, Mfn2, and PDZD8. We demonstrate that each tether exhibits a unique dynamic signature and spatial confinement pattern, with tethering complexes assembling and disassembling on subsecond timescales. Based on these measurements, we conclude that distinct subtypes of contact site exist, and can be grouped according to the dynamic properties of specific tethers. We observe heterogeneity in tethering protein dynamics across different cell types and at spatially discrete ER-organelle contacts within the same cell. Furthermore, several tethering proteins exhibit specific alterations to their dynamic behavior in response to nutrient deprivation or ER calcium depletion, suggesting that the physiological state of cells impacts ER-organelle contacts by changing tethering complex dynamics. Fascinatingly, we find that molecular tethers harboring certain disease-associated mutations demonstrate altered dynamics at the single molecule level, with this impaired behavior correlating with downstream cellular pathogenesis. Taken together, this work provides initial insights into the single-molecule dynamics of tethering proteins at ER-organelle contact sites. Alterations in these dynamics appear to be a key component in dictating the functional heterogeneity of contact sites, and potentially underlie certain ER-associated disease states.

Regulation of Endoplasmic Reticulum Architecture by the Er-shaping Protein Climp63.

F. S. Mesquita, P. A. Sandoz, L. Abrami, L. Abriata, G. P. Brambilla, S. Ho, G. Knott, G. Van der Goot; EPFL, Lausanne, SWITZERLAND.

The Endoplasmic Reticulum morphology is structural defined by ER-shaping proteins and divided in functional compartments, which include, the nuclear envelope, rough ER (predominantly sheet-like cisternae decorated by membrane-bound ribosomes) and smooth ER (interconnected tubular network that spans to the cell periphery). ER sheets constitute flat surfaces that accommodate ER-ribosome interactions which contribute to the biosynthesis of secretory proteins, and ER-microtubule links that regulate ER morphology. Regulation of ER architecture and interactions with Ribosomes or Microtubules can be modulated by sheet-promoting proteins such as CLIMP63. However, the molecular mechanisms that coordinate sheet formation, dynamics and functional specificity are not understood. Here, we have

characterised the effect of CLIMP63 post-translation modifications in ER morphology and interactions with different cellular components. We have determined enzymes that regulate CLIMP63 stability and uncover novel CLIMP63 regulators which affect both ER-architecture and function.

P2263/B514

Isoform-specific Differences in the Function of Hereditary Spastic Paraplegia-associated Protein Spastin in Endoplasmic Reticulum Morphogenesis and Cellular Homeostasis.

C. A. Lee, C. Blackstone; National Institutes of Health, Bethesda, MD.

Hereditary spastic paraplegias (HSPs) are a genetically diverse group of inherited neurodegenerative disorders selectively affecting the longest corticospinal motor neurons; they are characterized most prominently by the progressive spasticity of the lower limbs. Molecular etiologies of HSPs are complex and caused by mutations in one of more than 60 identified genes. However, the most common forms, representing about half of all affected patients, are due to autosomal dominant mutations in one of three tubular ER-shaping proteins: spastin, atlastin-1, and REEP1. Therefore, ER-shaping defects appear to be a common pathogenic mechanism, however, it is not known how ER morphology defects contribute to degeneration and dysfunction of corticospinal motor neurons. Mutations in the *SPAST* gene are the most common causes of HSP, and the *SPAST* gene product spastin is a microtubule-binding and -severing AAA ATPase protein. A single *SPAST* mRNA transcript produces two isoforms (M1 and M87) with different subcellular localizations and functions. The full-length M1 isoform contains an N-terminal 86-amino acid domain that is absent in the shorter M87 isoform. This N-terminal region harbors a membrane-bound hydrophobic hairpin that confers ER localization and generates membrane curvature to shape the tubular ER. The more abundant M87 spastin is largely cytosolic and has been functionally implicated in endosomal trafficking and cytokinesis. While the overwhelming majority of mutations in *SPAST* will affect the expression of both isoforms, it is not known which isoform contributes to HSP pathogenesis. Here, we have used CRISPR/Cas9 gene editing to generate isoform-specific knockout cell lines. Knockout of M1 spastin results in aberrant peripheral ER morphogenesis and loss of tubular ER polygonal networks, indicating that M1 is necessary for proper tubular ER formation and organization. Isoform-specific roles of spastin in ER morphogenesis and dynamics were also examined in cells specifically expressing each spastin isoform, as well as spastin isoforms harboring the ATPase defective, HSP-associated mutation K388R. Expression of M1 spastin K388R but not M87 spastin K388R results in ER membranes trapped on microtubules. Furthermore, fluorescence recovery after photobleaching (FRAP) and single-molecule imaging approaches were used to examine the specific dynamic nature of each spastin isoform. Understanding the functional contributions of each isoform will be crucial for understanding the etiology of HSP and for finding new therapeutic targets.

P2264/B515

Microtubule Polyglutamylation Controls Organelle Distribution.

P. Zheng[1], C. Obara[2], J. Nixon-Abell[1], J. Lippincott-Schwartz[2], C. Blackstone[1]; [1]NINDS, NIH - Bethesda, MD, Bethesda, MD, [2]Janelia Research Campus, Ashburn, VA.

Organelle distribution plays central roles in cell function. While microtubule plays key roles in organelle distribution, how microtubule modification affects this function is largely unknown. Here, we show that three endoplasmic reticulum (ER) membrane proteins, Climp63, p180 and Kinectin preferentially binds centriolar, perinuclear and peripheral microtubules, respectively, to maintain a balanced distribution of

the perinuclear ER. We further show that p180 and Kinectin do so by specifically binding mono- and poly-glutamylated microtubules, respectively. Depletion of Climp63, KTN or p180, or manipulating microtubule populations or glutamylation status dramatically changed the distribution of the ER, especially perinuclear ER. We further show that this change in ER distribution also leads to broad changes in the distribution of other organelles. Together, our data show that microtubule modification controls organellar distribution by regulating perinuclear ER morphology.

P2265/B516

Novel Transverse ER within Corticospinal Axons Revealed by FIB-SEM Reconstruction in a Hereditary Spastic Paraplegia Mouse Model.

N. Batchenkova[1], P. Zhu[2], J. Nixon-Abell[3], S. Pang[4], S. Saalfeld[4], J. Funke[4], H. Hess[4], C. Blackstone[2]; [1]NIH/NIAID, Bethesda, MD, [2]NIH/NINDS, Bethesda, MD, [3]University College London, London, UNITED KINGDOM, [4]HHMI Janelia Research Campus, Ashburn, VA.

The ER is an interconnected network of narrow tubules broadly distributed within cells and their process, including along the entire axonal length. Hereditary spastic paraplegias (HSPs) are often caused by mutations in structural proteins of the ER, including atlastin-1 and Reep1. Here we report on the structural disruption of the ER by the introduction of double mutations in mice, knocking in atlastin-1-K80A (GTPase-defective) and knocking out Reep1. These double mutant mice show an HSP phenotype, with prominent hindlimb impairment. To find the mechanism underlying this phenotype, we examined the corticospinal tracts in spinal cord. With transmission electron microscopy (TEM), we found a dramatic expansion of ER in axons. To obtain a more complete view of ER changes in axons, 3D reconstructions were carried out. The corticospinal tract area (40x30x70 µm) at L5 was imaged by FIB-SEM at 6 nm isotropic resolution. Amira software was used for the 3D reconstruction. Unlike the wild-type mouse whose axonal ER is tubular with some branching, axonal ER of the mutant mouse is defined by regularly-interspersed, transverse matrix-like structures connected to each other via tubules. The tubular matrices occupy most of the cross-sectional area of the axon. The reason for the change in ER structure remains under investigation, but these tubular matrices are reminiscent those seen in other cell types (Nixon-Abell J, et al. Science 2016) and the tubules connecting these structures were of normal axonal ER diameter (20-30 nm) as reported previously (Terasaki M, J Cell Sci 2018).

P2266/B517

ReepA Is Required for Endoplasmic Reticulum Clearance from Chromosomes but Not Endoplasmic Reticulum Partitioning to Spindle Poles in Dividing *Drosophila* Cells.

D. Karabasheva, J. T. Smyth; USUHS, Bethesda, MD.

The endoplasmic Reticulum (ER) is essential for biogenesis of lipids, proteins, and steroid hormones, as well as calcium signaling. The ER cannot be formed *de novo* and must be inherited during cell division. In animal cells, ER inheritance depends on partitioning of the organelle to the poles of the mitotic spindle via direct association with astral microtubules, and defining the specific mechanisms that link the ER to spindle microtubules is therefore essential to our understanding of developmental and physiological processes that depend on ER functions. It was recently shown in mammalian cells that Receptor Expression Enhancing Proteins (REEPs) 3 and 4 are required for clearance of the ER from chromosomes in mitotic cells, via a mechanism that involves direct association of the ER with spindle microtubules and focusing of the ER around spindle poles. Thus, in addition to ensuring exclusion of the ER from nuclei,

REEP proteins may also play a role in microtubule and spindle pole-dependent ER inheritance in dividing cells. To test this in an animal model, we generated *Drosophila* with a targeted deletion of the *REEPA* gene, the fly orthologue of human REEPs 3 and 4. *REEPA* homozygous mutant flies were fully viable and fertile, suggesting *REEPA* is not essential for normal animal development or overall physiology. In *vivo* analysis of syncytial embryonic nuclear divisions and dividing spermatocytes revealed that ER partitioning to spindle poles and association with astral MTs were largely unaffected in *REEPA* mutants, suggesting ReepA is not required for ER inheritance in these tissues. Surprisingly, however, close examination revealed abnormal strands of ER within the spindle, extending from the spindle poles towards the aligned chromosomes, in both *REEPA* mutant embryos and spermatocytes. We also observed abnormal accumulations of ER that were directly associated with chromosomes in interphase nuclei of *REEPA* mutant embryos and spermatocytes. These findings are consistent with results from human cells with both REEPs 3 and 4 suppressed, suggesting a highly conserved mechanism whereby REEP proteins are required to sequester ER membranes away from chromosomes during cell division and prevent ER entrapment in the newly formed interphase nuclei. Importantly though, our findings also suggest that REEP proteins are not the key factors that universally associate the ER with spindle microtubules and ensure proper partitioning of the organelle to daughter cells.

P2267/B518

Endomembrane Surfaces Regulate a PolyQ-Dependent Phase Transition.

W. T. Snead, S. Hu, A. S. Gladfelter; University of North Carolina at Chapel Hill, Chapel Hill, NC.

Compartmentalization of molecules into subcellular organelles is essential for life. Biomolecular condensates, composed of phase-separated protein and nucleic acid, are important centers of compartmentalization in diverse contexts. Phase separation is driven by weak, multivalent interactions, resulting in the formation of condensed structures that can display properties of liquid-like droplets. Although the ability to phase separate is an intrinsic feature of many proteins and nucleic acids, cells must regulate condensation to assemble functional structures at the appropriate time and location. The regulatory mechanisms that govern when and where condensates form are unknown. Our group discovered that biomolecular phase transitions play essential physiological roles in a multinucleate fungus (Zhang *et al., Mol Cell* 2015; Langdon *et al., Science* 2018). Specifically, the RNA-binding protein Whi3 undergoes a polyglutamine (polyQ)-dependent phase transition to generate distinct, functional condensates. These condensates form with different RNA transcripts that regulate either the cell cycle or cell polarity, and are positioned near nuclei or sites of polarized growth, respectively. How do cells control assembly and patterning of these different droplets in time and space? We hypothesized that Whi3 condensates may be patterned by endomembranes associated with nuclei and sites of polarity. Indeed, here we find that Whi3 condensates stably associate with the endoplasmic reticulum. Moreover, we find that membrane surfaces dramatically reduce the concentrations of Whi3 and RNA required to drive phase separation in *vitro* compared to free-diffusing molecules in solution. These results suggest that endomembranes regulate Whi3 condensation by restricting molecular diffusion to a two-dimensional surface. How are condensates recruited to endomembranes in cells? We find that a molecular chaperone complex associated with the endoplasmic reticulum plays an important role in recruiting Whi3 to membranes. Further, this chaperone complex modifies the biophysical properties of Whi3 condensates, suggesting that the identities of membrane-associated condensates are determined by active cellular processes. Collectively, these findings provide key insight into the biophysical

mechanisms that govern the assembly, patterning, and emergent properties of biomolecular condensates.

Mitochondrial Physiology

Proteomic Screening Identifies Novel Interactors of MICU1 Independent of the Mitochondrial Calcium Uniporter.

D. Tomar[1], M. Thomas[2], D. Kolmetzky[1], O. Salik[3], J. F. Garbincius[1], P. Jadiya[1], J. W. Elrod[1]; [1]Lewis Katz School of Medicine at Temple University, Philadelphia, PA, [2]Temple University, Philadelphia, PA, [3]Ursinus College, Philadelphia, PA.

MICU1 is an EF-hand-containing mitochondrial protein that gates the mitochondrial Ca^{2+} uniporter channel (mtCU) and directly interacts with the pore-forming subunit MCU. Previous reports suggest that genetic loss-of-function phenotypes associated with MICU1 deletion are not entirely mtCU dependent. This suggests that MICU1 may have cellular functions independent of its role in regulating the mitochondrial calcium uptake through the uniporter. To discern novel MICU1 functions, we employed a biotinylation-based proteomic approach in *Mcu*$^{-/-}$ and *Micu1*$^{-/-}$ cells to detect MICU1 interactors employing a fusion construct containing BioID2, a small biotin ligase for proximity-dependent labeling. Expression of MICU1-BioID2 in *Mcu*$^{-/-}$ cells, coupled with appropriate controls, allowed the identification of mtCU-independent interactors. The LC-MS analysis of biotinylated proteins after avidin-based purification identified the Mitochondrial Contact Site and Cristae Organizing System (MICOS) components IMMT, CHCHD2, and CHCHD3 as MICU1 interacting partners (MICU1-BioD2 expressed in Micu1$^{-/-}$ cells to avoid aberrant expression). These same MICOS components were identified in MCU$^{-/-}$ cells, suggesting that MICU1 may be involved in the regulation of MICOS independent of the mtCU. Fast protein liquid chromatography (FPLC), blue native-PAGE, co-immunoprecipitation, live-cell Ca^{2+} imaging, confocal and super-resolution imaging methods were used to confirm novel MICU1 interactions and sub-mitochondrial localization. Further, the deletion of the *Chchd2* resulted in the loss of MICOS and acute changes in cristae organization without any observable effect on $_{m}Ca^{2+}$ uptake. These results suggest that MICU1 likely serves cellular functions independent of the mtCU and may serve as a key sensor/regulator of Ca^{2+}-dependent signaling in other mitochondrial processes that are essential for cellular function.

P2269/B520

Insulin Receptor Preserves Mitochondrial Function by Binding VDAC1 in Insulin Insensitive Mucosal Epithelial Cells.

R. Titone, D. M. Robertson; UT Southwestern Med Ctr, Dallas, TX.

Purpose: Maintenance of the corneal epithelium is essential for the preservation of vision. Unlike other epithelial cells, corneal epithelial cells (CECs) do not require insulin for glucose uptake, but do require insulin for mitochondrial respiration. In this study, we examined the role of insulin and insulin receptor (INSR) in mediating metabolic activity, mitochondrial stability and mitophagy in CECs and bronchial epithelial cells, a second mucosal epithelial cell type. Methods: Telomerized human corneal epithelial (hTCEpi) cells and bronchial epithelial cells (HBECs) were cultured in serum-free keratinocyte growth medium with (KGM) or without (KBM) supplements. Cells were treated with or without insulin for 24 or

48 hours. To examine the role of INSR, cells were transfected with siRNA oligonucleotides. Immunoprecipitation, mitochondrial fractionation, western blotting and immunofluorescence were used to determine the expression and subcellular localization of INSR and mitochondrial proteins. Mitochondrial morphology and function were analyzed by using mitotracker-TMRE staining and electron microscopy. Mitochondrial activity was measured using a Seahorse Metabolic Flux an alyzer. Results: in hTCEpi cells, 48 hours in KBM shifted cells towards a glycolytic phenotype that was associated with a loss of mitochondrial membrane polarization and a reduction in expression of mitochondrial proteins. In HBECs, KBM shifted cells to a more respiratory phenotype with no changes in mitochondrial polarization or protein expression. Treatment with insulin blocked these effects in hTCEpi cells, but further increased respiration in HBECs. INSR knockdown in hTCEpi cells also showed a reduction in mitochondrial protein expression and function, along with a decrease in mitophagy markers PINK1 and LC3-II. Surprisingly, INSR bound VDAC1 in mitochondria in hTCEpi cells. INSR was undetectable in mitochondria from HBECs. Conclusions: These data confirm differential roles for insulin and INSR in regulating metabolic activity in the corneal and bronchial epithelium. These findings further suggest that the INSR-VDAC1 interaction in the mitochondrial membrane is essential to maintain mitochondrial homeostasis in the corneal epithelium. Additional studies are needed to define the underlying mechanism(s) that mediate mitochondrial homeostasis in mucosal epithelia.

P2270/B521

Time-dynamics of Mitochondrial Membrane Potential Reveal an Inhibition of ATP Synthesis in Mitosis.

J. Ho Kang[1], G. Katsikis[1], M. Stockslager[1], D. Lim[1], M. Yaffe[1], S. Manalis[1], **T. P. Miettinen**[1,2]; [1]Massachusetts Inst Technology, Cambridge, MA, [2]University College London, London, UNITED KINGDOM.

The energetic demands of a cell are believed to increase during mitosis. Cellular ATP levels decrease from G2/M transition through metaphase-anaphase transition, consistent with elevated consumption. The rates of ATP synthesis during mitosis, however, have not been quantified. Here, we monitor mitochondrial membrane potential of single lymphocytes and demonstrate that cyclin-dependent kinase 1 (CDK1) activity causes mitochondrial hyperpolarization from G2/M until the metaphase-anaphase transition. By using an electrical circuit model of mitochondria, we quantify the time-dynamics mitochondrial membrane potential under normal and perturbed conditions to extract mitochondrial ATP synthesis rates in mitosis. We found that mitochondrial ATP synthesis decreases by approximately 50 % during early mitosis, when CDK1 is active, and increases back to G2 levels during cytokinesis. Consistently, acute inhibition of mitochondrial ATP synthesis failed to delay cell division. Our results provide a quantitative understanding of mitochondrial bioenergetics in mitosis and challenge the traditional dogma that cell division is a highly energy demanding process.

P2271/B522

Quantitative Variation in Mitochondrial 3243A>G Mutation Produce Discrete Changes in Energy Metabolism.

R. P. McMillan[1], S. Stewart[2], J. A. Budnick[3], C. C. Caswell[3], M. W. Hulver[1], K. Mukherjee[2], **S. Srivastava**[2]; [1]Department of Human Nutrition, Foods and Exercise, Virginia Tech, Blacksburg, VA, [2]Fralin Biomedical Research Institute at Virginia Tech Carilion, Roanoke, VA, [3]Department of Biomedical Sciences and Pathobiology, Center for One Health Research, VA-MD College of Veterinary Medicine, Virginia Tech, Blacksburg, VA.

Mitochondrial DNA (mtDNA) 3243A>G tRNALeu$^{(UUR)}$ heteroplasmic mutation (m.3243A>G) exhibits clinically heterogeneous phenotypes. While the high mtDNA heteroplasmy exceeding a critical threshold causes mitochondrial encephalomyopathy, lactic acidosis with stroke-like episodes (MELAS) syndrome, the low mtDNA heteroplasmy causes maternally inherited diabetes with or without deafness (MIDD) syndrome. How quantitative differences in mtDNA heteroplasmy produces distinct pathological states has remained elusive. Here we show that despite striking similarities in the energy metabolic gene expression signature, the mitochondrial bioenergetics, biogenesis and fuel catabolic functions are distinct in cells harboring low or high levels of the m.3243A>G mutation compared to wild type cells. We further demonstrate that the low heteroplasmic mutant cells exhibit a coordinate induction of transcriptional regulators of the mitochondrial biogenesis, glucose and fatty acid metabolism pathways that lack in near homoplasmic mutant cells compared to wild type cells. Altogether, these results shed new biological insights on the potential mechanisms by which low mtDNA heteroplasmy may progressively cause diabetes mellitus.

P2272/B523

CoA Biosynthesis Enzyme Localization and PANK2 Loss of Function Studies Indicate Compartmentalized CoA Synthesis Is Required for Metabolic Switching to β-oxidation.

S. M. H. Nordlie[1,2,3], A. Prieto Rodriguez[4], U. Hadziahmetovic[3], R. D. Schafer[2,3], J. Liu[2,5], B. S. Guida[2,3], C. Santos-Ocaña[4], S. Padilla-Lopez[2,3], M. C. Kruer[2,3,1]; [1]Arizona State University, Tempe, AZ, [2]Barrow Neurological Institute at Phoenix Children's Hospital, Phoenix, AZ, [3]Departments of Child Health, Neurology, Genetics and Cellular Molecular Medicine, University of Arizona - College of Medicine Phoenix, Phoenix, AZ, [4]Universidad De Sevilla, Sevilla, SPAIN, [5]University of Arizona College of Medicine - Phoenix, AZ, Phoenix, AZ.

Pantothenate kinase (PANK) performs the rate-limiting step in Coenzyme a (CoA) biosynthesis. There are four catalytically active PANK protein isoforms: PANK1α, PANK1ß, PANK2 and PANK3, each with different subcellular localizations. Mutations in the *PANK2* gene cause the disease Pantothenate Kinase Associated Neurodegeneration (PKAN). Organelle-specific acetyl-CoA concentrations are known to regulate metabolism in response to changing cellular conditions, recent data indicates that tightly regulated, compartmentalized CoA pools may exist as well. Here we show through cellular fractionation that not just PANKs, but a full complement of CoA biosynthetic enzymes exists in the cytosol, mitochondria, and nucleus. *De novo* organelle-specific CoA biosynthesis would allow for direct manipulation of local CoA and acetyl-CoA pools. In the mitochondria this could be necessary to meet the increased CoA demand during β-oxidation, while in the nucleus it would provide independent control over acetyl-CoA concentration regulating histone acetylation. PANK2 is known to be activated by acylcarnitines, abundant in high fat conditions, and it is the only PANK protein localized to both the

mitochondria and nucleus. Therefore, we hypothesize that PANK2 is required to meet the increased mitochondrial CoA demand during β-oxidation (compared to glucose respiration) and to support the *de novo* production of acetyl-CoA in the nucleus used for histone modification. To test these hypotheses, nuclear acetylation status and β-oxidation in PANK2-deficient cells vs. controls was studied in glucose vs. palmitate growth conditions. Control cells exposed to palmitate showed major changes in nuclear acetylation while PANK2 knockdown HEK293T cells did not respond to palmitate in the same manner. PKAN patient-derived fibroblasts (*PANK2* null) exhibited a diminished respiratory response when challenged with palmitic acid compared to control fibroblasts as measured by the Seahorse XF an alyzer. Our findings indicate that PANK2 is required to support metabolic shifts from glucose to fatty acid metabolism, suggesting that compartmentalized CoA synthesis is required for rapid shifts in cellular metabolism.

P2273/B524

Igfbp-3 Preserves Mitochondrial Function during Hyperosmolar Stress in Corneal Epithelial Cells.

D. M. Robertson, E. Bogdan, R. Titone, W. L. Stuard, M. Zhu; University of Texas Southwestern Med Ctr, Dallas, TX.

Purpose: Hyperosmolar stress induces mitochondrial dysfunction that results in corneal epithelial surface damage in patients with dry eye disease. The purpose of this study was to characterize the role of the insulin-like growth factor binding protein-3, IGFBP-3, in corneal epithelial cells exposed to hyperosmolar stress. Methods: Telomerase-immortalized human corneal epithelial (hTCEpi) cells were cultured in defined keratinocyte growth (with supplements) or basal (no supplements) media (330 mOsm). NaCl was added to bring osmolarity values up to 450 and 500 mOsm and cells were cultured for 6 or 24 hours with or without 500 ng/ml recombinant human (rh)IGFBP-3. Mitochondrial respiration, ATP production, and spare respiratory capacity was measured using a Seahorse Metabolic Flux an alyzer. Cell cycle was measured using a Celigo Imaging Cytometer. Intracellular IGFBP-3 was assessed using western blot and secreted IGFBP-3 was quantified using ELISA. Mitochondrial (mt)DNA was visualized using SYBR green staining and imaged using confocal microscopy. JC-1 staining was used to assess mitochondrial membrane polarization. Mitochondrial calcium levels were measured using Rhodamine (Rhod-2). Results: Hyperosmolar culture induced cell cycle arrest in G0/G1 at 6 hours. There was a decrease in mitochondrial calcium, membrane polarization, mitochondrial respiration and ATP production at 6 and 24 hours of hyperosmolar culture. Intra- and extracellular IGFBP-3 was attenuated at 24 hours. Supplementation with rhIGFBP-3 preserved mitochondrial respiration. Similarly, SYBR green staining was decreased at 450 mOsm. This decrease was not evident in cells treated with rhIGFBP-3. Conclusions: Taken together, these findings suggest that IGFBP-3 plays a critical role in cellular homeostasis during stress. Further studies are necessary to determine how IGFBP-3 mediates stress responses in the corneal epithelium.

P2274/B525

Role of ALS-linked UBQLN2 in Maintaining Mitochondrial Function.

B. C. Lin, J. J. Wu, B. M. Polster, M. Karbowski, M. J. Monteiro; University of Maryland-Baltimore, Baltimore, MD.

Amyotrophic Lateral Sclerosis (ALS) is a debilitating neurodegenerative disorder that induces fatality through the loss of motor neurons. ALS can be caused by mutations in ubiquilin-2 (UBQLN2), a protein

that maintains cellular proteostasis by binding ubiquitinated misfolded proteins and clearing them through the autophagy and proteasomal degradation systems. These functions help to deter protein aggregation, a hallmark pathological feature of ALS. However, the underlying mechanism by which UBQLN2 mutations cause ALS pathogenesis remain unclear. To discover the pathophysiologic mechanisms that cause disease, we generated transgenic mouse lines with neuron-specific expression of either human wild-type UBQLN2 (WT356 line) or a UBQLN2 ALS mutant (P497S line). The P497S mouse line, but not the WT356 line, developed motor neuron disease. Spinal cord and hippocampal tissues were isolated from these transgenic lines and used to generate a large-scale proteomics profile. Proteomics indicated a systematic downregulation of mitochondrial proteins in the lumbar spinal cords of the P497S mutant compared to the WT and non-transgenic lines. Transmission electron microscopy of spinal cord motor neurons showed significant structural deterioration of cristae in the mitochondria of the P497S mutant. As cristae are vital for oxidative phosphorylation and ATP production, mitochondrial function was likely impaired as well. Seahorse respiration assays on isolated mitochondria from the spinal cord and hippocampus indicated that mitochondrial state 3 respiration, a measure of ADP to ATP conversion, becomes severely perturbed as P497S mice age. To investigate the role of UBQLN2 in maintaining mitochondrial structure and function, we used CRISPR-Cas9 to generate HeLa and motor-neuron-like NSC-34 knock-out cell lines of UBQLN2. Inactivation of UBQLN2 caused an attenuation of mitochondrial respiration and ATP production, and this functional defect was further exacerbated by oxidative switching from glycolytic media (glucose) to oxidative media (galactose). These functional defects could be rescued through re-expression of WT UBQLN2 into the knock-out line. These studies suggest that UBQLN2 protein is required for proper maintenance of mitochondrial function and suggests that the ALS P497S mutant causes mitochondrial dysfunction through a loss-of-function mechanism.

P2275/B526

Structural Basis of Mitochondrial Coenzyme Q Biosynthesis by the Human Coq7-coq9 Complex.

H. Aydin; University of California, San Francisco, San Francisco, CA.

Coenzyme Q (CoQ) is a redox-active lipid that is essential for cellular respiration, and serves as a cofactor for numerous mitochondrial enzymes and extramitochondrial functions. Most eukaryotic CoQ is produced by the CoQ biosynthetic pathway, and a majority of the proteins that participate in CoQ production (COQ1-11) are located on the matrix face of the mitochondrial inner membrane. These proteins interact with each other in a highly cooperative manner, and form various subcomplexes and a high-molecular weight complex – complex Q – in mitochondria. However, the mechanistic details of this dynamic network of protein-protein interactions and complex Q assembly pathway is not well understood. Here, we report a 3.6 Å electron cryo-microscopy structure of the human COQ7-COQ9 biosynthetic complex. The structure reveals four copies of each molecule forming a hetero-octameric complex. We observe many charge-charge and hydrophobic interactions on three different molecular interfaces between the hydroxylase COQ7 and the lipid-binding COQ9. Our atomic models also show clearly discernible ligand densities inside the hydrophobic cavities of both molecules. These data provide novel insights into the molecular architecture of complex Q components, and a foundation for gaining mechanistic insights into the molecular functions that facilitate CoQ biosynthesis.

P2276/B527

Hypoxia-mediated Downregulation of Mitochondrial Pyruvate Carrier (mpc) through Interplay with Notch Signaling Pathway Prevents Cancer Cells from Hypoxia-induced Apoptosis.

D. Shin, **E. Koh**; YONSEI university school of medicine, Seoul, KOREA, REPUBLIC OF.

Mitochondrial pyruvate carrier (MPC), which is essential for mitochondrial pyruvate usage, mediates the transport of cytosolic pyruvate into mitochondria. Previous reports have shown that the MPC is a key regulator of glycolysis in tumor cells and reduced expression of MPC is associated with stemness of cancer cells. However, the mechanism by which MPC downregulated is largely unknown. In the present study, we found that MPC1 is transcriptionally downregulated under prolonged hypoxic conditions (1% O_2) in human hepatocellular carcinoma cell lines (Hep3B and Huh7). We also showed that Hey1 and Hey2, Notch signaling target genes, are necessary for the reduced expression of MPC. Furthermore, HIF-2α -dependent upregulation of DEC1(Stra13/Bhlhe40), the basic-helix-loop-helix transcription factor, is necessary for Hey1 and Hey2 expression but not sufficient for transcriptional repression of MPC1. We also elucidated that hypoxia-induced apoptotic cell death in PLC/PRL5 cell line, in which MPC expression did not change under hypoxia, was relieved upon MPC1 downregulation using siRNA or CRISPR/Cas9 system. We also showed that Hep3B cells which stably expressed MPC protein induced cell death only when they exposed to hypoxic condition. Taken together, the present data demonstrate that Notch signaling pathway under hypoxia suppresses pyruvate-dependent oxidative phosphorylation and promotes cancer cell survival through downregulating MPC expression. This work was supported by a National Research Foundation of Korea (NRF) Grant funded by the Korean Government (MSIP) (NRF-2017R1A2B4007462, NRF-2017R1A2B4009674 and NRF-2011-0030086)

P2277/B528

The Ribonucleoprotein Clueless Affects the Metabolism by Regulating the Abundance of Enzymes Associated with Glycolysis and Respiratory Chain Components.

A. Sen, R. T. Cox; Uniformed Services University, Bethesda, MD.

The majority of cellular ATP is produced in mitochondria and functional mitochondria are vital for maintaining proper cellular homeostasis. In order to carry out their many biochemical functions, mitochondria must import approximately 1800 nucleus-encoded proteins. An y aberrations in these proteins or in the import mechanisms can cause a cascade of mitochondrial defects. Much is known about the canonical pathways involved in the import of nucleus-encoded proteins; proteins are translated by free ribosomes in the cytoplasm, bind chaperons and are targeted to the organelle. However, there is emerging evidence supporting co-translational import occurs, but the mechanism is not well-defined. We are investigating the role of the Drosophila ribonucleoprotein Clueless (Clu) in this process. *clu* mutants have defective mitochondria and the flies are sick and uncoordinated. Clu interacts with outer mitochondrial membrane proteins such as Tom20, Porin and PINK1. We have also shown that Clu binds mRNA and associates with ribosomal proteins. The mammalian counterpart, Cluh, was shown to preferentially bind nucleus-encoded mitochondrial mRNAs. We are currently determining Clu's molecular mechanism and whether Clu assists with mitochondrial protein import. We used immunoprecipitation followed by mass spec analysis to identify potential Clu interactors. We also analyzed the mitochondrial proteome from *clu, Sod2* and *Pink1* mutants using TMT mass spectrometry. These analyses reveal that Clu preferentially interacts, as expected, with the ribosomal proteins from both 60S and 40S ribosomal subunits as well as various core translation factors. Surprisingly, in addition

to proteins involved in translation, we found that Clu associates with glycolytic enzymes and several other metabolic enzymes. We confirmed that Clu binds to *Pyruvate kinase* and *Enolase* using reciprocal CoIPs. Moreover, we show that starvation causes Clu to dissociate from many of its potent interactors. Our TMT results show that a subset of OXPHOS complex members are specifically less abundant in *clu* mutants. We also confirmed that the changes in protein abundance are not due to altered transcription. Lastly, we found that the altered protein profile is *clu* specific, and not due to general mitochondrial damage, by comparing TMT from Sod2 and PINK1 mutants as controls. As a ribonucleoprotein Clu is expected to preferentially bind ribosomal proteins and core translation factors. But, surprisingly, Clu also associates with glycolytic enzymes and especially, the OXPHOS components, are severely reduced in *clu* mutants. Our data supports a model whereby Clu affects cellular metabolism by controlling the availability of enzymes associated with glycolysis and mitochondrial oxidative phosphorylation.

P2278/B529

Alcohol-induced Defects in Mitochondrial Structure and Dynamics Are Further Altered by Lipid Droplet Accumulation.

R. Mitra, R. Adhikari, P. Tuma; the Catholic University of America, Washington DC, DC.

Although the progression of alcoholic liver disease is well-described clinically, much less is understood about the molecular basis of the disease. Over a dozen years ago, we determined that microtubules are hyper acetylated in alcohol exposed hepatocytes, liver slices and in livers from ethanol-fed rats. We have since correlated alcohol-induced microtubule acetylation with known alcohol-induced defects in protein sorting including basolateral secretion, basolateral-to-apical transcytosis and the nuclear translocation of STATs. More recently, we have established that in hepatic cells treated with alcohol and oleic acid (to mimic the Western diet and fatty liver) that lipid droplets are virtually stationary. By overexpressing the tubulin specific acetyltransferase, αTAT1, we further determined that impaired droplet motility was explained by microtubule hyper acetylation. Our attention is now focused on known alcohol-induced defects in mitochondrial structure and dynamics in the absence or presence of the Western diet in the context of acetylated microtubules. From live cell imaging of vital dye-labeled mitochondria, we determined that mitochondria were virtually stationary in alcohol-treated cells and that they appeared much shorter. This result is consistent with recent reports that determined that microtubule acetylation enhances mitochondrial fission. Surprisingly, mitochondria in alcohol-treated cells in the presence of oleic acid, were longer than in control implying decreased fission. This might be explained by the finding that mitochondria form tight associations with lipid droplets (referred to as peridroplet mitochondria). When viewed by EM, we observed abundant mitochondria-droplet associations consistent with this hypothesis. We are now overexpressing αTAT1 in control and oleic acid treated-cells to further discriminate the role of microtubule acetylation in mitochondria-droplet contacts and dynamics and are examining droplet-mitochondria contact sites in control cells compared to ethanol-treated cells in absence or presence of lipid droplets to better understand mitochondria dysfunction in alcoholic liver disease.

Near-infrared Light Exposure Is Associated with Increases in Mitochondrial Activity.

T. R. Oliver, C. Rono; Spelman College, Atlanta, GA.

Photobiomodulation (PBM) is the use of red or near-infrared (NIR) light at low power densities, to produce beneficial physiological effects on cells or tissues. This exposure to low-level NIR light has been shown to reduce pain, inflammation, and promote wound healing. It has also been shown to have several beneficial neurological effects, such as improvements on major depressive disorder and Alzheimer's Disease, as well as traumatic brain injury and stroke. Cytochrome c oxidase (CCO), the last enzyme in the electron transport chain (ETC), is believed to be the major chromophore for NIR light. The exact mechanism by which NIR mediates PBM is still not clearly understood. As CCO is a member of the ETC, the goal of this study was to characterize the effect of NIR light exposures shown to mediate PBM on mitochondrial activity. Exposure to 2.88 J/cm2 of NIR light (673 nm), 24-hours prior, induces resistance to cell death in retinal pigmented epithelial cells exposed to a 1 sec pulse of 2 μm laser radiation. Thus, we focus on this exposure in this study. The fluorescent molecule tetramethylrhodamine, ethyl ester (TMRE) was used to assay mitochondrial activity. TMRE is a cell permeant, positively-charged, red-orange dye that readily accumulates in active mitochondria due to their relative negative charge. Depolarized or inactive mitochondria have decreased membrane potential and fail to sequester TMRE. Results from our analysis suggest that exposure to 2.88 J/cm2 of NIR light (673 nm) results in increased mitochondrial activity.

Branched-Chain Amino Acids Control Mitochondrial Metabolite Carriers Via the Mitochondrial-Derived Compartment Pathway.

M. Schuler, A. M. English, J. M. Shaw, A. L. Hughes; University of Utah, Department of Biochemistry, Salt Lake City, UT.

Mitochondria are double membrane-bound organelles that fulfill central tasks in cellular metabolism. Metabolite transport into and out of mitochondria is mediated by carrier proteins of the SLC25A family embedded in the inner mitochondrial membrane. Despite being critical regulatory points in cellular metabolism, it remains unclear how mitochondrial carriers are modulated in response to changes in the intracellular nutrient status. We recently identified a new subcellular structure that forms from yeast mitochondria, called the Mitochondrial-Derived Compartment (MDC). In aging yeast cells, MDCs are formed in response to defects in lysosomal amino acid storage and target select mitochondrial proteins for degradation. However, the function of the MDC pathway and the underlying signal activating MDC formation are not known. Here we present new evidence that MDCs are conserved from yeast to mammals and control the levels of metabolite carriers on mitochondria in response to intracellular amino acid elevation. Using super-resolution live-cell imaging, we demonstrate that MDCs are large (1um), organelle-like structures that selectively sort and remove metabolite carriers and their associated import receptor Tom70 from yeast and mammalian mitochondria. We show that MDCs form from mitochondria in response to intracellular amino acid elevation with branched-chain amino acids (BCAAs) being the most potent inducers of MDC formation. Our data indicates that BCAA catabolism by the branched-chain amino acid transaminases *BAT1* and *BAT2* is a major driver of MDC formation in yeast and that downstream products of BCAA degradation directly activate MDC-dependent remodeling of mitochondria. By contrast, the MDC pathway is unresponsive to other common mitochondrial stressors,

including ROS generators, inhibitors of the mitochondrial respiratory chain and membrane potential uncouplers. Since MDCs sort and remove metabolite carriers from mitochondria, we propose that the MDC pathway provides cells with a mechanism to fine-tune mitochondrial metabolite transport in response to BCAA elevation by controlling the level of select SLC25A carriers on mitochondria. In support of this idea, our preliminary data indicate that overexpression of mitochondrial carriers directly activates MDC formation in yeast, whereas deletion of the carrier receptor Tom70 reduces MDC formation. Our current experiments are focused on testing how MDC formation affects cellular and mitochondrial metabolism and identifying the machinery and metabolic signaling mechanisms that control selective sorting and removal of nutrient carriers from mitochondria via the MDC pathway.

Characterization of Mitochondrial Metabolic Oscillations in Live Rodents.

Y. Ng[1], D. Chen[1], W. Losert[2], R. Weigert[1]; [1]Laboratory of Cellular and Molecular Biology, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, MD, [2]College of Computer, Mathematical, and Natural Sciences, University of Maryland, College Park, MD.

Mitochondria are specialized cellular compartments that function in energy production and calcium homeostasis. Although these organelles have been primarily investigated in cell cultures, very little is known about their morphology, function, and dynamic properties in live multicellular organisms. To address this issue, we used Intravital Subcellular Microscopy (ISMic), an imaging approach that enables the visualization of biological processes in live animals. In rat salivary glands, we previously discovered that: 1) mitochondrial metabolic activity exhibits rapid and periodic oscillations under basal conditions, and 2) mitochondrial oscillations are synchronized throughout the salivary epithelium via gap junctions. Importantly, dysfunctional mitochondrial oscillations are linked to many metabolic diseases e.g. obesity, cardiovascular disease, developmental defects and cancer, thus prompting us to ask: i) what is the physiological role of mitochondrial oscillations and ii) how oscillations are orchestrated at the whole organismal level. Here, we extended our characterization in rat and mouse tissues under both physiological and pathological conditions. Under basal conditions, we found that mitochondrial oscillations occur in all tissues tested, with substantial differences in their period, amplitude, and coordination, that most likely reflect the metabolic status of the tissues analyzed. Additionally, we identified that the metabolic oscillatory pattern is significantly altered in aged mice and during tumor progression in a mouse model for head and neck squamous cell carcinoma. In conclusion, we provided for the first time a detailed quantitative analysis of the characteristics of the metabolic oscillations under basal conditions, which can be served as a baseline to study these processes during pathological states.

P2282/B533

Mitochondria-localized β-actin Is Essential for Priming Antiviral Innate Immune Signaling by Regulating Irf3 Protein Stability.

P. Percipalle[1,2]; [1]New York University Abu Dhabi, Abu Dhabi, UNITED ARAB EMIRATES, [2]Stockholm University, Stockholm, SWEDEN.

Antiviral innate immunity acts as a defensive barrier to viral infection in both immune and non-immune cells. The viral nucleic acids present in the cytoplasm after viral replication can activate sensors such as RIG-I-like receptors RIG-I and MDA5, or cytosolic DNA sensors cGAS to initiate signaling transduction.

Activation of this signaling cascade leads to phosphorylation of protein kinase TBK1, which in turn phosphorylates and activates transcription factor IRF3 to up-regulate type-I interferons α and β and suppression of viral replication. IRF3 is essential for sustained antiviral responses and alteration of mitochondrial function can affect antiviral immune signaling. However, whether mitochondrial defects affect IRF3 protein stability remains unclear. We recently reported the presence of a mitochondrial β-actin pool that regulates the mitochondrial genome. Loss of mitochondrial β-actin leads to decreased mitochondrial DNA transcription and impairs mitochondrial membrane potential (MMP). Mitochondrial β-actin is, therefore, essential for mitochondrial quality. In the present study, we discovered a novel function for the mitochondrial β-actin pool in the maintenance of IRF3 stability at the protein level. Using a genomics approach, we found that the lack of β-actin not only causes systematic down-regulation of genes involved in antiviral innate immune pathways, but also impairs the induction of antiviral response genes upon viral mimic stimulation. This seems to result from the instability of IRF3 in β-actin knockout mouse embryonic fibroblasts (KO MEFs). We show that reintroduction of β-actin in mitochondria of KO MEFs can rescue the stability of IRF3 and the induction of antiviral genes. We propose that mitochondria-targeted β-actin is essential for the IRF3 protein stability and effective activation of antiviral immune responses by controlling mitochondrial quality. Future studies can focus on the mechanistic basis of the link between β-actin-dependent mitochondrial quality and IRF3 stability.

P2283/B534

Mitochondrial Nucleoids Self-assemble Via Phase Separation.

M. Feric[1,2], T. G. Demarest[3], J. Tian[3], D. L. Croteau[3], V. A. Bohr[3], T. Misteli[2]; [1]NIGMS, Bethesda, MD, [2]NCI, Bethesda, MD, [3]NIA, Baltimore, MD.

Mitochondria contain an autonomous and spatially segregated genome. The mitochondrial DNA (mtDNA) is coated by architectural proteins to form physically discrete mitochondrial nucleoids, which are non-membrane bound nucleoprotein complexes of uniform size. Beyond the direct binding of protein to mtDNA, the physical mechanisms that govern how mt-nucleoids assemble, how they are maintained, and how they contribute to function remain unclear. Here, we provide direct evidence that mt-nucleoids arise from phase separation of nucleic acids and proteins. We show that the main mtDNA packaging protein mitochondrial transcription factor a (TFAM) readily phase separates into viscoelastic droplets in vitro. Mutation analysis of TFAM reveals that multivalent interactions, intrinsically disordered domains, and charged residues contribute to the observed phase behavior. Addition of mtDNA promotes the formation of multiphase structures with gel-like properties. With regards to in vivo properties of nucleoids, pharmacological disruption with known mtDNA intercalators induces liquid-like fusion events between individual mt-nucleoids and global coarsening within the mitochondrial network. In support of a link to aging, which is associated with increased reactive oxygen species production and mitochondrial dysfunction, we find that cells derived from patients with the premature aging disease Hutchinson-Gilford Progeria Syndrome (HGPS) have an increased number of damaged mitochondria with accumulation of mt-nucleoid markers. The atypical organization and enlarged structures of mt-nucleoids in the damaged mitochondria in HGPS cells resemble those generated in vitro and are associated with impaired mitochondrial function. Together, these results suggest that mt-nucleoids represent phase separated droplets of protein and mtDNA in vivo. The phase behavior of mt-nucleoids represents a novel framework for understanding their assembly, maintenance, and organization, with potential implications for normal aging.

P2284/B535

Identifying Regulatory Genes of Mitochondrial DNA Using High-throughput Imaging an alysis.

K. K. Gov[1], K. Subramanian[1], J. Bonner[1], M. Mattiazzi Ušaj[2], H. Tan[1], B. An drews[2], J. Nunnari[1]; [1]University of Califonia, Davis, Davis, CA, [2]University of Toronto, Toronto, ON, CANADA.

Mitochondria are semi-autonomous organelles containing their own genetic material. Mitochondrial DNA (mtDNA) encodes for essential proteins required for energy production via oxidative phosphorylation and is packaged into protein-DNA structures, termed nucleoids. Mutations in mtDNA and altered mtDNA copy number are linked to human diseases, including metabolic disorders. We conducted a genome-wide high-throughput high-content imaging screen in budding yeast to investigate how nucleoid structure and copy number are maintained in cells. We generated and imaged cells expressing fluorescent cytosolic, mitochondrial, and nucleoid markers using the yeast knockout library of approximately 6,000 mutants. Using CellProfiler and an unsupervised machine learning outlier detection program, we identified genes that when deleted, caused nucleoid phenotypes that significantly deviated from wild-type with a high penetrance. To further classify these phenotypes and to find additional mutations that fit specific classes of morphological profiles, we are using a supervised machine learning program trained for each phenotypic category on approximately 400 manually labeled individual cells. Ultimately, we aim to elucidate the mechanisms of mtDNA maintenance by identifying and characterizing the nuclear genes associated with mtDNA regulation.

Mitochondrial Transplantation Regenerates Tendinopathy: in Vivo Study.

J. Lee, J. Hwang, J. Kim, Y. Choi, K. Min, Y. Choi; CHA University, Seongnam, KOREA, REPUBLIC OF.

Tendinopathy refers to painful conditions associated with tendons. Its main clinical symptom is activity-related pain. As its pathophysiology, inflammatory mechanisms has been highlighted. Several cytokines are activated to modulate inflammation and mitochondrial dynamics required for tendon homeostasis are also impaired. Mitochondria are known to be associated with tendon regeneration. However, there are scanty references of the action of mitochondria in tendon. Previously, we showed that direct mitochondrial transfer into muscle cells improved their metabolic function. Out hypothesis is that direct mitochondrial transplantation will also be effective in animal model of tendinopathy. First, we established a rat tendinopathy model after injection of collagenase I into Achilles tendons for 2 weeks. Isolated mitochondria were injected locally into Achilles tendons. At 2 and 4 weeks after collagenase injection, rats were sacrificed for tendon harvesting. Then, tendon tissues were analyzed to measure the change of inflammatory signaling pathway (Nuclear Factor-kβ (NF-kβ)) and tenocyte-specific markers (tenascin C (TNC), and matrix metalloproteinase 1 (MMP1)) by western blotting. We confirmed that isolated mitochondria were transplanted efficiently in tendon using confocal analysis. As a result, transplanted mitochondria (Red) were detected in extracted tendon and merged with recipient tendons (Green). Also, up-regulated p65 subunit of NF-kβ level was suppressed to normal conditions. TNC and MMP1 were increased 2.5 fold in the collagenase-injected group and inhibited in the mitochondrial transplanted group markedly. In conclusion, mitochondrial transplantation provides novel protection for tendinopathy-induced inflammatory environments. These results infer that the mitochondrial transplantation would be one of therapeutic options for tendinopathy.

Gating Mechanism of the Extracellular Entry to the Lipid Pathway in a TMEM16 Scramblase.

B. Lee[1,2], G. Kelashvili[2], H. Weinstein[2], A. Accardi[2]; [1]Korea Brain Research Institute, Daegu, KOREA, REPUBLIC OF, [2]Weill Cornell Medicine, New York, NY.

Members of the TMEM16/ANO family of membrane proteins are Ca^{2+}-activated phospholipid scramblases and/or Cl^- channels. A membrane-exposed hydrophilic groove in these proteins serves as a shared translocation pathway for ions and lipids. However, the mechanism by which lipids gain access to and permeate through the groove remains poorly understood. Here, we combined quantitative scrambling assays and molecular dynamic simulations to identify the key steps regulating lipid movement through the groove. Lipid scrambling is limited by two constrictions defined by evolutionarily conserved charged and polar residues, one extracellular and the other near the membrane mid-point. The region between these constrictions is inaccessible to lipids and water molecules, suggesting that the groove is in a non-conductive conformation. A sequence of lipid-triggered reorganizations of interactions between these residues and the permeating lipids propagates from the extracellular entryway to the central constriction, allowing the groove to open and coordinate the headgroups of transiting lipids

P2287/B538

Functional an alyses of the Udp-galactose Transporter Solute Carrier Family 35 Member A2 (slc35a2) Using the Binding of Bacterial Shiga Toxins as a Novel Activity Assay.

D. Li, S. Mukhopadhyay; University of Texas at Austin, Austin, TX.

SLC35A2 transports UDP-galactose from the cytosol to the lumen of the Golgi apparatus and endoplasmic reticulum for glycosylation. Mutations in SLC35A2 induce a congenital disorder of glycosylation. Despite the biomedical relevance, mechanisms of transport via SLC35A2 and the impact of disease-associated mutations on activity are unclear. To address these issues, we generated a predicted structure of SLC35A2 and assayed for the effects of a set of structural and disease-associated mutations. Activity assays were performed using a rescue approach in ΔSLC35A2 cells and took advantage of the fact that SLC35A2 is required for expression of the glycosphingolipid globotriaosylceramide (Gb3), the cell surface receptor for Shiga toxin 1 (STx1) and 2 (STx2). The N- and C-terminal cytoplasmic loops of SLC35A2 were dispensable for activity, but two critical glycine (Gly-202 and Gly-214), glutamate (E-75 and E-221), and lysine (Lys-78 and Lys-297) residues in transmembrane segments were required. Residues corresponding to Gly-202 and Gly-214 in the related transporter SLC35A1 are supposed to form a molecular notch to retain α-helices interaction when alternating between the Golgi- and cytoplasmic-facing states during transport. E-75 and Lys-78 form an EXXK motif that is conserved across SLC35A subfamily members. Our results suggest that a similar transporting mechanism may be involved in all SLC35A subfamily members. Among the disease-associated mutations tested, SLC35A2 function was completely inhibited by F65L, Y130C, S213F, and G282R, providing a straightforward mechanism of disease. Interestingly, some of the disease-associated mutations (V331I, N235Q, V258M, and Y267C) did not affect SLC35A2 function, suggesting that complexities beyond the loss of transporter activity may underlie disease due to these mutations. Overall, our results provide new insights into the mechanisms

of transport of SLC35A2 and improve understanding of the relationship between SLC35A2 mutations and disease.

P2288/B539

Characterization of a Novel Cancer-associated Splice Variant Isoform of the Nucleotide Sugar Transporter SLC35A3.

D. Fu, K. P. Alcedo, R. Rivera-Soto, N. T. Snider; University of North Carolina at Chapel Hill, Chapel Hill, NC.

Adaptation of the cellular secretory pathway to meet the metabolic and environmental demands of cancer cells is critical for oncogenesis and tumor growth. N-linked glycosylation represents a key regulatory step in the processing of membrane-bound and secreted proteins and is mediated by members of the SLC35 family of nucleotide sugar transporters. We report here the first characterization of a novel cancer-associated splice variant of the SLC35A3 transporter, which facilitates the transport of UDP-N-acetylglucosamine from the cytoplasm into the Golgi. The aim of the study was to compare the molecular and functional properties of the canonical SLC35A3 protein isoform 1 (NP_036375) with the SLC35A3 splice variant isoform 2 (NP_001258614). We examined SLC35A3 expression, localization, and function in human hepatocellular carcinoma (HCC), the most common form of primary liver cancer. We performed RNAseq analysis on paired surgical specimens from adjacent non-tumor and tumor tissue from HCC patients. Changes in mRNA isoform expression were validated via qPCR using sequence-specific primers. We generated expression plasmids encoding each isoform and examined protein expression, localization, and function in HCC cells. Glycosylation changes were monitored by click-chemistry approaches and lectin immunoblotting. Compared to normal human liver, HCC cell lines (HuH7, Hep3B, MHCC97, SNU423, SNU449, and PLC/PRF/5) expressed 3-15 fold less mRNA encoding SLC35A3 isoform 1, and 5-25 fold more mRNA encoding SLC35A3 isoform 2. Similarly, in primary HCC tumors, isoform 2 was selectively upregulated over isoform 1 ($p=0.00659$). Immunoblot analysis of lysates from primary HCC tumors revealed abundant expression of protein consistent with the predicted size of SLC35A3 isoform 2. Both isoforms showed strong co-localization with the Golgi marker GM130 when expressed in HCC cells. Expression of SLC35A3 isoform 2 did not alter the addition of terminal sialic acid moiety in glycoproteins. However, lectin binding assay using dolichos biflorus agglutinin (DBA) lectin revealed an increased in glycosylated proteins enriched in N-Acetylgalactosamine (GalNAc) in cells transfected with SLC35A3 isoform 2, suggesting a shift in GalNAc transport into the Golgi. Furthermore, we observed a reduction in glycosylated protein levels using griffonia simplicifolia lectin (GSL), with specificity for D-galactose, in cells transfected with SLC35A3 isoform 2. In conclusion, we show that HCC is associated with increased expression of SLC35A3 isoform 2. This possibly leads to a shift in GalNAc- and D-galactose-associated transport into the Golgi, and subsequent altered glycosylation of proteins in HCC. Future studies will address detailed functional mechanisms of SLC35A3 isoform 2 in HCC.

P2289/B540

Identifying the Amino Acid Residues Responsible for a Gating Function in Pdr5, a Major Yeast Multidrug Efflux Pump.

M. Alhumaidi, J. Golin; the Catholic University of America, Washington, DC.

The yeast ABC asymmetric transporter Pdr5 is the founding member of a subfamily of fungal transporters that cause broad drug resistance when they are overexpressed. Pdr5 acts as a one-way

gate or molecular diode to prevent reentry of substrates once they are expelled. The first evidence for a molecular gate or diode mechanism was inferred from the behavior of a Ser 1368 Ala mutation in Pdr5 This mutant exhibited significant drug reflux during transport, but otherwise had no observable biochemical deficiencies. Alignments of Pdr5 with other Pdr subfamilies revealed highly conserved residues adjacent to Ser-1368 in transmembrane-helix 11 and extracellular loop 6 which are found in the carboxyl-terminus half of the transporter. A similar set of residues in the amino terminal portion was also conserved. An important question is whether the molecular diode is made up of residues from both halves of pdr5. Mutants in these residues were constructed and they have tested for their relative drug resistance and their transport and gating capability. Our data indicate that two mutants, S678Y (amino terminal half), and F1369A, behave much like the Ser1368ala mutant. Several other mutants have phenotypes suggesting that they have a gate that is slow to open and close.

P2290/B541

Nonsynonymous Mutations in the Yeast Multidrug Transporter Pdr5 Can Increase Expression by Increasing Mrna Half-life.

H. Rahman[1], A. Rudrow[1], J. Carneglia[1], S. Joly[1], D. Nicotera[1], M. Naldrett[2], J. Choy[1], S. Ambudkar[3], J. Golin[1]; [1]The Catholic University of America, Washington, DC, [2]University of Nebraska-Lincoln, Lincoln, NE, [3]NCI, National Institute of Health, Bethesda, MD.

Multidrug resistance is a huge clinical problem for the cancer chemotherapeutic and treatment of fungal infection. Enhanced expression of the ABC transporter protein is one of the leading mechanistic explanation of this broad resistance. PDR5, a major efflux ABC transporter protein, mediates broad-spectrum resistance in *Saccharomyces cerevisiae*. Previous work established that mutations in transcription factors lead to Pdr5 overexpression. We report the novel observation that a series of nonsynonymous mutations in an unconserved stretch of amino acids found in the yeast multidrug efflux pump Pdr5 increases expression, thus enhancing multidrug resistance. Cycloheximide chase experiments ruled out the possibility that the increased steady-state level of PDR5 was caused by increased protein stability. Quantitative-RT PCR experiments demonstrated that the mutants had levels of Pdr5 transcript that were two to three times as high as in the isogenic wild-type strain. Further experiments with metabolic labeling of mRNA with 4-thiouracil followed by uracil chasing showed that the half-life of Pdr5 transcripts was specifically increased in these mutants. Our data demonstrate that the nucleotides encoding unconserved amino acids may be used to regulate expression.

P2291/B542

The Molecular Mechanism Underlying Growth Inhibition of *Saccharomyces Cerevisiae* by Supplementing Lysine to the Medium Containing Proline as Sole Nitrogen Source.

H. Ichimura, T. Kaneko, S. Yamaguchi, N. Murao, T. Sekito, M. Kawano-Kawada; Ehime Univ., Ehime, JAPAN.

The budding yeast *Saccharomyces cerevisiae* can grow on the medium containing proline as sole nitrogen source (SD+Pro). It has been shown that the addition of lysine (Lys) to the SD+Pro inhibits the growth. We found that the deletion of *AVT4* encoding a transporter, which exports neutral and basic amino acids from vacuoles, further suppressed the growth in SD+Pro+Lys medium. To dissect these effect of lysine, we cultured wild-type cells in SD+Pro or SD+Pro+Lys and measured the amino acid contents of the whole cell, vacuoles, and culture medium. When compared with cells cultured in

SD+Pro, cells cultured in SD+Pro+Lys contained much less amount of proline, whereas they contained the a large amount of lysine. In *avt4*Δ cells, such high and low contents of lysine and proline, respectively, were sustained for longer time than in wild-type cells. Consistently, proline remained in the medium for longer time in the case of *avt4*Δ cells. A major part of cellular lysine in both wild-type and *avt4*Δ cells cultured in SD+Pro+Lys was located in vacuoles. We found that Put4, a plasma membrane transporter for the proline uptake, was translocated into the vacuolar lumen in the presence of lysine. In addition, the expression of Put4-20, a mutant which constitutively localizes to the plasma membrane, recovered the growth of both the wild-type and *avt4*Δ cells in SD+Pro+Lys. These suggest that the growth inhibition by addition of lysine is due to the reduction of cellular proline uptake, and vacuolar lysine accumulation may block the targeting of Put4 to the plasma membrane. Then we examined the involvement of TORC1 activity, which regulates the expression and subcellular localization of Put4. The deletion of *GTR1 and GTR2*, which blocks TORC1 activation, resulted in the growth recovery in SD+Pro+Lys. We found that the addition of lysine extended the phosphorylation of Sch9, a substrate of TORC1. These suggests that lysine has some effect to activate TORC1 though it is not utilized as a nitrogen source.

P2292/B543

Vacuolar Amino Acid Transport Is Regulated by the GATA Transcription Factors.

A. Sato, T. Kimura, E. Murakami, M. Hyodo, S. Kodama, M. Kawano-Kawada, T. Sekito; Ehime Univ., Ehime, JAPAN.

Vacuoles in the budding yeast *Saccharomyces cerevisiae* actively uptake amino acids and accumulate more than 50% of cellular amino acids in nutrient-rich condition, whereas they release the accumulated amino acids with newly generated ones by autophagy under nitrogen starvation condition. Such conversion of amino acid flux across the vacuolar membrane suggests that the activities of vacuolar amino acid transporters are regulated in a manner dependent on nutritional condition. The AVT transporter family includes vacuolar amino acid transporters such as Avt1, Avt3, Avt4, Avt6 and Avt7. Avt4 is a vacuolar exporter for neutral and basic amino acids. Previous microarray analysis suggested that its expression increases under nitrogen starvation condition and is regulated by the GATA transcription factors, Gln3 and Gat1, which are responsible for the transcription of genes related to the nitrogen metabolism to adapt cells to the change in the availability and quality of nitrogen source. Our real-time PCR analysis supported the previous microarray results. Mutations in the putative GATA binding sites in the *AVT4* promoter reduced the expression of *AVT4*. In addition, Gat1-myc^{13} specifically precipitated the *AVT4* promoter fragment containing these GATA binding sites in the chromatin immunoprecipitation assay. These results suggest that the GATA transcription factors directly drive the *AVT4* transcription. Confirming the microarray results, real-time PCR analysis showed that *AVT1* and *AVT7* expressions were also down-regulated by the deletion of the GATA transcription factors. In addition, we newly found that *AVT6* is also regulated by the GATA transcription factors. Taken together, these results suggest that the GATA transcription factors broadly regulate the vacuolar amino acid transport system. Considering the physiological roles of GATA transcription factors, our results in this study strongly suggest that the vacuolar compartmentalization of amino acids by their transport across the vacuolar membrane is incorporated to the cellular nitrogen metabolism.

P2293/B544

The Role of Basigin as an Immune Mediator in the CNS.

A. Gonzalez, J. D. Ochrietor; University of North Florida, Jacksonville, FL.

Chronic inflammation is a hallmark of many neurodegenerative disorders, including Alzheimer's disease (AD), Parkinson's disease (PD), and multiple sclerosis (MS). Although the central nervous system (CNS) can stave peripheral pathogens from crossing the blood-brain barrier (BBB) through a network of continuous nonfenestrated endothelia, astrocytes, and pericytes, prolonged exposure to a pathogen can comprise this barrier. An increase of IL-6 can stimulate vascular cell adhesion molecule 1 (VCAM-1), leading to increased permeability of the BBB, effectively allowing the infiltration of T-cells and cytokines, such as IL-6. T-cells, as well as macrophages, are lined with surface receptors that detect pathogens and elicit further immune responses, particularly toll-like receptor 4 (TLR4). TLR4 has been demonstrated to detect lipopolysaccharide (LPS), found on the outer membrane of Gram-negative bacteria. Recently, a member of the immunoglobulin superfamily (IgSF), Basigin, has been shown to interact with TLR4. Studies have also indicated that Basigin is expressed on endothelial cells and can spur angiogenesis. The present study aims to address the expression pattern of Basigin and TLR4 in brain tissue stimulated with LPS for a variation of time to mirror acute and chronic inflammation, as well as different life stages to determine whether the expression pattern is dynamic. Isolated brain tissue and neural retina from mice at postnatal day 7 and 30 were incubated in DMEM ± LPS for 3, 6, 12, or 24hrs. Total RNA and protein were purified from the isolated tissue and used in quantitative reverse transcription PCR (qRT-PCR) and direct enzyme-linked immunosorbent assay (ELISA). The results of the study suggest expression of Basigin is elevated after 24 hours of incubation in LPS relative to control in the 30-day old animals, but not in the 7-day old animals. This elevation in expression was not observed at other incubation periods. Expression of TLR4 did not change between age groups or incubation periods. The data suggest that expression of Basigin, but not TLR4, changes from neonate to adolescent age. This may leave the neonatal CNS more susceptible to an inflammatory response.

P2294/B545

The Ig0 Domain of Basigin Variant-1 Stimulates Il-6 Expression in Raw 264.7 Monocytes.

A. D. Tompa, J. D. Ochrietor; University of North Florida, Jacksonville, FL.

There are two main protein products of the Basigin gene. One protein, known as Basigin-variant-1 is expressed in the neural retina, specifically by the photoreceptor neurons. The other protein, known as Basigin-variant-2 is expressed throughout the body, including monocytes, as well as Müller glial cells and the retinal pigmented epithelium of the eye. A study by this laboratory indicates that the two Basigin gene products interact via their extracellular domains. A different study by another research group indicates that the Ig0 domain of Basigin-variant-1 can elicit an immune response in several cell lines. The purpose of the present study was to determine if the region of the Ig0 domain of Basigin-variant-1 thought to interact with Basigin-variant-2 is the same region that elicits an immune response. Recombinant versions of the Basigin-variant-1 Ig0 domain were incubated with mouse monocytic RAW 264.7 cells. After 24 hours, the cell culture medium was collected and assayed for the expression of the pro-inflammatory cytokine interleukin-6 (IL-6) via an ELISA. Cells treated with a control protein generated from the expression vector used to make the Basigin-variant-1 recombinant proteins served as the control. The data indicate that the region of the Ig0 domain used to interact with Basigin-variant-2 does indeed stimulate production of a significantly greater amount of IL-6 than the control protein.

The data suggest that Basigin-variant-1 interacts with Basigin-variant-2 to stimulate a proinflammatory response in monocytes. This study is important for a better understanding of immune response aspects of diabetic retinopathy and other diseases in which the retinal pigmented epithelium is compromised.

Ampa and Nmda Receptor Alterations Mediate Enhanced Escalation of Methamphetamine Self-administration.

M. Chojnacki, S. Jayanthi, J. Cadet; Molecular Neuropsychiatry Research Branch, National Institute on Drug Abuse, NIH, Baltimore, MD.

Objectives: Methamphetamine addiction is often studied using rodent self-administration models whereby animals associate lever presses with intravenous drug infusions. Some investigators have used a pre-injection of the drug of interest before introducing rodents to the self-administration apparatus. This experimental approach usually causes steeper escalation of drug taking behaviors. The present experiment was aimed at identifying potential changes in the hippocampi of rats that had undergone a similar procedure using methamphetamine as the self-administered drug. **Methods:** Rats were first injected with either saline or methamphetamine intraperitoneally. Two weeks later, the animals underwent surgery for catheter placement. During self-administration, pressing a lever resulted in intravenous injections of methamphetamine. Rats also underwent tests for relapse to drug taking one day and one month after withdrawal from drug self-administration. We then used PCR and Western Blotting to measure potential changes in mRNA and protein expression levels of glutamate receptors. **Results:** Rats that received the methamphetamine injection before drug self-administration escalated drug intake more than the animals that received saline pre-injection. In the hippocampus, these rats showed decreased levels of *GluA2*, *GluA3*, and *GluN2c* mRNA levels in comparison to other animals. In addition, GLUA1 protein levels were decreased in the methamphetamine-preinjected rats. **Conclusion**. These observations suggest that decreased expression of hippocampal AMPA receptors may participate in escalation of methamphetamine intake. Identification of molecular mechanisms involved in drug taking behaviors may facilitate the development of better therapeutic anti-addiction interventions in the future.

Putative Yeast Polycystin Channel Pkd2p Localizes to the Cleavage Furrow and Drives Cell Separation during Cytokinesis.

Q. Chen, Z. Morris, D. Sinha, A. Poddar, B. Morris; University of Toledo, Toledo, OH.

Human polycystin PKD2 is a non-selective transient potential receptor (TRP) channel. It co-assembles with another polycystin PKD1 into a tetrameric complex that is essential for many developmental processes. Loss of function mutations of either polycystins lead to Autosomal Polycystic Kidney Disease (ADPKD), one of the most common human renal disorders. Nevertheless, the cellular function of polycystins remains unclear. *Here* w*e showed that the fission yeast homologue of PKD2 supprisingly localizes to the cleavage furrow and modulates multiple steps of cytokinesis.* Like its human homologue, fission yeast *pkd2* is an essential gene. Pkd2p localizes to the plasma membrane during interphase but it is recruited to the cleavage furrow by the actomyosin contractile ring during cytokinesis. Its molecular number at the furrow peaks at the end of the ring constriction. Pkd2p is essential for maintaining the cell integrity during interphase. The *pkd2* mutant cells often deflate temporarily, causing a arrest of the

cytoskeletal turnover and the subsequent stress response. More interestingly, Pkd2p regulates both the contractile ring closure and the cell separation during cytokinesis. The contractile ring constricts more rapidly in the *pkd2* mutant than the wild-type cells, a defect rescued by the addition of an osmotic stabilizer sorbitol. In contrast, separation of the mutant cells is slower and often incomplete. These cytokinesis defects suggest that Pkd2p regulates turgor pressure at the cell division plane as a part of intracellular osmotic homeostasis. Lastly, a study of genetic interactions between the *pkd2* mutant and many other cytokinesis mutants found that Pkd2p act antoganostically against the Septation Initiation Network (SIN) pathway during cytokinesis. In conclusion, we discovered that the fission yeast homologue of polycystin Pkd2p is a novel regulator of cytokinesis through mediating intracellular osmotic homeostasis.

Characterization of Protein Signalosome Using Super-Resolution Microscopy.

N. Ud Din, A. Oshima, K. Machida, B. Mayer, J. Yu; Uconn Health Center, Farmington, CT.

Molecules are often organized in cellular space packed within organelles which are surrounded by lipid bilayer such as endoplasmic reticulum or Golgi apparatus. However, a variety of molecules, such as proteins and Ribonucleic Acids (RNA), have been found to form condensates in the cellular compartments without any defined boundaries. Similarly, membrane bound signaling molecules have also been observed to form aggregates similar to the condensates, also named as clusters. However, the biological or structural benefit of the formation of these clusters and how these molecules are spatially distributed within these structures are not fully understood. To understand the dynamics of the molecules in the cluster and to contribute to the theoretical and experimental knowledge of the condensates, we studied the cluster formation of Epidermal Growth Factor Receptors (EGFR). EGFR is a well-studied Receptor Tyrosine Kinases (RTK) which forms dimers after the stimulation by its ligand Epidermal Growth Factor (EGF), initiating signaling cascade by binding of the Src Homology 2 (SH2) domain containing molecules. EGFR is also implicated in several forms of cancer and is being used as a chemotherapeutic target. For this purpose, EGFR clusters were imaged using Super-Resolution Imaging technique called Stochastic Optical Reconstruction Microscopy (STORM) Imaging. For the immunochemical staining, a Halo tagged EGFR nanobody was used which gives the opportunity to stoichiometrically label total EGFR receptors. We observed that the number of clusters, as well as their size, was increased as a response to the ligand stimulation. To further analyze the spatial distribution of phosphorylated receptor molecules within the cluster, engineered Halo tagged Growth factor receptor-bound protein 2 (Grb2) probes, which bind specifically to activated SH2 binding sites on RTKs, were used for immunostaining. Our results show that Halo tagged Grb2 probes have a higher binding affinity towards the phosphorylated receptors. Moreover, by further modeling these clusters, we found that the phosphorylated molecules tend to concentrate within the core of the clusters, indicating Phosphatase activity on the peripheries of the cluster. Here we propose that the application of Halo tagged probes/nanobodies in STORM microscopy can greatly enhance the effectivity of Super-Resolution Imaging technique and help us model the clusters or other cellular structures.

F508del-CFTR Forms a Complex with NHERF2 and LPA_2 at the Plasma Membrane of Airway Epithelial Cells: Its Relevance in the Pathogenic Process of Cystic Fibrosis.

Z. Zhang[1,2], S. Kong[1], A. K. Singh[1], A. P. Naren[3], **W. Zhang**[1,4]; [1]Department of Pediatrics, University of Tennessee Health Science Center, Memphis, TN, [2]Department of Pulmonary Oncology, the First Affiliated Hospital of University of Science and Technology of China, Hefei, CHINA, [3]Department of Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, [4]Children's Foundation Research Institute, Le Bonheur Children's Hospital., Memphis, TN.

BACKGROUND: Cystic fibrosis (CF) is a life-shortening inherited disease caused by the absence or dysfunction of the CF transmembrane conductance regulator (CFTR) channel activity. Previously, we demonstrated that wild type-(WT-)CFTR forms a macromolecular complex with lysophosphatidic acid receptor 2 (LPA_2) and Na^+/H^+ exchanger regulatory factor-2 (NHERF2) at the plasma membrane of airway and intestinal epithelial cells, and that this complex regulates the LPA-induced inhibition of CFTR channel function and fluid secretion. The goals of this study were to investigate if the rescued F508del-CFTR complexes with NHERF2 and LPA_2, and if this complex plays a role in the pathogenic process of CF. **METHODS:** Study models: human CF bronchial epithelial cells, human tracheal and bronchial epithelial tissues, CF mice (*F508del*$^{-/-}$) *and* WT mice. Techniques: Western blotting, immunofluorescence imaging, proximity ligation assay, Ussing chamber, organoids fluid secretion assay, etc. **RESULTS:** (1) LPA_2 expression was elevated in tracheal and bronchial epithelial tissues from CF patients and in CF bronchial epithelial cells. (2) When rescued to the plasma membrane, F508del-CFTR complexes with NHERF2 and LPA_2 in human CF airway epithelial cells. By forming such a complex, the LPA_2-mediated signaling exerts an inhibitory effect on the channel function of F508del-CFTR. Disruption of this complex by using CO-068 potentiated the channel function of F508del-CFTR. (3) F508del-NHERF2-LPA_2 complex regulates IL-8 secretion in CF bronchial epithelial cells. Rescue of F508del-CFTR by using VX-809 slightly decreased the basal level of secreted IL-8 and significantly decreased the IL-1β-stimulated IL-8 secretion (11%). Inhibition of LPA_2 function by using a specific inhibitor Beck35 significantly decreased the basal level (44%) and IL-1β-stimulated IL-8 (~39%) secretion. CO-068 also attenuated the LPA-induced IL-8 secretion. (4) LPA_2 is expressed in primary neutrophils isolated from human blood. **CONCLUSIONS:** CFTR-NHERF2-LPA_2 complex plays a critical role in the pathogenic process of CF: in addition to regulating the CFTR-mediated airway fluid homeostasis, it also modulates IL-8 secretion from airway epithelial cells, which could contribute to the recruitment and excessive infiltration of neutrophils and the subsequent excessive lung inflammation. An tagonism of LPA_2 has a potential to augment CFTR function to improve the mucociliary clearance process, and to inhibit the release of IL-8 and other pro-inflammatory cytokines and chemokines, thereby attenuating the excessive CF lung inflammation. **Acknowledgement**: Supported by NIH grant (R01 HL123535 to W.Z.)

Transferrin Receptor 2 Requires Both Its Cytoplasmic Domain and the Ability to Bind Tf to Regulate Iron Homeostasis.

C. A. Enns, M. Kleven, J. Cahill, A. M. Wortham, A. Zhang; Oregon Hlth Sci University, Portland, OR.

Transferrin receptor 2 (TfR2) is an integral membrane protein with a N-terminal cytoplasmic domain (CD), a transmembrane domain, and a large ectodomain responsible for its dimerization and binding the serum iron-transport protein, transferrin (Tf). It is expressed predominantly in the liver and in erythroid precursors (1). The finding that deleterious mutations in TfR2 or lack of Tfr2 in mice are responsible for iron overload, led to the hypothesis that this receptor is involved in systemic iron regulation (2,3, rather than solely in Tf-mediated iron uptake. Iron homeostasis in the body is controlled by hepcidin, a small

peptide hormone secreted by the liver. Hepcidin downregulates the iron exporter ferroportin and limits the recycling of iron from macrophages and the transit of dietary iron from intestinal epithelial cell into the circulation. Under high iron conditions, hepcidin increases to limit the amount of iron entering circulation via macrophages and intestinal epithelial cells. Hereditary hemochromatosis type III is caused by a lack of TfR2, or deleterious mutations in TfR2, and results in a pathophysiology of abnormally low hepcidin levels for the amount of iron in the body. In this report, we sought to determine the domains of TfR2 necessary for regulation of hepcidin production by the liver. We found that both the CD of TfR2 and the ability of TfR2 to bind Tf are necessary for the protein to properly modulate hepcidin expression. Interestingly, the ability of TfR2 to internalize appears to be independent of its ability to upregulate hepcidin levels, implying that TfR2 is able to signal while still at the cell surface.

Influence of Genipin on the Activity and Presence of Amylin in Sh-sy5y and Rin-5f Cells.

T. Clemons; Spelman College, Atlanta, GA.

Amylin is a fibrillogenic protein co-secreted with insulin from pancreatic beta cells. Amylin has been shown to function in metabolism through its influence on glucose homeostasis, which includes sending satiety signals to the brain, inhibiting glucagon secretion and delaying gastric emptying. In addition to amylin's direct role on metabolism it has also been proposed to have an impact on amyloid beta, a major component of the amyloid plaques found in Alzheimer's disease. Alzheimer's disease brains have been shown to have amyloid plaque formation anddecreased expression of Uncoupling Protein 2 (UCP2), which is a protein that also has a role in metabolism. Traditionally, uncoupling proteins have been known to function as mitochondrial transporter proteins that create proton leaks across the inner mitochondrial membrane resulting in the dissipation of energy in the form of heat. Knowing that UCP2 is expressed in pancreatic beta cells and has been shown to have diminished levels in Alzheimer's disease brains the focus of this study was to examine the influence of UCP2 on the presence and expression of amylin in both RIN-5F cells (a pancreatic beta cell line) and SH-SY5Y cells (a neuroblastoma cell line). Immunocytochemistry experiments and ELISA assays were conducted with and without Genipin, an inhibitor of UCP2, to examine both the presence of amylin and the activity level of amylin, respectively. Initial studies indicate that pharmacologically inhibiting UCP2 impacts amylin activity level and possibly influences the presence of amylin.

Polyunsaturated Fatty Acids Inhibit the Formation of Myotubes by Activating the Free Fatty Acids Receptors 1 and 4 in C_2C_{12} Cells.

C. Puebla[1], G. B. Arías[1], F. Villavicencio[2], B. C. Avendaño[2], L. A. Cea[2]; [1]Instituto de Ciencias de la Salud, Universidad De O`Higgins, Rancagua, CHILE, [2]Instituto de Ciencias Biomédicas, Universidad Autónoma de Chile, Santiago, CHILE.

Introduction: Polyunsaturated fatty acids (PUFAs), both omega-3 and omega-6, are commonly consumed by the world population. Normally, the intake of omega-3 has positive effects on the cardiovascular system and on the contrary, the high intake of omega-6 would have harmful effects on health. PUFAs activate free fatty acid receptors 1 (FFAR1) and FFAR4, but their effect on muscle tissue has not been described. **Objective**: to demonstrate that the presence of PUFAs (omega-3 and omega-6) induce the activation of FFAR1 and/or FFAR4, which inhibit the formation of myotubes in C2C12 cells.

Methods: C2C12 cell line was used. These cells were differentiated (10 days) in DMEM medium supplemented with 5% horse serum, in the absence or presence of alpha-linolenic acid (ALA, omega-6) or linoleic acid (LA, omega-3), and agonist or antagonist of FFARs (GW9508 and GW1100, respectively). Myogenesis markers (e.g., MyHC and MyoG) were analyzed by Western blot (WB), immunofluorescence (IF) or PCR. Also, a protein kinase associated with FFARs, as AKT, was analyzed (total and phosphorylated) by WB. **Results**: the formation of myotubes (differentiation process) was verified by the expression of MyHC and MyoG. Myotube number decreased in presence (1 to 10 days) of ALA (100 µM), LA (100 µM) or the FFAR agonist: GW9508 (50 µM). Also, the presence of ALA or LA reduce the expression of phosphorylated AKT but this reduction is not present with GW1100 (FFAR1 antagonist). Also, the presence (1 to 10 days) of LA or ALA increase the expression of FFAR4 in C2C12 cells, and this increase was blocked in presence of GW1100 (10 µM). **Conclusion**: These results provide an active role for polyunsaturated fatty acids and their receptors (FFAR1 and FFAR4) in the muscle cells differentiation. **Acknowledgment**: This work was supported by FONDECYT: 11160536 (CP), 11160739 (LC).

Ca^{2+}Spikes Induced by Changes in Membrane Tension in ER Membranes Instructs the Polarized Trafficking of Cargoes in Astrocytic Processes.

Y. Niu, 20892[1], J. Lippincott-Schwartz[2]; [1]Visiting fellow, NIH, BETHESDA, MD, [2]Janelia research campus, 19700 Helix Drive, Ashburn, VA.

Calcium signaling with high spatial and temporal resolution in cells is known to regulate many biological processes. Nonetheless, the mechanism and functional significance of spontaneous calcium spikes found primarily in astrocytic processes is not fully understood. By developing an endoplasmic reticulum (ER)-anchored membrane tension sensor based on TSMods, we found that calcium spikes detected by GCaMP6f in astrocytic processes usually occur in regions of higher ER membrane tension. We next manipulated ER membrane tension in astrocytes by indirectly changing the lipid composition of ER membranes by an Auxin-inducible phospholipase system or by directly exerting additional force to the ER by photo-inducible, transient recruitment of kinesin. We found that calcium spikes detected by GCaMP6f increased when ER membrane tension increased, and vice versa. Co-expression of GCaMP6f with different vesicle markers/cargoes further revealed that increased local calcium spikes induced by increased ER membrane tension promoted anterograde transport of vesicles/cargoes into distal processes of astrocytes. Based on these results, we propose that increased membrane tension in theER facilitates Ca^{2+} release, which, in turn, triggers anterograde transport of vesicles into distal processes of astrocytes.

Unraveling Mtorc1 Activity Dynamics and Its Biological Roles in Cell Cycle Progression.

N. Komatsu; RIKEN Center for Brain Science, Wako, JAPAN.

Mechanistic target of Rapamycin complex 1 (mTORC1) is a kinase that integrates diverse range of extra/intracellular inputs such as growth factors, nutrients and intracellular ATP level. It controls various downstream cellular functions such as translation, metabolism and autophagy that ultimately drive cell growth. Aberrant activation of the kinase leads serious outcomes such as cancer and diabetes. The

mechanisms how mTORC1 activates has been energetically studied. Despite this, the dynamics when mTORC1 is activated in living cells is barely understood. Due to this lack of temporal information of mTORC1 activation, it is almost unknown that how mTORC1 controls its downstream functions in a coordinated manner (or sometimes selective manner) by utilizing dynamics of its own activity. To understand the entity of mTORC1 activity dynamics and dynamic encoding of information for cellular functions with it, I aimed to visualize mTORC1 activity in living cells. For this, I stably expressed Eevee-S6K, a previously developed intramolecular FRET probe which monitors the activity of S6 kinase direct downstream of mTORC1 into several cancer cells treated with MEK inhibitor, an inhibitor of Ras-ERK MAPK pathway. mTORC1(S6K) activity in probe-expressing cells were visualized by time-lapse FRET imaging. I found that mTORC1 activity in cells sensitive to MEK inhibitor (i.e. showing growth suppression by the inhibitor) monotonously deceased by MEK inhibitor treatment. On the other hand, cells resistant to MEK inhibitor (i.e. showing prolonged cell growth under the inhibitor treatment) showed fluctuations of mTORC1 activity at single cell level. Interestingly, both sensitive cells and resistant cells showed fluctuations of the activity but they seemed to be different from the temporal activity patterns of MEK inhibitor-treated resistant cells in terms of amplitude and frequency. These results indicate the possibility that information for cell growth is encoded in dynamics of mTORC1 activity. In this presentation, I would like to talk about the mTORC1 activity dynamics in MEK inhibitor-sensitive and resistant cancer cells. Recently, to address the dynamic encoding of cell proliferation with mTORC1 activity, I have been trying to visualize mTORC1 activity and cell cycle progression simultaneously by live cell imaging utilizing Eevee-S6K and Fucci(CA), a variant of Fucci fluorescent cell cycle indicator. I will also discuss the progress of the dual monitoring.

P2304/B556

Functional Characterization of the TSC-DYRK1A Interaction.

S. Joshi, V. Menon, L. Litovchick; Virginia Commonwealth University, Richmond, VA.

Functional characterization of the TSC-DYRK1A Interaction the Tuberous sclerosis complex (TSC) includes TSC1, TSC2 and the TBC1D7 subunits that together function as a principal inhibitor of the mTOR protein kinase complex 1 (mTORC1). mTORC1 is a master regulator of cell growth and proliferation that responds to signaling cues such as growth factors and nutrient availability. Proteomic studies in our lab revealed an interaction between the TSC subunits and DYRK1A, a ubiquitous protein kinase encoded by a gene located in the Down syndrome (DS) region on human chr21. In this study, we sought to validate the interaction of the TSC complex with DYRK1A and to determine its functional significance. Our analysis confirmed that DYRK1A interacts with TSC1 at the endogenous levels, and with TSC2 when overexpressed. Domain mapping of the DYRK1A-TSC interaction revealed that binding of TSC2 to DYRK1A requires TSC1. However, binding of TSC1 to DYRK1A does not require TSC2 as evidenced by the DYRK1A-TSC1 interaction observed in TSC2-null cells. Given that TSC is a major inhibitor of the mTORC1 pathway, we sought to assess the effect of DYRK1A loss on the mTORC1 activity. Interestingly, we did not observe any change in phosphorylation of mTORC1 substrates p70S6K and 4EBP1 under serum-starved conditions in the DYRK1A siRNA treated cells or in the CRISPR-Cas9 DYRK1A knockout (KO) cells. However, using FACS analysis, we noticed that human and mouse cells lacking DYRK1A appeared smaller in size compared to controls. We also observed that global protein synthesis rate was significantly reduced in DYRK1A KO cell lines using the puromycin-tagging assay. Interestingly, the decrease in global protein production was independent of the presence of TSC1. Therefore, it is possible that interaction of DYRK1A with the TSC complex could have an effect on the function of DYRK1A Kinase itself. Indeed, our

preliminary studies show that DYRK1A kinase activity towards its substrate Lin52 was decreased in the TSC1-null MEFs. Current studies are focused on confirming this effect using TSC1 knockdown human cell lines as well as the TSC1 rescue experiments in MEFs. Overall, our study introduces DYRK1A as a novel partner of the TSC complex that could mediate its non-canonical functions including mTORC1-independent regulation of cell proliferation and protein synthesis.

P2305/B557

Regulation of Phosphoinositide Turnover during Insulin Signaling.

S. Sharma[1], S. Mathre[1,2], V. Ramya[1], D. Shinde[1], A. Ghosh[1], P. Raghu[1]; [1]National Centre for Biological Sciences, Tata Institute of Fundamental Research, Bangalore, INDIA, [2]Manipal Academy of Higher Education, Manipal, Karnataka, INDIA.

Insulin signaling is an evolutionarily conserved inter-cellular communication pathway in metazoans. The core components that transduce insulin signal into changes in the activity of downstream effectors have been extensively studied. While most effectors studied in this pathway are proteins, other types of biomolecules including phosphoinositides also play an important role. Phosphoinositides are phospholipids that have a critical role in orchestrating many cellular signaling cascades in spite of their very low abundance on cellular membranes. During insulin signaling, a key event is the generation and robust control of small amounts of the lipid phosphatidylinositol 3,4,5-trisphosphate (PIP_3) by Class I phosphoinositide 3-kinase (PI3K) at the plasma membrane. Dysregulation in PIP_3 levels disrupt normal growth and metabolism. Mechanistic insights into regulation of the levels and the subcellular localization of these phosphoinositide lipids are useful in understanding ways by which the insulin signaling cascade maintains its signaling fidelity while allowing for feedback regulation and signaling crosstalk. We report that in *Drosophila*, interaction between the lipid kinases - Class I PI3K and phosphatidylinositol 5 phosphate 4-kinase (PIP4K), is required to maintain normal PIP_3 levels during insulin receptor activation. Depletion of PIP4K increases the levels of PIP_3 produced in response to insulin stimulation due to enhanced Class I PI3K activity. While PIP4K localizes on multiple intracellular membranes, its plasma membrane localization was sufficient to regulate PIP_3 levels. Interestingly, the catalytic ability of PIP4K was dispensable for this regulation, highlighting a need to explore both kinase-dependent and independent functions of such enzymes. Additionally, increased cellular insulin sensitivity seen upon loss of PIP4K partially suppresses insulin resistance phenotypes in *Drosophila* larvae. PIP4Ks could thus be key regulators of receptor tyrosine kinase signals affecting processes like tumour growth in cancers, T-cell activation and metabolism in Type II diabetes. Ongoing work suggests that the interaction between these kinases is a multi-step process and entails a need to also investigate the turnover of other related phosphoinositide lipids and the activity of associated effectors during insulin stimulation.

P2306/B558

Addition of Monomer Hapten and Hapten-specific IgG Inhibits Mast Cell Activation with Different Mechanisms.

R. Suzuki[1], Y. Inoh[2], S. Yokawa[2], R. Suzuki[3], T. Furuno[2], N. Hirashima[1]; [1]Graduate School of Pharmaceutical Sciences, Nagoya City University, Nagoya, JAPAN, [2]School of Pharmacy, Aichi Gakuin University, Nagoya, JAPAN, [3]Faculty of Pharmaceutical Sciences, Institute of Medical, Pharmaceutical and Health Sciences, Kanazawa University, Kanazawa, JAPAN.

Aggregation of IgE bound to high affinity IgE receptor (FcεRI) by multivalent antigen induces mast cell activation. Reportedly, disaggregation of aggregated FcεRI immediately terminated degranulation, and formation of co-ligated FcεRI and low affinity IgG receptor FcγRIIB blocked degranulation by inhibitory signal via SH2-containing inositol 5'-phosphatase 1 (SHIP1) phosphorylation. However, their molecular mechanisms to inhibit mast cell activation have been unclear in detail. Herein, using rat basophilic leukemia (RBL-2H3) and mouse bone marrow-derived mast cells (BMMCs), we investigated the inhibitory effects of monovalent hapten and hapten-specific IgG in FcεRI-mediated mast cell activation. Addition of multivalent hapten (TNP-OVA) induced sustained increase in intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$), which peaked at approximately 50 s after stimulation. When monovalent hapten (TNP-alanine) or hapten-specific IgG monoclonal antibody (anti-TNP IgG1) was added 50 s after TNP-OVA stimulation, $[Ca^{2+}]_i$ rapidly or gradually decreased, respectively. Further, addition of TNP-alanine after TNP-OVA stimulation completely discontinued β-hexosaminidase release, while the addition of anti-TNP IgG1 induced partial suppression of β-hexosaminidase release. Next, we investigated how the subsequent addition of TNP-alanine and anti-TNP IgG1 to mast cells activated with TNP-OVA affects the phosphorylated states of Syk and SHIP1. Interestingly, TNP-alanine addition after TNP-OVA stimulation immediately dephosphorylated the phosphorylated Syk. This dephosphorylation was transient and phosphorylation levels recovered at 5 min. The anti-TNP IgG1 addition did not induce Syk dephosphorylation and showed a similar pattern as TNP-OVA stimulation, but it induced SHIP1 phosphorylation that was not caused by TNP-alanine addition. Moreover, TNP-alanine or anti-TNP IgG1 addition after TNP-OVA stimulation inhibited TNF-α and IL-4 production through suppression of phosphorylation levels of Akt and ERK. These results suggested that the FcεRI dissociation and the co-ligation of FcεRI with FcγRIIB greatly blocked major cellular output in early phase such as degranulation and in late phase such as cytokine production, respectively.

P2307/B559

The Effect of Neuronal Growth Factors on Merlin Expression in Immortalized Schwann Cells.

A. Bohn, K. Kenney, A. L. Asirvatham, 18612; Misericordia University, Dallas, PA.

Regulation of Schwann cell growth in vitro is facilitated by heregulin, a neuron-secreted growth factor, and mitogens that activate the cyclic AMP pathway. Although the role of heregulin and forskolin has been characterized in Schwann cells, the impacts they have on the proteins merlin and ezrin have yet to be explored. Merlin, also known as "Moesin-Ezrin-Radixin-like protein" is commonly known as a Schwann cell tumor suppressor and as an A-kinase-anchoring protein (AKAP). It was hypothesized that the expression of merlin and ezrin proteins will not be altered in Schwann cells stimulated with mitogens. To determine the expression of merlin and ezrin, immortalized Schwann cell line CRL-2941 cultures were treated with control media (N2), heregulin (12.5 ng/ml), forskolin (1μM), and heregulin plus forskolin for 24 hours. Using western blotting, it was found that the expression of merlin

significantly increased with the treatment of 1μM forskolin (223.5 ± 22.14%) in comparison to heregulin treatment (147.16 ± 13.96%) but not with heregulin plus forskolin (179.35 ± 32.23%). Conversely, the expression of ezrin was highest when cells were stimulated with heregulin plus forskolin (130 ± 19.545%) in contrast to heregulin (94.97 ± 22.89%) or the forskolin treatment (97.57 ± 15.03%). To clarify the role of cAMP in the expression of ezrin, Schwann cells were treated with various concentrations of the phosphodiesterase inhibitor rolipram. Cells incubated with heregulin plus 10μM rolipram had the highest ezrin expression. Furthermore, protein levels of merlin were analyzed in Schwann cells treated with various concentrations of forskolin, at 0.5 μM, 1 μM 2 μM and 3 μM or forskolin plus heregulin for 12 and 24 hours. Although merlin exhibited a dose-dependent increase in expression with forskolin stimulation, the addition of heregulin resulted in a decrease in protein levels. Overall, cells from the 24-hour dose response exhibited higher merlin expression in comparison to the 12-hour treatment. To examine if the location of merlin is altered by the addition of heregulin and/or forskolin, immunofluorescence experiments were conducted. It was found that in cells treated with heregulin, merlin exhibited a cytoplasmic staining pattern, whereas treatment with forskolin or heregulin plus forskolin, revealed a nuclear location. This may have occurred because the addition of heregulin may have influenced the cells to proliferate, in which case merlin as a tumor suppressor is inhibited. In summary, these findings suggest that merlin is upregulated when the cAMP pathway is stimulated and downregulated when heregulin stimulates Schwann cell growth.

P2308/B560

Auto-dephosphorylation of Myosin Phosphatase Regulates Vascular Endothelial Barrier Funsction.

T. Kaneko-Kawano[1], M. Amano[2], K. Kaibuchi[2], K. Suzuki[1]; [1]Ritsumeikan University, Kusatsu, JAPAN, [2]Nagoya University, Nagoya, JAPAN.

Vascular endothelial cells form a selective barrier that controls the permeability of the vascular endothelium, which is critical for maintaining homeostasis. However, the mechanisms underlying the maintenance of endothelial barrier function are poorly understood. In this study, we report that a novel signaling pathway, auto-dephosphorylation of myosin phosphatase, maintains endothelial barrier function. Actomyosin contraction, which is regulated by phosphorylation of myosin light chain (MLC), increases vascular endothelial permeability. MLC phosphorylation is regulated by the balance between the enzymatic activities of myosin phosphatase and serine/threonine kinases (e.g., Rho-kinase). Myosin phosphatase, which suppresses actomyosin contractility via dephosphorylation of MLC, consists of three subunits: a myosin phosphatase targeting subunit (MYPT1), serine/threonine phosphatase catalytic subunit (PP1c), and a small 20-kDa subunit (M20). Myosin phosphatase activity is suppressed by phosphorylation of the MYPT1 subunit. Our previous in *silico* analysis predicted that myosin phosphatase dephosphorylates MYPT1, which enhances its phosphatase activity, and this auto-dephosphorylation pathway suppresses actomyosin contraction by phosphorylating MLC. Here, we provide experimental evidence supporting the predictions of our in *silico* analysis. We demonstrated that myosin phosphatase dephosphorylates MYPT1 and that its activity is promoted by this auto-dephosphorylation pathway in an in *vitro* phosphatase assay and inhibition of myosin phosphatase activity in cells. To examine the physiological function of myosin phosphatase auto-dephosphorylation, we generated a mutant that can inhibit this auto-dephosphorylation pathway. Overexpression of the mutant attenuated endothelial cell adhesion and increased permeability in human umbilical vein endothelial cells (HUVECs). Therefore, auto-dephosphorylation of myosin phosphatase regulates

endothelial adhesion and endothelial permeability. These results suggest that the auto-dephosphorylation of myosin phosphatase is essential for maintaining endothelial barrier function.

Nf-κB Pathway Modulates Autophagy in Metabolic Activated Macrophages.

Z. Cabail, J. Lin; SUNY-Old Westbury, Old Westbury, NY.

Obesity is associated with the incidence of multiple co-morbidities, including metabolic syndrome and insulin resistance, the latter contributing to the development of type 2 diabetes (T2D). Underlying the development of insulin resistance by obesity is a *chronic low-grade systemic inflammation*. This meta-inflammation results from the infiltration of immune cells into the adipose tissue (AT), driving a pro-inflammatory environment. However, the molecular mechanisms responsible for the initiation and maintenance of the inflammatory response in AT are poorly understood. Therefore, the goal of this study is to investigate the intracellular players that initiate and maintain chronic meta-inflammation. We hypothesized that activation of the pro-inflammatory pathway *Nuclear Factor-kappa-light-chain-enhancer of activated B cells B (**NF-κB**)* by free-fatty acids in obesity will result in inhibition of AT macrophage ***autophagy***, a normal physiological process that maintains homeostasis, preventing the autophagic capacity of regulating inflammation, which in turn will promote the polarization of non-inflammatory macrophages to a M1 pro-inflammatory state. We propose that the "missing link" between these two pathways is the *mammalian target of rapamycin* (**mTOR**), which has been proposed as a negative regulator of autophagy, and in certain tumors, its activation is Inhibitor of Kappa B kinase beta (IKK)-dependent. We tested this hypothesis using a murine macrophage cell line, RAW264.7, and exposed these cells to a lipid-rich microenvironment to mimic the cellular metabolic inflammation observed in obese AT. Immunoblotting showed that treatment of macrophages with saturated fatty acids such as palmitic, myristic, and stearic acid, resulted in the upregulation of the functional marker of M1 pro-inflammatory phenotype IL-1β. This polarization was mediated by NF-κB and mTOR pathway as shown by the increase levels of phospho-NF-κB p65 and phospho-mTOR compared to untreated cells. This was accompanied by a decrease of autophagy markers Light Chain 3 II (LC3II) and Beclin. We also found that the interplay between NF-κB and Autophagy pathways is TSC1/mTOR-mediated as shown by the rescue of autophagy after NF-κB activation was blocked using BOT-64, an IKKβ inhibitor, and this was accompanied by the recovery of TSC1 activity and the decrease of phospho-mTOR in the presence of BOT-64.

P2310/B562

Compulsive Oxycodone Self-administration Potentiates Cell Signaling in the Rat Striatum Via the Mitogen-activated Protein Kinase (MAPK) Signaling Cascade.

M. T. McCoy, 21224, C. A. Blackwood, B. Ladenheim, J. Cadet; Molecular Neuropsychiatry Branch, NIDA, Baltimore, MD.

Objectives: Oxycodone is a prescribed synthetic opioid drug whose abuse has reached epidemic proportion in the USA because of over-prescription of the drug for pain related to cancer and other medical problems. Although oxycodone has been prescribed for a long time, much remains to be done to understand the basic neurobiological effects that render the drug so addictive to humans. We reasoned that oxycodone-induced adaptations in signaling pathways might be one of the mechanisms involved in its addictive properties. In the present study, we thus sought to identify changes in the

phosphorylation states of striatal proteins involved in the MAPK pathway of rats during early withdrawal from escalated and non-escalated oxycodone self-administration. **Methods:** Male Sprague-Dawley rats were trained to self-administer oxycodone or saline by pressing a lever to receive 0.1 mg/kg/injection via an intravenous catheter for 3-hours during the first week of self-administration training. At the end of the first week, the oxycodone animals were split into 2 groups: (1) short access (ShA) rats that continue to self-administer drug for 3 hours throughout the study (4 weeks); (2) long access takers (LgA) rats that self-administer drug for 6-9 hours for the last 3 weeks of the study. At the end of the study, rats were euthanized 2h after the last self-administration session. We then isolated striatal proteins to measure the expression and phosphorylation states of proteins involved in the (MAPK) signaling cascade including PKC, ERK1 and 2, MSK1 and 2, and CREB. **Results:** Rats given long access, but not short access, to oxycodone escalated their intake of oxycodone to different levels, with some rats (LgA-H) taking very large amounts of oxycodone and others (LgA-L) taking much less drug. Biochemical analyses revealed increased abundance of several phosphoproteins of the MAPK signaling cascade in only the LgA-H animals. There was increased PKC phosphorylation in the LgA-H Group. Increased MSK1 phosphorylation was observed in both LgA-L and LgA-H groups whereas only the LgA-H group showed increased MSK2 phosphorylation. Activation of the cascade also led to increased phosphorylation of CREB that is a target for the MSK proteins. **Conclusion:** These observations suggest that escalation of oxycodone intake that may lead to addiction in humans activates the MAPK signaling cascade in the rat brain. Identification of genes and proteins that are targets of this cascade should help to develop better therapeutic agents to combat oxycodone use disorder. Harnessing Single-cell an alysis to Discover Kinase Network Vulnerabilities in Colon Cancer.

E. Alizadeh, C. A. Thorne; University of Arizona, Tucson, AZ.

Colon cancer is the second deadliest cancer affecting both men and women. Despite its pervasiveness and active research, new therapies developed over the past two decades have failed to be effective. One reason for this failure is due to tumor cell heterogeneity. Tracking single cell responses to drug treatment is critical for identifying the next generation of therapies that are effective against colorectal cancer. We study cancer at the single cell and sub-cellular level using automated microscope and software customized in our lab. We focus on characterizing novel protein kinases that colon cancer cells use to grow and resist therapeutic intervention. Kinases transmit cellular signals that play a key role in various cellular processes such as cell division, metabolism, survival, and more. Their dysregulation has been found in all forms of cancer including those arising from the colon, brain, lung, breast, prostate, and other organs. Therefore, kinases are regarded as important effectors in human pathology and represent strong candidates for therapeutic targeting. Understanding the characteristics of protein kinases can pave the way for effective cancer diagnosis and treatment. Here, we 1) characterize the function of under-studied protein kinases, 2) determine the heterogeneity of the cells by loss of kinase function. We combine cancer biology, automated microscopy, high-throughput image processing, and computational methods to quantify hundreds of cell-level “features” such as size, shape and use this information for mapping the cellular response to drugs treatments. In order to study the large sets of protein kinase networks, we use RNAi assay to knock down one kinase at a time in normal colon cells, with total of 489 kinases. Images of cells are captured using high throughput microcopy. Then, we process and segment the images of cells using Cell Profiler software. Next, we quantify their shape and texture using TISMorph software[1] to capture > 500 different cellular “features” quantifying the

response of cells to the loss-of-function of individual protein kinases. The experiment is done in triplicates and we show that the data is reproducible. Using hierarchical clustering we group the kinases based on their similarity in their "features". Then we map kinases with unknown functions to pathways populated with well-characterized kinases based on their similarity in their features. Thus, identifying new kinase function. In addition, the kinases which their loss of function lead to heterogeneous morphometric response of the cells are identified. **References** [1] E. Alizadeh, W. Xu, J. Castle, J. Foss, and A. Prasad, "TISMorph: a tool to quantify texture, irregularity and spreading of single cells," *PLoS One*, vol. 14, no. 6, p. e0217346, Jun. 2019.

Phosphatidylinositol 4-kinase Ii β Down Regulation Modulates Redox Signalling and Increases Radio-sensitivity in Mcf-7 Cells.

S. Chaudhry[1], M. Thoh[2], R. Checker[2], S. Sandur[2], **S. Gosukonda**[1]; [1]IndianInstitute of Technology Bombay, Mumbai, INDIA, [2]Bhabha Atomic Research Centre, Mumbai, INDIA.

Canonically type II phosphatidylinositol 4-kinases (PtdIns 4-kinase II) were involved in growth factor receptor signalling and vesicular trafficking. Recently these enzymes were shown to modulate apoptosis, cell adhesion, motility, and inflammatory responses in different cell types. Some of these effects were closely linked to redox homeostasis and ER stress. Involvement of PtdIns 4-kinase II β in these signalling pathways were investigated in human breast cancer cell line (MCF-7 cells) with the help of shRNA. Knockdown of PtdIns 4-kinase II β was correlated with increased ROS levels and decreased GSH GSSG ratio. Diphenyleneiodinium reduced ROS production suggesting a role for NADPH Oxidase. Concomitantly, these transfectants showed inhibition of NF-kappa B p65 translocation to nucleus and double-stranded DNA damage. In addition, these cells showed an increase in ER stress protein markers PERK, IRE-1α, BiP and PDI. Quantitative real time polymerase chain reaction experiments showed up regulation of GADD153 and down regulation of Bcl-2 and AKT3 mRNAs. At cellular level, these cells showed ER deformity. ROS scavengers, Caspase 9 and 12 inhibitors, ER-chemical chaperone rescued MCF-7 cells from PtdIns 4-kinase II β shRNA induced apoptosis. Gamma-irradiation of MCF-7 cells showed up regulation of PtdIns 4-kinase II β mRNA levels and PtdIns 4-kinase II β shRNA increased the radio-sensitivity. These results have potential implication in radiation therapy for cancer management.

P2313/B565

The Role of Selected Cell Signaling Pathways in Dibutyltin- Induced Synthesis of Interleukin-1 Beta.

J. Maise, S. Gabure, M. Whalen; Tennessee State University, Nashville, TN.

Dibutyltin (DBT) is an environmental contaminant primarily used to stabilize PVC plastic (polyvinyl chloride). It has also been used to deworm poultry. As a result of PVC plastics being used in pipelines and storage containers, DBT has been in drinking water, beverages, and seafood. The serum levels of DBT have been found in individuals as high as 0.3µM. Preliminary studies have shown that DBT induces increases of interleukin- 1 beta (IL-1β) production (intracellular + secretion) at lower concentrations and at higher concentrations it has shown decreases of IL-1β production in monocyte depleted peripheral blood mononuclear cells (MD- PBMC). IL-1β is a pro inflammatory cytokine that enables the human body to heal tissue if the body is injured or infected. Inappropriately elevated levels of IL-1β can cause chronic inflammation which is linked to cancer, autoimmune diseases, and diabetes. This study examines the role of certain cell signaling pathways that control immune cell production of IL-1β for

their role in DBT-induced increases in IL-1β production. The pathways that are examined are the mitogen activated protein kinases (MAPK) ERK 1/2 and p38 pathways. MD- PBMCs were exposed to the pathway inhibitors 1 hour prior to being treated with DBT at the various concentrations (0.25, 0.10, and 0.05). ERK 1/2 pathway was inhibited with the MEK inhibitor PD98059, and the p38 pathway was inhibited with the MEK inhibitor SB202190. The results of this study indicated that DBT utilized both the p38 pathway and ERK 1/2 pathway (cells from 5 separate donors) to stimulate increased IL-1β production. However, DBT appeared to rely more heavily on the p38 cell signaling pathway than the ERK 1/2 pathway to stimulate IL-1β produciton.

P2314/B566

Examining the Roles of Erk1/2 and P38 MAPK Pathways in the Dibutyltin-induced Increased Production of Interleukin-6 in Human Immune Cells.

S. Gabure, J. Maise, M. Whalen, L. Sushak; Tennessee State University, Nashville, TN.

Dibutyltin (DBT) is a compound that is used to prevent parasitic diseases in certain poultry, and it is also used in the manufacturing of plastics. DBT has been found in drinking water and seafood due to leaching from polyvinyl chloride plastics used in water pipelines and storage containers. Exposure to DBT results from the ingestion of these contaminated foods and beverages and consequentially has been found in humantissues with concentrations as high as 0.3 μM. Previous studies indicate that in human immune cells, DBT can increase and decrease the secretion of the pro-inflammatory cytokines; tumor necrosis factor alpha (TNFα), interferon gamma (IFNγ), interleukin 1 beta (IL-1β), and Interleukin-6 (IL-6). Overproduction or abnormal levels of IL-6, can lead to chronic inflammation and inflammatory diseases such as Rheumatoid Arthritis, Lupus Erythematosus, and Crohn's Disease. To determine whether DBT is affecting the immune cell's ability to produce IL-6 or solely the secretion of this protein, in a previous study, the cellular production (both intracellular and secreted levels of IL-6) were investigated by using Enzyme Linked Immunosorbent Assays to measure secretion of IL-6 and Western Blots to measure intracellular levels of IL-6. The results indicate that when monocyte-depleted peripheral blood mononuclear cells (MD-PBMCs) were treated with DBT for a period of 24 hours with concentration ranging from 5-0.05 μM of DBT, there was an increased production of IL-6 in the lower concentrations (0.25-0.05 μM) in the cells from all donors. The ERK1/2 and p38 MAPK pathways regulate the production of IL-6, therefore the objective of this study was to examine their role in DBT-induced increases in IL-6 production by using the MEK inhibitor PD98059 to block the ERK 1/2 pathway and the SB202190 inhibitor to block p38 MAPK activity. When the MD-PBMCs were exposed to the inhibitors one hour prior to the 0.25-0.05 μM of DBT treatment, the results show that DBT-induced increases in IL-6 were dependent on both the p38 and ERK 1/2 MAPK pathways. DBT stimulates pathways that should normally be activated in response to infection or injury leading to inappropriate elevation of the potent inflammatory stimulus IL-6. Supported by NIH grant 2U54CA163066.

Activation of Nrf2/HO-1 by a Novel Peptide Yd1 Attenuates Inflammatory Symptoms through Suppression of TLR4/MYyD88/NF-kB Signaling Cascade.

H. Na[1], M. Alam[1,2], H. An n[1], J. Park[1], N. Hong[1], S. Lee[1,2,3]; [1]Kyungpook National University, Daegu, KOREA, REPUBLIC OF, [2]Food and Bio-Industry Research Institute, Kyungpook National University, Daegu, KOREA, REPUBLIC OF, [3]knu BnC, Daegu, KOREA, REPUBLIC OF.

We found that a multifunctional peptide YD1, purified from the strain *Bacillus amyloliquefaciens* from kimchi, possessed potent anti-inflammatory activity. The modulatory effect of YD1 on the toll-like receptor 4 (TLR-4) / Myeloid differentiation primary response 88 (MyD88) / nuclear factor kappa B (NF-κB) and Nuclear factor (erythroid-derived 2)-like 2 (Nrf2) pathway, was investigated in lipopolysaccharide (LPS) stimulated RAW264.7 cells and carrageenan (CA)-induced mice model. YD1 suppressed the magnitude of nitric oxide (NO) and prostaglandin E2 (PGE_2) by down-regulating inducible nitric oxide synthase (iNOS) and cyclooxygenease-2 (COX-2). YD1 also down-regulated the mRNA levels of macrophage biomarkers (e.g., IL-1β, IL-6, and TNF-α,) and inhibited nuclear translocation of NF-κB in the RAW264.7 cells as well as in CA-induced inflammatory mice. Our results concluded that YD1 might control macrophage polarization through modulating the cross-talk between the following three mechanisms: 1) attenuating LPS-induced nuclear translocation of NF-κB; 2) activation of Nrf2 and consequently inducing HO-1 expression. 3) HO-1 selective inhibitor SnPP diminished the inhibitory effects of YD1 on the activation of the NF-κB pathway and the pro-inflammatory cytokines. Collectively, YD1 exhibited anti-inflammatory activity via suppressing pro-inflammatory macrophage polarization. Therefore, our findings provide new evidence for the potential of YD1 in the treatment of chronic inflammation related diseases and oxidative stress.

Inhibition of Melanogenesis by *Syzygium Cumini*Seed Extract Via Regulation of MAPKs/MITF Signaling Pathway.

H. An n[1], M. Alam[1,2], J. Park[1], H. Na[1], N. Hong[1], S. Lee[1,2,3]; [1]Kyungpook National University, Daegu, KOREA, REPUBLIC OF, [2]Food and Bio-Industry Research Institute, Inner Beauty/Anti-Ageing Center, Kyungpook National University, Daegu, KOREA, REPUBLIC OF, [3]knu BnC, Daegu, KOREA, REPUBLIC OF.

Melanin, the primary factor of skin color, is chiefly produced in response to ultraviolet (UV) irradiation and make defense against the detrimental effects of UV into skin, but its overproduction causes hyperpigmentation disorders such as freckle, hyperpigmentation, and melasma. In the current study, several whitening materials have cytotoxicity to the skin, therefore the development of natural ingredients without reverse effects is necessary. Hence, the aim of this study was to investigate the efficacy of the ethanolic extracts of *Syzygium cumini* seeds (CSEE) against melanogenesis and sought to its underlying mechanisms in Melan-a cells. CSEE significantly inhibited the mushroom tyrosinase activities in a dose-dependent manner. CSEE treatment also meaningfully suppressed the melanin content as well as the cellular tyrosinase activity in Melan-a cells. Furthermore, CSEE treatment strongly abolished the expression of microphthalmia-associated transcription factor (MITF) and its downregulated protein such as tyrosinase (TYR) and tyrosinase-related protein-1 (TYRP-1). CSEE treatment caused the activation of MAP kinase phosphorylation (ERK1/2 and p38), leading to down-regulation of tyrosinase and MITF, resulting in the attenuation of melanin production in Melan-a cells. An d then, treatment of U0126 (ERK1/2 inhibitor) and SB202190 (p38 inhibitor) restored the expression

of protein that was decreased treated with CSEE. In addition, through HPLC analysis and single compound tyrosinase inhibitory assay analysis, we knew quercetin, chlorogenic acid, coumaric acid, and caffeic acid were contributed to inhibitory activity of CSEE. Collectively, these results suggested that CSEE could be a potential natural source for the development of new anti-melanogenic agents.

Protective Effects of a Chinese Black Tea Aqueous Extract on UVB-irradiated Photoaging Via MAPKs/Nrf2-mediated Down-regulation of MMP-1 in Keratinocyte Cells.

N. Hong[1], M. Alam[1,2], P. Zhao[3], H. Na[1], H. An n[1], J. Park[1], S. Lee[1,2,4]; [1]Kyungpook National University, Daegu, KOREA, REPUBLIC OF, [2]Food and Bio-Industry Research Institute, Inner Beauty/Anti-Ageing Center, Daegu, KOREA, REPUBLIC OF, [3]Proya, Hangzhou, CHINA, [4]knu BnC, Daegu, KOREA, REPUBLIC OF.

Skin photoaging is mainly caused by ultraviolet B (UVB) irradiation, related with stimulation of collagen degradation and up-regulation of matrix metalloproteinases (MMPs). Fuzhuan-brick tea (FBT) is used as a beverage and as a nutritional supplement by the ethnic groups of Southern/Western China. The aim of this study was to investigate the anti-photoaging effects of Fuzhuan-brick tea aqueous extract (FBTA) in UVB-mediated HaCaT cells. FBTA exhibited potent antioxidant activity and ameliorated oxidative stress by suppressing intracellular reactive oxygen species (ROS) generation without any toxicity. FBTA activated messenger RNA (mRNA) and protein expression levels of antioxidant enzymes and phase II detoxifying enzymes, specifically heme oxygenase-1 (HO-1). FBTA up-regulated the nuclear factor erythroid 2-related factor 2 (Nrf2)-mediated pathway in HaCaT cells through the phosphorylation of p38 and extracellular signal-regulated kinase (ERK). FBTA also down-regulated the expression of MMP-1, whereas up-regulating type I procollagen production via Nrf2 signaling pathway. Overall, these results suggested that FBTA has potential to be a great functional ingredient for the preparation of UVB-stressed skin photoaging, in that the remedy can be applied for the development of cosmetic products and medicines.

P2318/B570

***Spatholobus Suberectus* Stem Extracts: Inhibition of UVB-induced Skin Aging by Modulating MAPK/AP-1 Signaling-mediated Down-regulation of MMPs.**

J. Park[1], M. Alam[1,2], K. Kwon[1], H. An n[1], H. Na[1], N. Hong[1], S. Lee[1,2,3]; [1]Kyungpook National University, Daegu, KOREA, REPUBLIC OF, [2]Food and Bio-Industry Research Institute, Inner Beauty/Anti-Ageing Center, Kyungpook National University, Daegu, KOREA, REPUBLIC OF, [3]KNU BnC, Daegu, KOREA, REPUBLIC OF.

Traditionally, the stem of *Spatholobus suberectus* has been applied to treat inflammation-induced thrombosis. It has also been reported that *Spatholobus suberectus* have the potential to regulate cartilage-related MMPs and TIMPs and anti-inflammatory activity. In this presentation, we demonstrated that aqueous and ethanolic extracts of the stem of *Spatholobus suberectus* (SSW and SSE) inhibited UV-induced skin photo-aging in HaCaT cells. SSW and SSE extracts were identified by HPLC and they have the major active components which were gallic acid, catechin, vanillic acid, syringic acid and epicatechin. SSW and SSE showed that significantly decreased the elastase enzyme activity and quenched UVB-induced generation of cellular reactive oxygen species in the cells. Our results confirmed that SSE could regulate the expression of MMPs, TIMP-1, COL1A1, ELN and HAS2 at their transcriptional and translational level and suppress the UVB-induced phosphorylation of MAP kinases, c-Jun and NF-κB.

Furthermore, we found that a combination of syringic acid, epicatechin and vanillic acid revealed strong synergistic effects on elastase inhibitory activity in which the combination index was CI= 0.28. Collectively, our results indicate that SSE might be useful as a natural ingredient for the remedy of UVB-induced skin aging.

P2319/B571

Effects of Crowding Agents and Osmolytes on Wnk1 and Wnk3 Kinases.

M. Drozdz, R. Akella, J. Humphreys, H. He, E. Goldsmith; Department of Biophysics, the University of Texas Southwestern Medical Center, Dallas, TX.

WNK kinases are major regulators of electro-neutral cotransporters that control blood pressure and cell volume. The regulation of these cotransporters occurs via the phosphorylation by WNKs and their substrate OSR1 (Oxidative Stress Responsive Kinase 1). Mutations in *WNK1 and WNK3* genes were determined to cause Familiar Hyperkalemic Hypertension (also known as pseudohypoaldoseronism II, or Gordon's Syndrome) and breast cancer, respectively. A goal of this study is to explain how osmotic stressors affect WNKs activity. Our previous studies determined that WNK kinases are inhibited by chloride and activated by osmotic stress induced by crowding agents (such as PEG400, Ficoll, hemoglobin) or osmolytes (such as sorbitol, sucrose). Based on DSF (Differential Scanning Fluorimetry), we saw stability differences in WNK kinases caused by these small molecules. We also demonstrated that crowding agents and osmolytes induce auto-phosphorylation of WNKs 1 and 3. These actions were opposed by chloride. Understanding the molecular mechanism of WNK kinases osmotic sensing will be helpful in finding potential drug targets for hypertension, breast cancer and related disorders.

P2320/B572

Do Strad Pseudokinases Specify the Lkb1 Functions? the Ampk Activation Case.

P. Maurin, M. Santoni, J. Borg, **M. Sebbagh**; CRCM - INSERM - U1068, Marseille, FRANCE.

Currently, there is no doubt that the LKB1 kinase, causally linked to the Peutz-Jeghers syndrome, is at the center of an important signalling node affecting numerous cellular processes whose deregulation contributes to diseases such as cancer. Although downstream signalling events of this kinase were extensively studied, signals that regulate LKB1 functions remain almost completely uncharacterized. This question has a fundamental relevance and has to be addressed to improve our understanding of LKB1-associated disorders. Structurally, LKB1 is composed of a serine-threonine kinase domain with poor catalytic activity flanked by a C-terminal CAAX sequence that serves as a prenylation site, and a putative N-terminal nuclear localization sequence (NLS). Full LKB1 kinase activity requires its interaction with STRAD (STE-20 Related ADaptator) proteins (STRADα or STRADβ), which are ubiquitously expressed pseudokinases. Since STRAD pseudokinases reveal the LKB1 kinase activity, they appear to be the first level of LKB1 complex regulation. Hence, we have decided to address whether STRAD pseudokinases specify LKB1 functions. After defined the relative abundance and LKB1 activity related to each STRAD paralogues we assessed involvement of each STRAD in phosphorylation and activation of the best characterized LKB1 substrate: AMPK. Our results establish LKB1/STRADα complex is the most abundant and has a preponderant role in LKB1 stabilization and AMPK activation. Indeed, in several cell types invalidated for each STRAD, individually or concomitantly, derived from Knock out mouse models or cell lines genetically modified by CripRCas9, we demonstrate that LKB1/STRADβ has fewer catalytic activity toward AMPK, in *vitro* and in *vivo,* than the LKB1 complex formed with STRADα. To conclude, our

results, demonstrate that both LKB1 complexes comprised either STRADα or its paralogue STRADβ have specific features such as catalytic activity efficiency towards substrates, role in LKB1 stability and beyond in cell signalling consequences. Although some functions or substrates should be shared by both complexes, STRAD pseudokinases appear to determine specific LKB1 functions.

P2321/B573

Examining the Role of MTORC2 at Mitochondria.

I. Yudushkin; University of Vienna, Vienna, AUSTRIA.

Mammalian mechanistic target of rapamycin (mTOR) kinase coordinates cellular anabolic reactions with the availability of cellular nutrients. In cells, mTOR exists in the context of two structurally and functionally distinct complexes, mTORC1 and mTORC2. While mTORC1 is the subject of intense research, the regulation and cellular functions of mTORC2 are not well understood. We have previously characterized the intracellular localization and regulation of the endogenous mTORC2 by PI3K (Ebner *et al*., JCB 2017). Among other cellular membrane compartments, we and others have reported mTORC2 activity at the mitochondria, although its exact function and targeting to mitochondrial membranes remain enigmatic. Here, we examined mitochondrial respiration in mouse embryonic fibroblasts obtained from the wild type and mSin1-knockout mice (a gift of Dr. Estela Jacinto, Rutgers). We show that mSin1$^{-/-}$ MEFs demonstrate significantly higher basal oxygen consumption rate (OCR) and spare respiratory capacity than the wild type cells, though both WT and mSin1$^{-/-}$ MEFs have similar mitochondrial mass. The observed effects were Akt- and rapamycin-independent, but sensitive to mTOR inhibitor Torin1, suggesting the effects were mTORC2-specific. Further, in addition to the obligate components of mTORC2 - mTOR, mRictor and mLST8 - LC-MS/MS analysis of the mSin1-GFP interaction partners identified a number of mitochondrial membrane transporters, including SLC25A3, SLC25A5 and SLC25A6, involved in the control of oxidative phosphorylation. Inhibition of the ADP/ATP translocase by carboxyatractyloside increased mTORC2 activity at mitochondria in HEK293T cells and attenuated basal respiration in WT MEFs. Our results suggest that mTORC2 controls the efficiency of mitochondrial respiration. We propose that in addition to control of the mitochondrial hexokinase, mTORC2 could modulate the efficiency of oxidative phosphorylation through the control of mitochondrial transporters, including those of the SLC25 family.

P2322/B574

Insp8 Regulates Cellular Phosphate Homeostasis and Calcification.

X. Li, S. Shears; National Institute of Environmental Health Sciences, Durham, NC.

Phosphate (Pi) has multiple functions that direct the survival of all living organisms. It is required for mineralization of cartilage, bone, and dentin. In its organic form, Pi is a component of genomic material, it serves as an energy currency, and it is ubiquitous in cell signaling. Thus, regulation of Pi uptake and efflux pathways across cells is essential to life, but the underlying mechanisms in humans are largely unknown. Here, we demonstrate that Pi is regulated by 'IP8', an inositol pyrophosphate (PP-IP) cellular signal. We found Pi efflux was blocked when cellular [InsP8] was reduced, either genetically (KO of the diphosphoinositol pentakisphosphate kinases (PPIP5Ks) that synthesize InsP8), or pharmacologically (cell treatment with 2.5 µM of dietary flavonoid, or 10 µM N2-(m-trifluorobenzyl), N6-(p-nitrobenzyl) purine, to inhibit inositol hexakisphosphate kinases upstream of PPIP5Ks). Significantly, attenuated Pi efflux by PPIP5K KO cells was quantitatively phenocopied by KO of XPR1 itself. Moreover, Pi efflux from PPIP5K

KO cells was rescued either by stable transfection of wild-type PPIP5K1 (a kinase-dead mutant was inactive), or, in a dose-dependent manner, by liposomal delivery of a metabolically-stable, methylene bisphosphonate (PCP) analogue of InsP8; PCP-analogues of other PP-InsPs were all ineffective. To place these observations in a cellular biology context, we studied differentiation of the Soas-2 osteosarcoma cell-line. Loss of XPR1-mediated Pi efflux in PPIP5K KO cells enhanced a differentiation program: elevated expression of osteocalcin, osteonectin and alkaline phosphatase, and acceleration to the mineralization endpoint. Our data suggest catalytically-compromising PPIP5K mutations might extend the genetic repertoire for XPR1 dysregulation; PPIP5Ks may be therapeutic targets for bone maintenance.

Direct Mitochondrial Transfer Improves Insulin Resistance through Ameliorating Mitochondrial Dysfunction in C2c12 Myotubes.

C. Yeon-Kyung[1], H. Jung Wook[1], L. Ji Min[1], K. Ji Kwang[1], K. Kyung-Soo[2], C. Yong-Soo[1]; [1]CHA University, Seongnam, KOREA, REPUBLIC OF, [2]CHA Bundang Medical center, Seongnam, KOREA, REPUBLIC OF.

Mitochondrial dysfunction in muscle is associated with insulin resistance in patients with type 2 diabetes mellitus (T2DM). Several studies attempted that insulin resistance was reduced by improving mitochondrial dysfunction. However, there are few studies whether direct mitochondrial transfer improve insulin resistance in muscle cell. The aim of this study was to evaluate the efficacy of direct mitochondrial transfer for insulin resistance in C2C12 myotubes. We prepared a model of insulin resistance by treating palmitic acid (PA) in mouse skeletal muscle cell line (C2C12). Then, mitochondria-derived from C2C12 cells were centrifuged with host cells to investigate changes in IR. We compared changes in glucose uptake and insulin signal pathway-related proteins. The induction of IR was verified by glucose uptake, and then the generation of oxidative stress by PA treatment was observed. As a result, oxidative stress and mitochondrial fragmentation are reduced through healthy mitochondrial transfer. Furthermore, this study reveals the improvement of insulin sensitivity by upregulating Glut4 expression, IRS1-Akt phosphorylation and mitochondrial dynamics-related proteins. Our results indicated that direct mitochondrial transplantation could attenuate insulin resistance. Therefore, understanding mitochondrial dysfunction responsible for IR is beginning to define the target for the treatment of T2D.

P2324/B576

Regulation of Discoidin Domain Receptor 1 Kinase Activity by the Intracellular Juxtamembrane Region.

D. Sammon, E. Hohenester, B. Leitinger; Imperial College London, London, UNITED KINGDOM.

Introduction the discoidin domain receptor (DDR) DDR1 is a collagen-binding receptor tyrosine kinase (RTK) which controls cellular proliferation and migration. Aberrant DDR1 signalling is implicated in the progression and poor prognosis of several diseases, including many cancers. DDR1 is therefore an attractive target for pharmacological intervention. However, unlike many other RTKs, the processes governing DDR signalling are poorly characterised. Our study aimed to better understand these processes by investigating the functional role played by the intracellular juxtamembrane (JM) region of

DDR1. **Materials and Methods** X-ray crystallography was performed on the intracellular domain of DDR1 with diffraction data collected at Diamond Light source. Immunoblotting of Baculovirus expressed DDR1 constructs was used to monitor receptor autophosphorylation over time, and the identity of phosphorylated tyrosine residues was confirmed by tandem mass-spectroscopy (MS/MS). Enzyme kinetics of each DDR1 phosphoform were determined using a luciferin/luciferase-based ADP-Glo™ assay. **Results** We solved a 2.5 Å resolution crystal structure of the DDR1 cytoplasmic domains. The structure revealed that the DDR1 JM region inserts into the kinase active site, disrupting the transition between inactive and active catalytic states. This JM autoinhibition is shown to be relieved through a concerted two-step process beginning with the phosphorylation of tyrosine residues within the JM region. This initial catalytic event enables kinase activation loop autophosphorylation and facilitates the transition to an active conformation. Through isolating different phosphoforms of DDR1 we also show that JM phosphorylation alone is sufficient to drive a marked increase in substrate affinity (Km decreases 100 fold). Subsequent activation loop phosphorylation results in a five-fold increase in catalytic rate. **Discussion** These data identify the DDR1 JM region as a novel regulator of signalling, highlighting that phosphorylation of this region is the critical first step in DDR1 activation. This study will aid future structure-guided design of inhibitors that can specifically target DDR1 and which may have therapeutic applications.

Smoothened Stimulation by Membrane Sterols Drives Hedgehog Pathway Activity.

I. Deshpande[1], J. Liang[1], D. Hedeen[2], K. Roberts[3], Y. Zhang[3], B. Ha[3], N. Latorraca[3], R. Dror[3], P. Beachy[3], **B. Myers**[2], A. Manglik[1]; [1]University of California, San Francisco, San Francisco, CA, [2]University of Utah School of Medicine, Salt Lake City, UT, [3]Stanford University School of Medicine, Palo Alto, CA.

Hedgehog (Hh) signaling within the primary cilium is fundamental to embryonic development and tissue regeneration. Aberrant signaling postnatally leads to several malignancies including basal cell carcinoma, the most common human cancer, and medulloblastoma, the most common pediatric brain tumor. At the ciliary membrane, Hh proteins bind to and inhibit the transmembrane cholesterol transporter Patched1 (PTCH1), permitting activation of the seven transmembrane (7TM) transducer Smoothened (SMO) via a poorly understood mechanism. Here, we present the crystal structure of active SMO bound to the agonist SAG21k and an intracellular-binding nanobody that stabilizes a physiologically relevant active state. An alogous to other G protein-coupled receptors (GPCRs), activation of SMO is associated with subtle motions in the extracellular domain and larger changes intracellularly. In contrast to recent models that have emphasized lipid binding to the SMO extracellular cysteine-rich domain (CRD), we find a cholesterol molecule critical for SMO activation bound deep within the 7TM pocket. Mutational analysis reveals that this 7TM sterol binding site is essential for SMO activation in cultured cell and in *vitro* systems, and is supported by molecular dynamics simulations of SMO-sterol interactions. We propose that PTCH1 inactivation enables a transmembrane sterol to access this 7TM site, potentially through a hydrophobic tunnel, driving SMO activation. Our present studies are now focused on three outstanding challenges: 1) biochemically identifying the endogenous molecule that binds the SMO 7TM sterol site under native physiological conditions; 2) understanding how SMO integrates the information relayed through its CRD and 7TM sterol binding sites to ensure appropriate levels of Hh pathway activity in vivo; 3) understanding how PTCH1 can selectively and specifically inhibit SMO without affecting other sterol-dependent signaling processes. These results delineate the structural basis for PTCH1-SMO

regulation, highlight the deep evolutionary connections between SMO activation and sterol biology, and suggest a new strategy to overcome clinical resistance to SMO inhibitors.

Investigating the Mechanism of Modulating Hippo-yap Activities by Perturbing the Cellular Membrane Cholesterol Homeostasis.

S. Park[1,2], J. Kim[2], Y. Paik[2,1]; [1]Sungkyunkwan University, Seoul, KOREA, REPUBLIC OF, [2]Samsung medical center, Seoul, KOREA, REPUBLIC OF.

Objectives; Activation of hepatic stellate cell (HSC) is a major hallmark of liver fibrosis and requires Hippo-YAP signaling pathway activation. Notwithstanding that external stimuli are translated into the pathway through the plasma membrane where most of cellular cholesterol locates, how membrane cholesterol homeostasis modulates the process hasn't been extensively studied. **Methods;** Multiple reported stimuli were used as means to activate Hippo-YAP pathway. The activation of the pathway was addressed by target gene expression with RT-PCR and Hippo kinases activation with western blot. Several pharmacological reagents were used to modulate membrane cholesterol level and to modify cholesterol status. Furthermore, siRNA-, shRNA-mediated knock-down, ectopic expression, and chemical inhibitors were adopted to manipulate the functions and the expression of proteins. Various cell lines with different tissue origins were also used to confirm our findings. **Results;** Based on the previous reports, several stimuli were selected and tested to efficiently induce YAP activation in HSC; agonists of several GPCR family members, TGF-b1, and high external stiffness. By using siRNAs and antagonists, we also demonstrated that Spingosine-1-phosphate (S1P) induces YAP target gene expression through S1PR2 and Gα13 and Gαq/11 act at the downstream. Treatment with diverse cholesterol modulating agents, such as MβC, HPβC, and Fillipin, surprisingly synergistically enhanced YAP target gene expression upon several stimuli, which was efficiently reverted by supplementation of exogenous cholesterol. Western blot showed that dephosphorylation of Hippo pathway kinases induced by S1P were even more increased by MβC pre-treatment, indicating that perturbing the plasma membrane cholesterol level affect the canonical Hippo pathway. Furthermore, the MβC pre-treatment also showed the similar enhanced effect upon the stimuli that were known to directly induce Rho/ROCK/Hippo-YAP activation independent of membrane receptors, suggesting that the effect of MβC were not confined to the membrane level and were transmitted to the cytosol. Western blot and RT-PCR evidenced that two isoforms of ROCK were differently regulated by the cholesterol perturbing agents, at both transcription and post-transcription levels. **Conclusion;** Acute perturbation of membrane cholesterol homeostasis shapes Hippo-YAP signaling pathway through differently regulating ROCK-1 and ROCK-2.

Rapid Regulation of Oxidative Phosphorylation by Insulin in Human Embryonic Stem Cells.

Z. Ren, H. Zhong, C. Song, C. Deng, W. Liu, G. Chen; University of Macau, Macau, CHINA.

Insulin is an extrinsic factor essential for human embryonic stem cell (hESC) maintenance and differentiation, and the functions are always carried out through transcription and translation over hours or even days. Emerging studies suggest that insulin is important for energy metabolism, which is increasingly recognized as an active control of cell functions, but in hESCs how insulin signal transduction influences energy balance and whether there is immediate impact are largely unknown. Here we show that the presence of insulin rapidly stimulates substrate-specific oxidative phosphorylation (OXPHOS) in

hESCs. Pharmacologic and genetic manipulations reveal that insulin regulates OXPHOS through PI3K/AKT/GSK3 cascade within minutes before significant changes in the expression of metabolic enzymes occur. Intriguingly, we observed that insulin-dependent OXPHOS is hESC-specific, and it diminishes in differentiated cell types. Moreover, we noticed that insulin or GSK3 inhibition could significantly suppress the activation of caspase. Collectively, these results suggest that insulin regulated OXPHOS in a rapid mode and insulin is continuously required to maintain full mitochondrial capacity in hESCs. Our findings provide molecular insights into the association of insulin signal transduction and mitochondrial energy metabolism, and highlight the necessity of insulin in the consistency and accuracy of metabolic analyses in intact hESCs.

Nuclear HCAR1 Promotes Cancer Cell Migration.

M. Mohammad Nezhady[1,2], G. Cagnone[2], S. Chemtob[1,2]; [1]Molecular Biology Program, Faculty of Medicine, Université de Montréal, Montreal, QC, CANADA, [2]CHU Sainte-Justine Research Centre, Montreal, QC, CANADA.

G-protein Coupled Receptors (GPCRs) are major class of receptors virtually involved in every biological processes. More than 40% of all pharmaceuticals target GPCRs indicating their pathophysiological significance. One of the most significant dimensions in GPCR biology is nuclear localization of certain GPCRs having different function than their surface counterpart. HCAR1 is a GPCR and the endogenous receptor of lactate. Lactate through HCAR1 can inhibit lipolysis and inflammation, promote angiogenesis and cancer progression. We hypothesized that HCAR1 has nuclear localization exerting different function in the nucleus. We performed immunofluorescent staining followed by confocal imaging, biochemical fractionation and electron microscopy to determine HCAR1 localization pattern. To investigate the potential translocation of HCAR1 from plasma membrane to the nucleus upon ligand binding, fluorescent activating peptide technology was adopted using a cell impermeable fluorogen pulse chase. Site directed mutagenesis identified HCAR1 domains involved in its differential localization. We screened for activation of potential intranuclear signaling pathways upon lactate stimulation on isolated nuclei and performed ChIP-seq with HCAR1 to elucidate its potential direct gene regulatory function. Our data shows intact HCAR1 is localized to the nucleus and nuclear membrane independent of ligand binding and ICL3 and phosphorylation of S305 in the C-terminal domain are responsible for this localization pattern. We show nuclear Akt, Erk1/2 and p38 phosphorylation upon lactate stimulation, and this phosphorylation pattern is lost in the nuclei of KD cells, proving nuclear HCAR1 activates intranuclear signaling pathways. ChIP data shows lactate induces redistribution of HCAR1 in the genome toward gene loci and transcription start sites. Ontological analysis indicates HCAR1 is enriched for genes involved in cellular movement upon lactate binding. Cell scratch assay proves KD cells have ~50% lower migration rate. While re-introduction of RNAi resistant WT HCAR1 rescued the migratory phenotype, rescue with Delta ICL3 or S305A mutants behaved like total KD demonstrating nuclear HCAR1 governs cell migration. Taken together, we prove nuclear localization of HCAR1 and provide evidence for its function as signaling receptor in the nucleus/nuclear membrane and direct gene regulatory functions. Previous studies have shown that HCAR1 has a crucial role in progression and metastasis of many cancers. Based on our data, we hypothesis that dual function of nuclear HCAR1 significantly contributes to its role in cancer pathology. Our next aim is to validate this hypothesis in animal model and determine nuclear HCAR1 contribution to these phenomena.

P2329/B581

Endosomal G Protein-coupled Receptor Signaling Modulates Liver Cell Metabolism.

E. L. Sanchez, M. von Zastrow; University of California, San Francisco, CA.

Upon activation by specific ligands, G protein-coupled receptors (GPCRs) signal via cyclic AMP (cAMP) production. The classical model of GPCR signaling describes that cAMP production occurs at the plasma membrane. However, work from our lab and others has revealed a new model of GPCR signaling, which includes cAMP production from the endosomal membrane. Using the Beta2-Adrenergic Receptor (B2AR) as a model GPCR, our lab has shown that endocytosis is a required component to achieve the cAMP production necessary for downstream transcription. Microarray analysis identified a subset of transcriptional targets whose level of expression were significantly endocytosis-dependent. The top transcriptional target identified was Phosphoenolpyruvate Carboxykinase 1 (PCK1), a major control point of gluconeogenesis. As these studies were completed in HEK293 cells, we were interested to explore these mechanisms in a more physiologically relevant system. We chose to pursue this line of experiments in liver cells, as it is known that GPCR signaling is intimately connected to metabolic regulation in this organ. We have chosen to study B2AR as well as the Glucagon Receptor (GCGR), both of which are Gscoupled GPCRs which signal through cAMP. qRT-PCR analysis of samples in the presence or absence of the drug Dyngo, a dynamin inhibitor, indicates that endocytosis-dependent transcription exists in primary mouse hepatocytes downstream of both B2AR and GCGR activation. Importantly, this transcriptional mechanism includes regulation of key gluconeogenic genes PCK1, G6PC, and PGC1α. Current work is focused on examining how B2AR and GCGR endosomal signaling and trafficking impact metabolic regulation. Future work will examine how endosomal GPCR signaling is altered in hepatocytes from animals with dysregulated metabolism, such diabetes or non-alcoholic fatty liver disease.

Fgf Signaling Promotes Myoblast Proliferation through Activation of Wingless Signaling.

K. Vishal, R. Cripps; San Diego State University, San Diego, CA.

Indirect flight muscles (IFMs) are the largest muscles in *Drosophila* and are made up of about 3000 myonuclei per fiber. The generation of these giant muscles requires a large pool of adult muscle precursors (AMPs). The myoblasts that give rise to these muscles are associated with larval wing imaginal disc, and increase in number from 10-12 in first instar larvae to over 2500 by the end of the third larval instar. Previous studies have shown that Wingless (Wg) and Notch signaling are required for the regulation of myoblast proliferation. However, other factors that control the scaling up of the myoblast pool are largely unknown. Here, we examine the role of Fibroblast growth factor (FGF) signaling in the proliferation of wing disc associated myoblasts. First, we visualized the accumulation of different components of the FGF signaling cascade in the wing imaginal disc We find that the FGF receptor (Heartless) and downstream effectors (Dof and Pointed) are present in myoblasts, whereas, FGF ligands (Thisbe and Pyramus) are expressed in surrounding epithelial cells of the wing disc. Next, we show that attenuation of FGF signaling results in diminished myoblast pool. This reduction in the pool size is due to decreased myoblast proliferation. By contrast, activating FGF signaling increases the myoblast pool size and restores the proliferative capacity of *htl* knockdown flies. To further dissect the function of FGF signaling in the amplification of the AMPs, we examined cross-talk between FGF and Wg signaling. Our results demonstrate that Heartless acts through up-regulating β-catenin/armadillo to promote myoblast proliferation. Finally, we show that FGF mediated regulation of myoblast

proliferation is dependent on Cyclin E expression. Our studies identify a novel role for FGF signaling during IFM formation and uncover the mechanism through which FGF coordinates with Wingless signaling to promote myoblast proliferation.

Fgfr Activates Non-canonical Tgfβ Signaling in Kinase-independent Manners, Contributing to Thyroid Eye Disease.

C. Chou[1], T. Lu[1], E. Yen[2], S. Shih[3,4,5], C. Shih[6], Y. Wei[7], S. Liao[7], **F. Tsai**[1,8]; [1]National Taiwan University Institute of pharmacology, Taipei City, TAIWAN, [2]Department of Genomic Medicine, University of Texas MD an derson Cancer Center, Houston, TX, [3]Department of Internal Medicine, National Taiwan University College of Medicine, Taipei City, TAIWAN, [4]Department of Internal Medicine, National Taiwan University Hospita, Taipei City, TAIWAN, [5]Center of anti-Aging and Health Consultation,National Taiwan University Hospital, Taipei City, TAIWAN, [6]Department of Ophthalmology, Zhongxing Branch, Taipei City Hospital, Taipei City, TAIWAN, [7]Department of Ophthalmology, National Taiwan University Hospital, Taipei City, TAIWAN, [8]Department of Internal Medicine, National Taiwan University Hospital, Taipei City, TAIWAN.

FGFR activates non-canonical TGFβ signaling in kinase-independent manners, contributing to thyroid eye disease. Chien-Hsiang Chou[1], Ting-Xuan Lu[1], Er-Yen Yen[7], Shyang-Rong Shih[2, 3,4], Chih-Wei Shih[6], Yi-Hsuan Wei[5], Shu-Lang Liao[5] and Feng-Chiao Tsai[1,3] [1]Institute of Pharmacology, National Taiwan University College of Medicine, Taipei, Taiwan. [2]Department of Internal Medicine, National Taiwan University College of Medicine, Taipei, Taiwan. [3]Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan. [4]Center of anti-Aging and Health Consultation, National Taiwan University Hospital, Taipei, Taiwan. [5]Department of Ophthalmology, National Taiwan University Hospital, Taipei, Taiwan. [6]Department of Ophthalmology, Zhongxing Branch, Taipei City Hospital, Taipei, Taiwan. [7]Department of Genomic Medicine, University of Texas MD an derson Cancer Center, Houston, TX, USA. Thyroid eye disease (TED), or Graves' ophthalmopathy, is an autoimmune disorder caused by excessive extraorbital fibrosis and adipogenesis, both of which are regulated by orbital fibroblasts. Recent therapeutic advances indicated the potential of targeting growth factors including IGFs and VEGFs to treat TED. We thus explored if the major growth factor of fibroblast-FGF-was also involved in TED. Our recent results revealed high serum FGF1 and FGF2 levels in TED patients. We also noticed that FGF increased lipogenesis and decreased fibrogenesis in HS68 cells and orbital fibroblasts, indicating the importance of FGFR signaling in the pathogenesis of TED. We further elucidated how FGFR signaling altered the differentiation of orbital fibroblast. Both literature results and our preliminary findings revealed that the kinase activity of FGFR suppressed TGFβR signaling, reducing α-SMA formation and fibrogenesis. Interestingly, unlike FGFR inhibitors that increased α-SMA levels in fibroblasts, FGFR depletion via knockdown abolished the effect of TGFβ to increase α-SMA, indicating that FGFR might also alter TGFβ signaling in kinase-independent manners. Moreover, the canonical TGFβ pathway via Smad3 activation was unaffected during FGFR knockdown, suggesting the kinase-independent role of FGFR on TGFβR was through non-canonical TGFβR signaling. We are currently working on the mechanisms of this kinase-independent non-canonical FGFR-TGFβR signaling, with the hope to improve current treatment for TED in the near future.

Function Study of Leg1 on Protection of Liver Development of Zebrafish Under Oxidative Stress.

J. Wang, female, Y. Bai; ZhejiangUniversity, Hangzhou, CHINA.

Function study of Leg1 on protection of liver development of zebrafish under oxidative stress Bai Yun [1], Hu Minjie [1], Wang Jinyang [1], Huang Heping [1], Xie Aixuan [1], Peng Jinrong [1] *and Chen Jun [2] * 1 College of an imal Sciences, 2 College of Life Sciences, Zhejiang University, Hangzhou, China pengjr@zju.edu.; chenjun2009@zju.edu.cn Unlike mammals and birds, teleost fish undergo external embryogenesis, and therefore their embryos are constantly challenged by stresses from their living environment. These stresses, when becoming too harsh, will cause arrest of cell proliferation, abnormal cell death or senescence. Such organisms have to evolve a sophisticated anti-stress mechanism to protect the process of embryogenesis/organogenesis. However, very few signaling molecule(s) mediating such activity have been identified. liver-enriched gene 1 (leg1) is an uncharacterized gene that encodes a novel secretory protein. In the zebrafish genome, there are two copies of leg1, namely leg1a and leg1b. In this report, we show that leg1a mutant exhibits a stress-dependent small liver phenotype that can be prevented by chemicals blocking the production of reactive oxygen species. Further studies reveal that Leg1a binds to FGFR3 and mediates a novel anti-stress pathway to protect liver development through enhancing Erk activity. This finding may explain the adaption of teleost fish in coping with environmental changes.

Genome-Wide CRISPR/Cas9 Screening Towards Identification of the Lacritin Homeostasis Receptor.

K. Dias Teixeira[1], M. Adli[1], J. Doench[2], G. Laurie[1]; [1]University of Virginia, Charlottesville, VA, [2]Broad Institute of MIT and Harvard, Cambridge, MA.

Introduction: Homeostasis of the surface of the eye appears to be controlled almost entirely by lacritin, a prosecretory mitogenic glycoprotein constituent of tears. In mouse dry eye and a human dry eye-like cell system, exogenous lacritin restores homeostasis by transiently accelerating epithelial autophagy and restoring oxidative phosphorylation through mitochondrial fusion. Although we understand in general how lacritin works, many details are missing - including the signaling receptor. Lacritin pro-homeostatic and mitogenic signaling in corneal epithelia involves Ca^{2+} signaling through calcineurin, AKT, FOXO1/ATG7 and FOXO3/ATG101. Rather than acting alone, the unknown receptor partners with a transiently deglycanated form of the cell surface proteoglycan syndecan-1. To capture these details that could be relevant to drug cross-reactivity, our goal was to identify the lacritin main receptor using a genome-wide CRISPR/Cas9 screen of human corneal epithelial cells (HCET). **Methods:** HCET cells were transduced at MOI of 0.3 with lentiviral Human CRISPR Knockout Pooled Library that comprises four sgRNAs targeting each of 19,114 annotated human protein coding genes. We then model the loss of homeostasis in dry eye by introduction of IFNG and TNF, followed by rescue with 'N-94', a synthetic peptide representing lacritin's C-terminal active domain. sgRNA's in cells that could no longer respond to N-94 were subjected to PCR amplification and next generation sequencing. The change in abundance of perturbations from sample to sample was then calculated using log-normalized data to generate log-fold-change (LFC) values, displayed in volcano-plots. **Results:** Our screen revealed multiple genes involved in lacritin pro-homeostatic signaling. One first screen hit was the G protein coupled receptor 87 (GPR87). Validation studies demonstrated that knocking down GPR87 expression prevents rescue of HCET cells stressed with IFNG and TNF by N-94. These data indicate that GPR87 has a critical role in lacritin homeostasis signaling. Our screen also identified many key players in the Hippo Pathway

including LATS1 and the transcription factor TEAD4. ShRNA knockdown of TEAD4 expression also abrogated lacritin homeostasis activity, suggesting a role for the Hippo Pathway in the lacritin homeostasis regulation. Further validation assays using GPR87$^{-/-}$ and TEAD4 $^{-/-}$ cells are under way.

P2334/B586

Investigating the Mechanism of Cytoplasmic Receptor Tyrosine Kinase Signaling.

G. Uribe, E. Dine, J. E. Toettcher; Princeton University, Princeton, NJ.

Receptor tyrosine kinases (RTKs) are a family of transmembrane receptors that activate signaling cascades to control cell proliferation, differentiation and growth. The classical model states that upon ligand binding, RTKs become dimerized leading to autophosphorylation and recruitment of downstream effectors to activate various signaling pathways, including the Ras/Erk mitogen-activated protein kinase (MAPK) pathway. In some cancers, chromosomal translocations lead to changes in RTK structure and localization that turn a plasma-membrane bound receptor into a cytosolic-localized kinase fused to a higher-order oligomer clustering partner. While these translocations are well-documented, how cytosolic receptors are able to activate downstream signaling remains unclear. To further investigate this question, we have created cytosolic versions of these receptors that are fused to an optogenetic construct that oligomerizes in response to blue light. Through our system, we found that some receptors are able to signal from the cytosol, such as fibroblast growth factor receptor (FGFR), and others are only able to signal when bound to the plasma membrane, such as epidermal growth factor receptor (EGFR). Interestingly, we find that although EGFR does not trigger downstream signaling, it autophosphorylates in response to oligomerization which is generally thought to be the first step in signal pathway activation. We predict that these differences in signaling arise from contact with downstream adaptor proteins, such as FGFR's interaction with membrane-bound fibroblast growth factor receptor substrate 2 (FRS2). Subsequent experiments and analysis with our system will establish how various RTKs are able to induce and maintain MAPK signaling.

P2335/B587

An Unexpected Role for Ripk3 in Regulating Growth Factor Receptor Expression and Signaling in Endothelial Cells.

S. Gao[1,2], C. T. Griffin[1,2]; [1]University of Oklahoma Health Sciences Center, Oklahoma City, OK, [2]Oklahoma Medical Research Foundation, Oklahoma City, OK.

Receptor-interacting protein kinase 3 (RIPK3) is considered to be an essential mediator of necroptosis, which is a form of programmed necrotic cell death. However, other roles for RIPK3 have started to emerge in recent years, including roles in inflammatory cytokine production and cellular metabolism. Curiously, RIPK3 is highly and specifically expressed in endothelial cells (ECs) during murine embryonic vascular development, but our lab recently reported that excessive RIPK3 is detrimental to murine vascular integrity at midgestation in a necroptosis-independent manner. However, the mechanism by which RIPK3 regulates vascular integrity is unclear. We first questioned whether RIPK3 might impact vascular sprouting, which is active at the embryonic time point at which RIPK3 protein is highly expressed in ECs in vivo. Indeed, we found that RIPK3 knockdown attenuated vascular sprouting in an in vitro sprouting assay using human umbilical vein endothelial cells (HUVECs). Since vascular endothelial growth factor a (VEGFA) signaling is an important trigger of vascular sprouting, we next tested whether RIPK3 impacted VEGFA signaling in HUVECs. We found that RIPK3 knockdown surprisingly leads to

enhanced degradation of the vascular endothelial growth factor receptor VEGFR2 after stimulation with VEGFA. However, RIPK3 knockdown also paradoxically upregulates two key signaling pathways following VEGFA stimulation: ERK and Akt. Interestingly, a similar opposing effect on receptor degradation and signaling is also seen in RIPK3-depleted HUVECs following stimulation with three other vascular growth factors: epidermal growth factor (EGF), fibroblast growth factor (FGF), and transforming growth factor beta (TGFβ). Taken together, our data indicate that RIPK3plays a novel role in regulating receptor degradation and modulating ligand-induced signaling in ECs. Ongoing work is addressing the mechanism by which RIPK3 regulates these cellular processes and the in vivo implications for vascular sprouting and integrity.

P2336/B588

MAPK Feedback Phosphorylation of RGS Controls Its Spatiotemporal Localization and Alters Endocytosis through the Kelch Repeat Protein Kel1 during the Yeast Pheromone Response.

W. C. Simke, **J. B. Kelley**, A. J. Hart; University of Maine, Orono, ME.

G-protein coupled receptor (GPCR) signaling pathways regulate myriad cellular processes that require detection of an extracellular signal and conversion of that signal into a cytosolic response. The budding yeast, *Saccharomyces cerevisiae*, grows towards potential mating partners using a GPCR pathway to track the external gradient by initiating Rho-mediated cell polarization. This pathway makes use of two branches, a Gβγ branch that leads to Rho polarization and a MAPK cascade, and a less well understood Gα branch that anchors MAPK to the membrane to regulate formin activity. The mating pathway is desensitized by the regulator of G-protein signaling (RGS), Sst2. It has long been known that there is a MAPK feedback phosphorylation to the RGS, but this modification was found to have no effect on signaling from the Gβγ branch of the pathway. We hypothesized that the phosphorylation event serves to regulate the spatial and temporal dynamics of the RGS during the pheromone response to control where MAPK is active. Using a combination of live cell imaging in microfluidic devices and computational image analysis, we show that phosphorylation of the RGS results in loss of its localization to the site of polarization, and alters the pattern of active Gα-MAPK complex at the leading edge of the cell. In addition to the changes in localization of the RGS and its target Gα, we also came across two surprising results: 1) the ability to phosphorylate the RGS is required for the cell to successfully complete cytokinesis prior to beginning the mating response and 2) phosphorylated RGS leads to a decrease in endocytosis. These results lead us to consider the role of the formin regulator and member of the mitotic exit network, Kel1. Kel1 is a kelch repeat containing protein that has previously been found to interact with the RGS. Here we show that Kel1 is required for proper RGS localization, and provide evidence that RGS regulates Kel1 in a phosphorylation dependent manner. We propose that this newly discovered role for an RGS protein in the regulation of vesicle trafficking may function to fine tune the balance of endocytosis and exocytosis to promote the cell growth required for pheromone induced morphogenesis.

P2337/B589

Acetylcholine-induced Paneth Cell Granule Secretion Via Muscarinic M3 Receptor in Mouse Small Intestine.

Y. Yokoi[1], K. Nakamura[1,2], R. Sugimoto[1], S. Ohira[1], M. Kikuchi[2], T. Ayabe[1,2]; [1]Graduate School of Life Science, Hokkaido University, Sapporo, JAPAN, [2]Department of Cell Biological Science, Faculty of Advanced Life Science, Hokkaido University, Sapporo, JAPAN.

Background: Paneth cells at the base of small intestinal crypts secrete granules rich in antimicrobial α-defensin peptides and regulate the intestinal microbiota by killing pathogens. The involvement of dysbiosis, imbalance of the intestinal microbiota, in many diseases such as obesity and inflammatory bowel disease suggests the involvement of Paneth cell granule secretory responses in certain diseases. Since cholinergic carbamylcholine stimulates Paneth cell granule secretion, acetylcholine (ACh), an endogenous cholinergic neurotransmitter, may regulate the secretion. However, mechanisms including ACh receptor (AChR) expression and downstream signal cascades in Paneth cells remain largely unknown. **Objective:** We aimed to clarify mechanisms of Paneth cell granule secretion in response to ACh in cultured three-dimensional enteroids composed of small intestinal epithelial cells. **Methods:** Paneth cell granule secretion was visualized and quantified in mouse enteroids by granule area obtained by confocal microscopy before and after ACh stimulation. Functional muscarinic AChRs (mAChRs) and signaling was analyzed using antagonists selective for each mAChR subtype (M1-M5) and with inhibitors of protein kinase C (PKC) and inositol triphosphate receptor (IP3R). In addition, gene expression of each *mAChR in* Paneth cells was analyzed by quantitative PCR using singly-isolated Paneth cells. Ca^{2+} dynamics were analyzed by time-lapse Förster resonance energy transfer (FRET) imaging. To determine localization of submucosal cholinergic nerves, whole-mount immunostaining of small intestinal tissues against choline acetyltransferase (ChAT) and PGP 9.5 was performed, followed by tissue clearing. **Results:** Paneth cells secreted granules in response to ACh in a dose-dependent manner. Paneth cells expressed *M1*, *M3*, *M4*, *M5* genes but not *M2* among mAChR subtypes. Granule secretion was substantially inhibited only when enteroids were pretreated with M3 antagonist but not by others. Inhibitors of PKC and IP3R, the known major downstream molecules of M3 signaling significantly suppressed Paneth cell granule secretion. Rapid increase of intracellular Ca^{2+} concentration in Paneth cells was observed in response to ACh, followed by granule secretion. Immunostaining analysis further revealed that $PGP9.5^{+}$ $ChAT^{+}$ nerve endings were joined at the Paneth cell basement membrane, evidence that cholinergic nerve-derived ACh is involved in granule release. **Conclusion:** Paneth cells recognize ACh via the M3 receptor and secrete granules containing α-defensins via intracellular PKC and IP3R signals with increased cytosolic Ca^{2+} mobilization. This study contributes to understanding enteric pathophysiology related to disruption of Paneth cell.

P2338/B590

Protein Kinase a Inhibitor Protein (PKI) Levels Modulate ERK Activation Downstream of GPCR-cAMP Signaling.

J. J. Hoy, N. Salinas Parra, J. Park, R. Iglesias-Bartolome; LCMB, National Cancer Institute, Bethesda, MD.

Protein kinase a (PKA)-inhibitor (PKI) proteins bind with high affinity to PKA and block its kinase activity, modulating the extent and duration of PKA-mediated signaling events. While PKA is a well-known regulator of physiological and oncogenic events, the influence of PKI proteins in these pathways has remained elusive. Here, by measuring activation of the MAPK pathway downstream of GPCR-Gαs-cAMP

signaling, we study how the expression levels of PKI protein can alter the balance of activation of two major cAMP targets: PKA and EPAC. Intracellular cAMP signaling mediated through two major effectors (PKA and EPAC) was modeled in HEK293 cells with over-expression or RNAi depletion of PKIs. Transcriptional programming alterations were determined with transcription factor-driven luciferase reporter assays. PKI expression was modulated to assess their role in switching signaling outcomes. Activating cAMP signaling downstream of Gαs with Forskolin (FSK) resulted in PKA-mediated inhibition of ERK phosphorylation. Over-expression of PKI and its subsequent inhibition of PKA rescued ERK activation. Utilizing a construct consisting of the PKA-inhibitory domain of PKI, these effects were confirmed to be due to specific inhibition of PKA signaling. Interestingly, activating mutations of Gαs and ligand stimulation of Gαs-coupled GPCRs resulted in slightly increased ERK activation; however, this activation was significantly enhanced with PKI over-expression. cAMP-mediated ERK signaling was found to be dependent on EPAC1-RAP1; where PKI could only partially rescue ERK activation in the absence of EPAC1. Modulation of PKI expression also significantly altered transcriptional programing downstream of the Gαs-cAMP signaling axis. Over-expression of PKI was shown to shift transcriptional activity away from PKA-CREB regulated genes towards those activated via ERK signaling. Together, these results indicate that PKI acts as a molecular switch driving cAMP signaling away from PKA and potentiating MAPK signaling.

P2339/B591

Single-molecule Imaging and an alysis of the Dynamic Organization of Vascular Endothelial Growth Factor 2 (VEGFR-2) on the Surface of Live Endothelial Cells.

B. Da Rocha-Azevedo[1], S. Lee[2], A. Dasgupta[1], T. Kim[1], M. Kittisopikul[3,1], A. Vega[1,4], L. De Oliveira[1], K. Jaqaman[1,4]; [1]Biophysics, University of Texas Southwestern Medical Center, Dallas, TX, [2]Korea University, Seoul, KOREA, REPUBLIC OF, [3]Cell and Molecular Biology, Northwestern University Feinberg School of Medicine, Chicago, IL, [4]Bioinformatics, University of Texas Southwestern Medical Center, Dallas, TX.

VEGFR2 is a receptor tyrosine kinase thatplays an essential role in promoting angiogenesis in response to its ligand VEGF. The canonical model has been that VEGF binds to VEGFR2 monomers, leading to VEGFR2 dimerization, autophosphorylation and downstream signaling. Recent studies suggest that VEGFR2 can dimerize in the absence of VEGF, and that VEGF affinity is higher to pre-dimerized VEGFR2. However, little is known about VEGFR2 spatiotemporal organization, including its oligomeric state, in its native plasma membrane environment in live endothelial cells. Therefore, we undertook a quantitative single-molecule study of VEGFR2 on the surface of live endothelial cells, labeling endogenous receptors and imaging the cell surface using TIRF microscopy, followed by automated single-molecule tracking and statistical data analysis. We found that VEGFR2 exhibits two movement types: (i) freely diffusing (~35%), with a mean diffusion coefficient of 0.18 um^2/sec; and (ii) confined/immobile (~65%). We observed a heterogeneity in VEGFR2's oligomeric state, with monomers, dimers and higher order oligomers/clusters. The freely diffusing molecules underwent more frequent interactions, but the confined/immobile molecules were on average of a higher oligomeric state. Addition of VEGF caused an almost immediate reduction in the diffusion coefficient of freely diffusing VEGFR2 molecules, followed by a more gradual shift (within 10 min) in the population from free to confined/immobile. Co-imaging of VEGFR2 and VEGF revealed that VEGF binds both monomeric and pre-oligomerized/clustered VEGFR2, with a preference for the latter, including those in the confined/immobile subpopulation. It also reduced the dissociation rate (to about one-half) of the dynamic interaction events. To understand better the link between VEGFR2 activation, its mobility and oligomeric state, we treated endothelial cells with the

VEGFR2 phosphorylation inhibitor AAL993. We found that AAL993 treatment increased the probability of free diffusion and the frequency of dynamic interactions both in the absence and presence of VEGF, suggesting that phosphorylation plays a critical role in the spatiotemporal organization of VEGFR2 at rest and upon ligand binding. Together, these observations depict a dynamic organization of VEGFR2 on the surface of endothelial cells that both affects and depends on VEGF binding and downstream activation.

Prostaglandin E2 Induces Skin Aging by E-Prostanoid 1 receptor in Normal Human Dermal Fibroblasts.

J. SHIM; Faculty of Cosmetics and Biotechnology, Semyung Univ., Jecheon, KOREA, REPUBLIC OF.

The production of collagen type I is decreased during aging, leading to skin wrinkle and impaired function. PGE2, a lipid derived signaling molecule derived from arachidonic acid by cyclo-oxygenase, inhibits collagen production and induces MMP1 expressions by fibroblasts in vitro. The inhibition of collagen expressions and the promotion of MMP1 by PGE2 have been accepted as the aging mechanisms. I demonstrated that EP1 plays an important role in PGE2 signaling in normal human dermal fibroblasts (NHDFs). When EP1 expression was suppressed with EP1 siRNA, there were no significant changes in mRNA levels of COL1A1/MMP1 between siRNA-transfected NHDFs and siRNA-transfected NHDFs with PGE2. These results show that EP1 is a receptor for PGE2. The phosphorylation of ERK1/2 after PGE2 treatment significantly increased by approximately 2.5 times. In addition, the exposure of NHDFs to PGE2 triggered an increase in intracellular Ca^{2+} concentrations. These results means that the PGE2 is directly associated with the EP1 receptor pathway-regulated ERK1/2 and IP_3 signaling in NHDFs. Molecular Mechanisms of STING Pathway Activation and Inhibition.

S. L. Ergun, D. Fernandez, L. Li; BIOCHEMISTRY DEPT, STANFORD UNIVERSITY, Stanford, CA.

The STING (STimulator of INterferon Genes) pathway is an innate immune signaling cascade which promotes essential anti-cancer, anti-viral, and anti-bacterial responses. Conversely, STING overactivation is linked to several autoimmune and inflammatory diseases such as Lupus, Multiple Sclerosis, heart attack, and Parkinson's disease. Despite its significance in the disease context, the precise molecular mechanism of STING activation and attenuation remains unclear. Using structural biology and biochemistry, we report that the metazoan second messenger 2'3'-cGAMP induces closing of the human STING homodimer and release of the STING C-terminal tail, which exposes a polymerization interface on the STING dimer and leads to the formation of disulfide-linked polymers via cysteine residue 148. Disease-causing hyperactive STING mutations either flank C148 and depend on disulfide formation or reside in the C-terminal tail binding site and cause constitutive C-terminal tail release and polymerization. Finally, bacterial cyclic-di-GMP induces an alternative active STING conformation, activates STING in a cooperative manner, and acts as a partial antagonist of 2'3'-cGAMP signaling. Our insights explain the tight control of STING signaling given varying background activation signals and provide a novel therapeutic hypothesis for autoimmune syndrome treatment.

Biological Role of Oxytocin Receptor in Dental Pulp Stem Cells.

J. Jung[1], J. Kim[2]; [1]CHA University, Seongnam, KOREA, REPUBLIC OF, [2]CHA Bundang Medical Center, Seongnam, KOREA, REPUBLIC OF.

Dental pulp stem cells (DPSCs) are mesenchymal stem cells in dental pulp, which induce the repair of damaged teeth. Oxytocin receptor (OXTR), a member of the G-protein coupled receptor, performs a variety of functions in living organisms such as smooth muscle contraction in lactation and delivery and various social behaviors including maternal behavior and pair bonds. Although many researches have been highlightedon the importance of OXTR, the biological function of OXTR in DPSCs is unknown. Here, we report the functional expression of OXTR in cultured human DPSCs (hDPSCs). Through genetic profiling and immunostaining procedures, we find that OXT and OXTR are expressed at high levels in human dental pulp and hDPSCs. Inhibition of OXTR increased the expression of osteo and odontogenic marker genes, promoting the hDPSC differentiation. The regulatory function of OXTR in the differentiation process is mediated by YAP, the downstream component of Hippo signaling pathway. Moreover, we find that OXTRs are involved in the extracellular matrix remodeling through regulating the expression of alpha-1 type I collagen (*COL1A1*) and matrix metalloproteinase-1 (*MMP1*) genes. These results demonstrate that OXTR mediates the intra- and extracellular functions of hDPSCs, indicating the biological importance of OXTR in pulp-dentin complex.

The Splice Variants of gáQ Mediate Phototransduction, Rhodopsin Synthesis, and Retinal Degeneration in Drosophila.

Q. Gu[1], J. Wu[1], J. Han[1,2]; [1]Southeast University, NANJING, CHINA, [2]Co-innovation Center of Neuroregeneration, Nantong University, Nantong, CHINA.

Heterotrimeric G proteins mediate a variety of signaling processes by coupling G protein-coupled receptors to intracellular effector molecules. In *Drosophila,* Gα49B gene encodes several Gqα splice variants and Gqα-PD isoform plays a predominant role in fly phototransduction. However, *Gqα-PD* null mutant flies still exhibit a residual light response, indicating other Gqα splice variants or additional G protein α subunits are involved in phototransduction. Here, we isolate a mutant fly with abolished light responses and the reduced rhodopsin level, and identify mutations in Gα49B gene and its two homologous gene, *CG30054* and *CG17760*. We demonstrate that Gqα splice variant Gqα4 mediates the residual light response in *Gqα-PD* null mutants. We further reveal that depletion of all Gqα splice variants leads to rapid light-dependent retinal degeneration, which is due to the formation of Rh1/Arr2 stable complexes. In addition, we reveal that Gqα homology CG30054 mediates rhodopsin synthesis whereas another Gqα homology CG17760 is expressed in pigment cells. Our study clarify the essential role of different Gqα splice variants in fly phototransduction and reveal the novel role of Gqα4 homology CG30054 in rhodopsin synthesis. Moreover, we demonstrate that completely depletion of Gqα protein also leads to rapid retinal degeneration.

CXCR4 Localized at Intracellular Compartments Are Post-translationally Modified in Response to Plasma Membrane CXCR4 Activaton.

M. DeNies, S. Schnell, A. Liu; University of Michigan, an n Arbor, MI.

The role of G protein-coupled receptor (GPCR) localization in regulating signaling has become increasingly apparent as distinct signaling events at the plasma membrane as well as endosomes and the Golgi have been shown. In addition, agonist-induced receptor post-translational modifications (PTM) have also been implicated in modulating both receptor regulation and signaling. Using wildtype and mutant CXC chemokine receptor 4 (CXCR4) that have distinct plasma membrane and intracellular compartment distribution, we investigated the role of receptor localization on agonist (CXCL12)-dependent CXCR4 PTM and signaling. Surprisingly, modulating CXCR4 plasma membrane localization did not change CXCL12-induced AKT phosphorylation or total receptor PTM. Furthermore, upon blocking receptor internalization, we found that both plasma membrane and internal pools of CXCR4 underwent CXCL12-dependent PTM. In contrast to previous reports where cell permeable agonist could potentially directly activate internal receptors, CXCL12 is membrane impermeable and, in accordance with our results, cannot directly activate CXCR4 at intracellular compartments. Receptor PTM is dependent on plasma membrane CXCR4 as removal of surface proteins abrogates CXCL12-induced CXCR4 PTM entirely. To investigate the functional significance of cells activating plasma membrane and internal pools of CXCR4, we monitored transcript levels of downstream CXCL12 target gene, EGR1. Surprisingly, cells with low plasma membrane CXCR4 expression exhibited significantly elevated agonist-induced EGR1 transcript levels compared to cells with high plasma membrane localization. Together these results suggest a model where plasma membrane receptors can communicate information to receptors at intracellular compartments upon ligand stimulation, by an unknown mechanism. Notably, CXCR4 activation of downstream transcriptional targets does not strictly correlate with CXCR4 plasma membrane expression, and this may have important implications when devising therapeutic strategies that consider both plasma membrane and internal pools of receptors.

C-terminal Motifs Control Differential Desensitization, Internalization and Arrestin-coupling of Group II Metabotropic Glutamate Receptors.

N. Abreu, J. Levitz; Weill Cornell Medicine, New York City, NY.

Precise regulation of glutamatergic signaling is imperative for normal brain function. In particular, metabotropic glutamate receptors (mGluRs) are G protein-coupled receptors (GPCRs) that fine-tune synaptic transmission by initiating intracellular signaling cascades that lead to short and long-term forms of plasticity. Of particular interest are mGluR2 and mGluR3, which have 70% sequence identity, both couple to the $G_{i/o}$ pathway, and are commonly known as presynaptic autoreceptors that inhibit glutamate release. Accordingly, precise regulation of mGluR2/3 signaling is important to preserve synaptic function. GPCR signaling is typically regulated by GPCR kinases which phosphorylate the C-terminal domain (CTD), leading to subsequent β-arrestin binding and endocytosis of the receptor to prevent excessive surface signaling. Studies aiming to define the differential regulation of mGluR2 and mGluR3 have been limited due to the lack of receptor subtype-specific drugs, antibodies, and methods with poor spatial resolution. We sought to determine whether mGluR2 and mGluR3 have distinct regulation by using a heterologous system to express SNAP-tagged mGluRs and specifically track the

surface receptor population. We found that unlike mGluR2, mGluR3 stably couples to β-arrestins and is endocytosed following activation. Further analysis of the CTD revealed that mGluR3 contains "phosphorylation codes" for optimal β-arrestin binding and inserting these codes into the CTD of mGluR2 allows it to stably couple to β-arrestins. Moreover, we discovered that a melanoma-associated mutation in a mGluR3 phosphorylation code enhances basal β-arrestin coupling and endocytosis. These results provide insight into the mechanism of β-arrestin coupling, and differential regulation between mGluR2 and mGluR3 suggests that they serve different functions at the synapse.

P2346/B598

Characterization of gβγ-pi3k-akt-mtor Signaling Pathway in the Calcium-sensing Receptor N639k Mutant Present in Breast Cancer.

J. E. Del Rio-Robles MSc.[1], L. B. Orduña MSc.[1], A. Castillo MSc.[1], J. J. Hidalgo-Moyle MSc.[1], J. Vázquez-Prado PhD[2], G. Reyes-Cruz PhD[1]; [1]Departaments of Cell Biology, CINVESTAV-IPN, Ciudad de México, MEXICO, [2]Departaments of Pharmacology, CINVESTAV-IPN, Ciudad de México, MEXICO.

The calcium-sensing receptor (CaSR), a receptor coupled to G proteins (GPCR), physiologically regulates calcium homeostasis and of hormones, cytokines and growth factors secretion. This GPCR binds to three major groups of heterotrimeric G proteins: Gq/11, Gi/o and G12/13 and in cases such as cancer activates Gs. In addition, there is evidence that CaSR is capable of activating the PI3K-AKT-mTOR pathway through the βγ heterodimer and that this pathway regulates the secretion of certain chemotactic factors. It has been described that mutations in the intracellular loops produce an alteration in the coupling with the heterotrimeric G proteins having an impact on the signaling, however, there are few reports on the participation of the first intracellular loop with the coupling of the G proteins and its effect on the signaling. Considering that according to catalogue of somatic mutations in cancer (COSMIC) database CaSR is the second GPCR most mutated in cancer, we decided to study CaSR mutations in breast cancer. Preliminary results show that $CaSR_{N639K}$ mutant has a switch in the coupling of Gα proteins. In this work, we decided to further characterize the effect of the N639K mutant, located in the first intracellular loop of the CaSR, in the signaling pathway of Gβγ-PI3K-AKT-mTOR to examine the effect of Wortmannin, a PI3K inhibitor and Rapamycin, an inhibitor of the mTOR complex in the activation of AKT, S6 and its impact on chemotactic factors secretion. Results obtained show that $CaSR_{N639K}$ mutant has a reduced capacity, with respect to the $CaSR_{WT}$, to promote the signaling of the Gβγ-PI3K-AKT-mTOR pathway in response to extracellular calcium and the calcimimetic R-568. In addition, this effect correlates with a minor on chemotactic factors secretion, detected in conditioned media, specifically interleukin 8 (IL-8) and monocyte chemoattractant protein-1 (CCL2 / MCP-1), which were identified by flow cytometry. Our results suggest that the $CaSR_{N639K}$ mutant localized in the first intracellular loop produces an inactivating effect of Gβγ-PI3K-AKT-mTOR signaling pathway, affecting the secretion of chemotactic factors, which might also suggest that the first intracellular loop could be participating in the coupling with heterotrimeric G proteins.

P2347/B599

Effects of Tbbpa on Growth Factor Receptor Tyrosine Kinase Markers in a Human Uterine Endometrial 3d Culture Model.

L. Yu, 27709, J. Liu, N. P. Martin, L. Castro, Y. Yan, D. Dixon; National Institute of Environmental Health Sciences, RTP, NC.

Tetrabromobisphenol a (TBBPA) is a brominated flame retardant (BFR) widely used world-wide. It is ubiquitous in the environment and its exposures have led to detectable levels in humantissues. TBBPA is an endocrine-disrupting compound (EDC) and may mimic physiologic estrogen, or disrupt estrogen homeostasis resulting in excess estrogen levels. Due to TBBPA's estrogenic properties and its ability to induce endometrial cancer in female Wistar Han rats in a National Toxicology Program (NTP) 2-year bioassay, we were interested in evaluating its effects on human endometrial spheroids in culture. Additionally, in rats that had in *utero* and early-life exposures to TBBPA, we found increased uterine expression of growth factor receptor tyrosine kinases (RTKs) similar to those overexpressed in endometrial cancer in women, which is the seventh most common type of cancer in women. In this study, the human uterine endometrial epithelial cell (Ut-EEC), that was found to be a target cell type of cancer development in the NTP TBBPA rat bioassay was used to create a 3D culture system. Prior to formation of 3D cultures, 2D cells were characterized by immunocytochemistry for the epithelial cell markers, anti-pan cytokeratin and anti-epithelial antigen, and by "DNA fingerprinting" to determine the cultures were HeLa cell negative. We observed increased proliferation at low concentrations of TBBPA (10^{-6} µM - 1 µM), whereas higher concentrations (10 µM - 200 µM) decreased growth in 2D cultures of ht-EEC cells. The cells in 3D culture were treated with TBBPA at an concentration of 10^{-3} µM. The RTK arrays revealed TBBPA at 10^{-3} µM upregulated the expression of several activated RTKs, including EGFR, Insulin R and IGF-1R that have been reported to be biological markers of endometrial cancer in women. These data are consistent with what we have found in TBBPA in *utero* and perinatal rat studies, and provide evidence of TBBPA at human-relevant exposure levels may pose a potential hazard for human health, particularly in women. Therefore, this study not only provides a possible mechanism of TBBPA effects on human uterine endometrial cells, but also provides an appropriate 3D in *vitro* model for studying environmental toxicants that target endometrial epithelial cells.

P2348/B600

Appl1 and Akt2 Mediate Non-genomic Progesterone Signaling.

N. Nader[1], M. Dib[1], R. Hodeify[1], A. Al Elmi[1], R. Courjaret[1], A. S. Hammad[1], R. Dey[2], X. Huang[2], K. Machaca[1]; [1]Weill Cornell Medicine - Qatar, Doha, QATAR, [2]Weill Cornell Medicine, New York, NY.

The steroid hormone progesterone (P4) regulates many critical aspects of vertebrate reproductive and general physiology. P4 signaling is mediated through its nuclear receptors to modulate gene expression, or on a more rapid time scale through the so-called non-genomic signaling mediated by membrane P4 receptors (mPRS): α/β/γ/δ/ϵ, among other effectors. Signaling downstream of mPRs remains poorly understood. Here we show that the topology of mPRβ is opposite to that of G-protein coupled receptors (GPCR) with a cytosolic N-terminus and an extracellular C-terminus. Using *Xenopus* oocyte maturation as a well-established physiological readout of non-genomic P4 signaling, we found that mPRβ signaling requires APPL1 (Adaptor Protein containing Pleckstrin homology domain Phosphotyrosine binding domain and Leucine zipper motif 1) and the kinase AKT2. We further show that mPRβ non-genomic signaling requires clathrin-dependent endocytosis that is APPL1 dependent, resulting in a spatially

transient co-localization of mPRβ with the signaling partners APPL1 and AKT2 to mediate downstream signaling. We extended the *Xenopus* oocytes results to mammalian cells and found that APPL1 mediates P4-non genomic signaling in the Glutag enteroendocrine cells. Our findings are first to outline the early steps involved in mPRs non-genomic signaling.

Signaling Scaffolds and Microdomains

P2349/B601

The Role of Membrane Lipids on T Cell Antigen Receptor Triggering.

Y. Zhang, 100101, Y. Zhang, J. Lou; Institute of Biophysics, Chinese Academy of Sciences, Beijing, CHINA.

T cell antigen receptor (TCR) recognizes antigenic peptide conjugated major histocompatibility complexes (pMHC) to trigger T cell activation and induce immune response against invading bactrium or virus. The αβ TCR consists of a variable heterodimer that associates noncovalently with the CD3 and ζζ dimer to form a multisubunit complex across the membrane. Both TCR subunits do not contain any signaling module, its signaling activity depends on CD3s. Upon antigen recognition, the cytoplasmic domain of CD3s will be phosphorylated by Src-family kinase Lck to transduce the signal downstream. Yet how TCRs transmit the antigen recognition signal into the cell across the cell membrane remains elusive. Previous studies suggest that TCRs function as a force sensor, thus it is straight forward to propose that mechanical force may facilitate TCRs' transmembrane signaling. Here by combining molecular dynamics simulation, biochemical and cell biology studies, we found that mechanical force deforms cell membrane which directly leads to membrane reorganization. The reorganized membrane forms microdomain which help to activate both Lck kinase and the CD3 intracellular domains for effective phosphorylation on the various immunoreceptor tyrosine-based activation motifs (ITAM) of CD3s.

Tetraspanin Scaffold Regulation of Epidermal Growth Factor Receptor Organization and Signaling.

S. Restrepo Cruz, S. Pallikkuth, K. A. Lidke, D. S. Lidke, J. M. Gillette; University of New Mexico, Albuquerque, NM.

Molecular interactions on the plasma membrane can significantly influence the outcomes of signaling events crucial to cell function in both normal and disease states. Tetraspanins, a superfamily of transmembrane proteins, play a vital role as scaffolding proteins on the membrane, forming structural platforms termed Tetraspanin-Enriched Microdomains (TEMs). By facilitating compartmentalization, tetraspanins have been shown to act as regulators of cellular signaling, enhancing membrane recruitment of signaling proteins like PKCα, and altering the organization of adhesion molecules like integrin α4. Here, we assess the role of tetraspanin CD82 in the regulation of Epidermal Growth Factor Receptor (EGFR) signaling. Signaling by EGFR, a receptor tyrosine kinase, has been shown to depend on dimerization of receptors and subsequent internalization, processes that are subject to the dynamics of the plasma membrane. Disruption of EGFR signaling has been implicated in many disease states, including various cancers. Genetic and biochemical studies have previously shown that specific tetraspanins can be found to directly and indirectly influence EGFR signaling and internalization. However, the mechanisms by which tetraspanins modulate EGFR signaling are not fully understood. Using direct stochastic optical reconstruction microscopy (dSTORM) to achieve sub-diffraction limit resolution, we mapped the relative organization of EGFR with tetraspanin CD82 on the plasma

membrane of HeLa and HEK293 cells. Pair cross-correlation analysis of the distribution of these molecules reveals a positive association between EGFR and CD82, while clustering analyses show a re-organization of CD82 following EGF treatment. To further analyze the impact of CD82 on the function of EGFR, we generated cell lines overexpressing either CD82 or a CD82 palmitoylation mutant and measured EGFR phosphorylation following EGF stimulation. We find that while CD82 overexpression increases basal EGFR activation, signaling is significantly attenuated following stimulation. Moreover, our data suggests that the attenuation of EGFR signaling by CD82 involves integrin engagement with extracellular matrix. Collectively, these studies suggest that the CD82 scaffold directly interacts with EGFR to regulate signal transduction. Future studies will be directed towards understanding the contribution of tetraspanin-tetraspanin and tetraspanin-cholesterol interactions in the regulation of EGFR signaling and dynamics.

P2351/B603

Nik-related Kinase Suppresses Cell Proliferation by Modulating CK2-PTEN-Akt Signaling Pathway.

S. Naito, A. Endo, K. Denda, Y. Madoka, A. Kato, M. Komada, T. Fukushima; Tokyo Institute of Technology, Kanagawa, JAPAN.

Nik-related kinase (Nrk) is one of Germinal Center Kinase family proteins. Nrk expression is restricted to a few tissues including placenta and mammary gland. We had shown that Nrk plays important roles in the prevention of the development of placental hyperplasia and breast cancer. In this study, we investigated the mechanisms by which Nrk suppresses cell proliferation. Nrk harbors a kinase domain at the N-terminal region and uncharacterized CNH domain at the C-terminal region. We generated HEK293 cells with the doxycycline-inducible expression of Nrk or the mutants. The expression of wild-type Nrk suppressed cell proliferation and decreased Akt phosphorylation without affecting Erk phosphorylation. The expression of kinase-dead Nrk or a truncated form of Nrk lacking the kinase domain also suppressed cell proliferation and decreased Akt phosphorylation, indicating a kinase-independent action of Nrk. Neither truncated forms of Nrk lacking the middle region nor the CNH domain affected cell proliferation and Akt phosphorylation, indicating the requirement of these regions for Nrk action. Immunostaining analyses revealed that wild-type Nrk is localized at the plasma membrane in HeLa cells, and the CNH domain is required for the localization. To elucidate detailed mechanisms by which Nrk inhibits Akt signaling at the plasma membrane in a kinase-independent manner, we tried to identify Nrk-interacting proteins. Co-immunoprecipitation and LC-MS analyses revealed that Nrk interacts with casein kinase-2 (CK2). We confirmed that Nrk interacts with CK2 beta subunit by co-immunoprecipitation and immunoblotting, and found that the middle region of Nrk is required for the interaction. It is known that CK2 phosphorylates C-terminal sites of PTEN and inhibits PTEN activity, leading to the accumulation of PIP3 followed by enhanced Akt signaling. We found that doxycycline-induced expression of wild-type Nrk in HEK293 cells decreased PTEN phosphorylation at the C-terminal site as well as Akt phosphorylation, suggesting PTEN activation. The treatment with a PTEN inhibitor VO-OHpic restored Akt phosphorylation in Nrk-expressing cells, not in control cells. Taking these results together, we propose the following model by which Nrk suppresses cell proliferation: 1) Nrk is localized at the plasma membrane via the CNH domain; 2) Nrk interacts with CK2 via the middle region, and possibly inhibits CK2 activity; 3) Nrk thereby modulates CK2-PTEN-Akt signaling pathway at the plasma membrane and decreases Akt-mediated proliferative signaling, leading to the suppressed cell proliferation. Possibly through these mechanisms, Nrk prevents the development of placental hyperplasia and breast cancer.

P2352/B604

IQGAP1 Scaffolding Connects EGFR and Phosphoinositide Signaling to Cytoskeletal Reorganization.

V. S. Yerramilli[1], A. H. Ross[1,2], J. L. Reisinger[1,3], S. Scarlata[1], A. Gericke[1]; [1]Worcester Polytechnic Institute, Worcester, MA, [2]University of Massachussetts Medical School, Worcester, MA, [3]University of Alaska an chorage, an chorage, AK.

IQGAP1 is a multi-domain protein that acts as a scaffold for multiple signaling pathways, especially in cancer cells where it is seen to be overexpressed. While IQGAP1 is known to generate the lipid messenger PI(3,4,5)P_3 by scaffolding the phosphoinositide kinases PIPKIs and PI3K, the dynamics of this scaffold in intact, living cells remains unknown. Here, we delineate the spatial and temporal effects of IQGAP1 signaling in live cells under basal and stimulated conditions using fluorescence lifetime imaging microscopy and other biophysical techniques. We observe EGF-mediated changes in both IQGAP1 and EGFR distribution and see that IQGAP1 is involved in EGFR clustering. We also demonstrate that IQGAP1 interacts strongly with PIPKIγ at intracellular compartments and at the plasma membrane, and that it scaffolds PI3K and PIPKIγ in response to certain physiological changes. Additionally, we show that IQGAP1 scaffolds phosphoinositides with PI3K, PIPKIγ and EGFR, and forms clusters upon cell stimulation with EGF. Importantly, we show that IQGAP1 connects PI(3,4,5)P_3-mediated signaling and cytoskeletal signaling pathways by binding PIPKIγ in proximity of the cytoskeletal proteins talin and Cdc42. Our results support a model in which IQGAP1 mediates crosstalk between EGFR receptor activation, phosphoinositide signaling and the cytoskeleton.

P2353/B605

Localized Intercellular Transfer of Ephrin-As by Trans Endocytosis Provides a Memory of Signaling.

J. I. Valenzuela, **F. Perez**; Institut Curie / CNRS, Paris, FRANCE.

Alterations in different biosynthetic trafficking routes lead to losses in cellular polarity, which represent the earliest stages of carcinogenesis. We focused on the trafficking pathways of the tyrosine kinase receptor EphA2 and its membrane-bound ligand ephrinA1. EphA2 is frequently overexpressed in melanoma, gliomas, and around 10 different types of carcinomas where its levels are associated with poor prognosis. The colocalization of EphA2 with the basolateral protein E-cadherin and the presence of an usually apical sorting motif (GPI anchor) in ephrinA1 strongly suggest that both proteins are segregated from each other in their journey to the plasma membrane. To be able to study specifically, quantitatively and in real-time specific trafficking pathways our laboratory has developed a system called RUSH (Retention Using Selective Hooks), which allows to synchronize the secretion of virtually any protein. By using the RUSH system, we demonstrated that EphA2 and ephrinA1 have different kinetics of transport and are partially sorted from each other at the level of the Golgi apparatus. Upon arrival to the plasma membrane, we observed that ephrin A1/EphA2 complexes are locally formed at the tip of filopodia, at cell-to-cell contacts. Clusters of ephrin A1 from donor cells surf on filopodia associated to EphA2-bearing sub-domains of acceptor cells. Full-length ephrin A1 is transferred to acceptor cells by trans endocytosis through a proteolysis-independent mechanism. Trans-endocytosed ephrin A1 bound to its receptor enables signaling to be emitted from endo-lysosomes of acceptor cells. Localized trans-endocytosis of ephrin-A1 sustains contact-mediated repulsion on cancer cells. Our results uncover the essential role played by local concentration at the tip of filopodia and the trans-endocytosis of full-length ephrin to maintain long-lasting ephrin signaling.

P2354/B606

Cd47 Positions Sirpa to Prevent Integrin Activation and Engulfment.

M. A. Morrissey, R. D. Vale; UCSF, San Francisco, CA.

Macrophages must engulf dead cells, debris, and pathogens, while selecting against healthy cells to prevent autoimmunity. Healthy cells express CD47 on their surface, which activates the SIRPA receptor on macrophages to suppress engulfment. Cancer cells overexpress CD47 to evade clearance by the innate immune system, making the CD47-SIRPA signaling axis an appealing therapeutic target. However, the mechanism by which CD47-SIRPA inhibits engulfment remains poorly understood. Here, we dissect SIRPA signaling using a reconstituted target with varying concentrations of activating and inhibitor ligands. We find that SIRPA is excluded from the phagocytic synapse between the macrophage and its target unless CD47 is present. Artificially directing SIRPA to the kinase-rich synapse in the absence of CD47 activates SIRPA and suppresses engulfment, indicating that the localization of the receptor is critical for inhibitory signaling. CD47-SIRPA inhibits integrin activation in the macrophage, reducing macrophage-target contact and suppressing phagocytosis. Chemical activation of integrins can override this effect and drive engulfment of CD47-positive targets, including cancer cells. These results suggest new strategies for overcoming CD47-SIRPA inhibition of phagocytosis with potential applications in cancer immunotherapy.

P2355/B607

The Role of Non-motif Selectivity Determinants in Peptide-binding Domain Interactions.

M. Gao; Western Washington University, Bellingham, WA.

An important class of protein-protein interactions in the cell involve recognition of short linear motifs (SLiMs) or peptides which often have a relatively weak affinity and are transient. Dysregulation of SLiM-binding domains and target interactions are implicated in a number of human diseases. Due to the recognition of only a couple of amino acid positions by SLiM-binding domains, interaction networks overlap and specific targeting is hard to achieve. The PDZ domain was used as a model system in order to define the role of non-motif selectivity determinants in SLiM- or peptide-mediated interactions. They recognize the extreme C-terminus of target proteins and binding motifs are based on only two residues. Dissecting the binding networks of over 250 PDZ domains using only motif preferences is impossible. Likewise, two sequences can bind drastically different numbers of PDZ domains. For example, the C-terminal sequence of the human papillomavirus E6 oncoprotein (HPV16 E6) interacts with over a dozen PDZ domain-containing proteins, while the C-terminal sequence of cystic fibrosis transmembrane conductance regulator (CFTR) interacts with less than five, yet both contain identical motif residues. We reveal that single-residue substitution of peptides and structural biology allow us to determine non-motif selectivity determinants for multiple PDZ domains that target the HPV16 E6 oncoprotein. In addition, we present the first known crystal structure of a PDZ domain from choanoflagellates, our closest non-metazoan ancestor, and describe non-motif selectivity determinants in these unique organisms. We show that non-motif specificity is critical in order to characterize SLiM interactions networks in the cell.

Syndecan-4 Proteoglycan Regulates Caveolin1 Expression in Endothelial Cells.

T. Bergonci[1,2], M. Meneghetti[2], R. Cavalheiro[2], L. Teixeira[2], H. Nader[2]; [1]UCSD/SDSC, NIST, San Diego, CA, [2]Federal University of São Paulo, São Paulo, BRAZIL.

Syndecan-4 (Syn4) is a transmembrane heparan sulfate proteoglycan that has been shown to regulate focal adhesions and to play a crucial signaling center for proper communication between intracellular, cell-surface and cell-extracellular matrix. Normal vascular endothelial cells (EC) from rabbit aorta and Syn4 knockdown cells (shRNA-Syn4-EC) were transfected with vectors encoding caveolin1 targeted with mCherry fluorescent protein (CAV1-mCherry) and clathrin light chain targeted with mRFP fluorescent protein (CLC-mRFP). Cells were cultured in glass coverslips (12 mm, 3 days) in F12 medium supplemented with 10% fetal serum bovine, streptomycin and penicillin (both 100 IU/mL) at 37ºC in a humidified atmosphere (2.5% of CO_2). DAPI was used to stain nucleus. Images were captured to in *vivo* cells with a confocal scanning microscope equipped with a Plan-Apochoromat x63 objective (numerical aperture 1.4) under oil immersion. Heparitinase I and heparitinase II were heterologous produced. CAV1-mCherry and CLC-mRFP cells were treated with heparitinase I and II for 30 minutes and images were taken every 2 minutes. Total RNA were extracted from EC and shRNA-Syn4-EC cells and both semi-quantitative (RT) and quantitative (q; real-time) polymerase chain reaction (PCR) were performed. Total proteins were extracted from EC and shRNA-Syn4-EC cells and western blot were performed. Our results show that lack of Syn4 decreases Caveolin1 gene and protein expression. CAV1-mCherry cells treated with heparitinase I and II change Caveolin1 clusters dynamics in 10 minutes. Syn4 knockdown also induces C-myc, C-myb and Ebf2 transcription factor expression and downregulates Gata3 and microRNA204 expression. The gathered data shows the pivotal role of Syn4 in cell signal transduction and further pinpoint its importance for Caveolae clusters dynamics.

Ultrafine Carbon Black Promotes Lysosomal Membrane Permeabilization and Nlrp3 Inflammasome Activation.

S. H. Ball, J. L. Hibma, A. E. Rogers, **J. L. Brewster, 90263-3999**; Pepperdine University, Malibu, CA.

Carbon black (CB) particulates are a central component of diesel exhaust, and a major airborne pollutant of ultrafine particulate matter. CB exposure contributes to the adverse health effects of pollutants upon the lungs, heart, and nervous system. A primary source of damage is the chronic inflammation induced by exposure to airborne particulates. To examine the capacity for ultrafine CB (~30-130 nm in diameter) to accumulate in macrophage and to stimulate pro-inflammatory signaling, RAW264.7 mouse macrophage and THP-1 human monocytes were used. CB particles were hypothesized to enter immune cells by endocytosis where they accumulate, and larger particles are visible within vesicles and cytosol. The accumulation of CB in RAW264.7 cells was evaluated over a 36-hour period. At specific time points, cells were washed extensively and then lysed to release cellular components. Accumulated particulates were purified from lysates via centrifugation, and then quantified via absorbance readings (A595). Particles were shown to accumulate gradually over time, with significant accumulation being detected after 2 hours of exposure with doses of 25, 50 and 100 ug/ml. Additional studies used THP-1 monocytes to evaluate inflammasome signaling. THP-1 monocytes were stimulated with phorbol-12-13-acetate (PMA) to induce differentiation and adherence. To evaluate the hypothesis that CB accumulation impacts membrane integrity in lysosomes and phagolysosomes we assessed cathepsin B release into the

cytosol and Galectin-3 localization to lysosomal vesicles. Each of these assays provided support for a model of CB-induced lysosomal membrane permeabilization (LMP). In addition to LMP, we hypothesized that CB could stimulate the assembly of the inflammasome and a subsequent production and release of IL-1β. Differentiated THP-1 cells were stimulated with lipopolysaccharide (100ng/ml) to upregulate expression of inflammasome components such as NLRP3 and ASC proteins. Assessment of inflammasome assembly and activity was determined by measuring ASC oligomerization, formation of cytosolic ASC "specks", and accumulation of IL-1β in the extracellular environment. An alysis of ASC oligomerization as well as fluorescent tagging of ASC oligomer complexes (specks) provided some evidence for CB activation of the inflammasome, though a clear potential for LPS to similarly stimulate the inflammasome was observed. Further evaluation of these conditions and results will be discussed at the poster session. The future direction of this work will focus upon upstream mechanisms of inflammasome signaling that are affected by CB accumulation.

Mechanically Driven Cellular Competition Promotes the Collective Extrusion of Bacteria-infected Epithelial Cells.

E. E. Bastounis[1], P. Rhadhakrishnan[1], P. Engström[2], F. Alcalde[3], M. J. Gómez Benito[3], J. M. García Aznar[3], M. D. Welch[2], J. A. Theriot[1]; [1]University of Washington, Seattle, WA, [2]University of California, Berkeley, Berkeley, CA, [3]University of Zaragoza, Zaragoza, SPAIN.

Intracellular bacterial pathogens often alter the behavior of their host cells, including their mechanics, to promote their own survival and spread. For instance, food-borne *Listeria monocytogenes* secretes effector proteins that loosen the cortical tension of infected epithelial cells facilitating its spread from cell to cell or through basement membranes. What is less clear is whether host cells are capable of changing their biomechanics in response to infection in a way that would benefit the host by limiting bacterial spread. Inspired by this question, we followed Madin-Darby Canine Kidney epithelial cell monolayers infected with low levels of *L. monocytogenes*over the course of 3 days. We found that, as the bacteria replicate and spread intercellularly, the host cells containing bacteria get progressively squeezed by surrounding uninfected cells. Surrounding uninfected cells become highly migratory, elongate perpendicular to the tangent of the focus, and squeeze the infected cells that eventually get extruded. Extruded cells continue adhering to the cellular monolayer giving rise to "mounds" of infected cells. We hypothesized that cellular compression and extrusion of infected cells is driven by changes in the mechanics of uninfected and infected cells. Indeed, when we measured the traction forces that cells exert while residing on deformable matrices mimicking their natural environment, we found that infected cells weaken their cell-substrate adhesion-dependent forces over time as compared to nearby uninfected cells. Concurrently, infected cells get softer than surrounding uninfected cells, and collectively the monolayer behaves more like a fluid with a higher diffusion coefficient as compared to more solid-like cells from an uninfected monolayer, a behavior reminiscent of the jamming-unjamming transition. We are using 3D agent-based modeling to model infection-driven cellular extrusion in order to understand how changes in cellular stiffness, cell-matrix and cell-cell forces alone and synergistically can drive the observed cellular competition between infected and uninfected cells. The goal is to uncover how the mechanical forcesthat lead tothe creation of extrusion domains of infected cells are coordinated with the underlying biochemical changes associated with infection, and in particular with

innate immune defense pathways and NF-kB activation. Overall, our findings underline the dynamic remodeling capability of epithelial tissue and might hint at a potential mechanism employed by host epithelial monolayers to contribute to elimination of infected host cells.

Hydrostatic Pressure Gradient Causes Spatio-Temporal Calcium Oscillations and Alters Apico-Basal Polarity in Renal Epithelial Cells.

M. Choudhury[1], Y. Li[1], P. Mistriotis[1], E. Dixon[2], D. Maity[1], M. Benson[1], F. Qian[2], O. Woodward[2], K. Konstantopoulos2[1], S. Sun[1]; [1]Johns Hopkins University, Baltimore, MD, [2]University of Maryland, Baltimore, MD.

Using a novel microfluidic platform to recapitulate fluid transport activity of epithelial cells, we report that MDCK-II and human primary kidney epithelial cells can actively generate hydraulic pressure gradients across the epithelium. The fluidic flux declines with increasing hydraulic pressure until a stall pressure, at which the fluidic flux vanishes--in a manner similar to mechanical fluidic pumps. The developed pressure gradient translates to a force of 50-100 nanoNewtons per cell. For MDCK-II epithelium, basolateral hydrostatic pressure gradients lead to high frequency spatial and temporal calcium oscillations. Extracellular calcium chelation and inhibition of mechanosensitive ion channels indicate that local stretch in the plasma membrane due to fluid pressure caused intracellular calcium enrichment. Hydrostatic pressure also caused cell height to double within 15 minutes and subsequently recovered in 60 minutes. Change in cell height was coupled with high frequency plasma membrane invaginations, rapid F-actin turnover and decreased Na^+/K^+ ATPase expression on the basolateral domain. These results, together with data from osmotic and pharmacological perturbations of fluidic pumping, implicate a novel mechanism of mechanosensation, and provide further insights into the regulation of fluid transport in epithelial cell.

Epithelial Tissue Geometry Directs Emergence of the Bioelectric Field and Patterns of Growth.

B. B. Silver, C. M. Nelson; Princeton University, Princeton, NJ.

Cellular membrane voltage (Vm), defined as the electric potential difference between the cytoplasm and extracellular medium, forms gradients of bioelectricity across tissues. Manipulating Vm and the resulting bioelectric field powerfully influences proliferation, regeneration, and tumorigenesis at the tissue-scale. However, it remains unclear how Vm is coordinated to produce bioelectric gradients across tissues, or whether Vm is impacted by other factors in the cellular microenvironment, such as mechanical stress. Here, we used micropatterned epithelial tissues to investigate the relationship between tissue geometry, mechanical stress, and patterns of Vm. We found that cells located in high-stress regions of mammary epithelial tissues are more positively charged, or depolarized than those in low stress regions. This pattern of Vm correlates with the pattern of proliferation in the tissue. Inhibiting mechanical force transmission by deleting or mutating E-cadherin abolished the patterns of Vm and proliferation gradients within the tissues. These data suggest a role of mechanical force in the emergence of bioelectric fields. We further determined that intracellular Ca^{2+} is required for regulation of Vm by tissue geometry, implying a connection between bioelectricity and proliferation via calcium signaling in the context of mechanical force. Our data suggest that tissue geometry controls bioelectric gradients and proliferation through patterns of mechanical stresses.

P2361/B614

Role of Linker of Nucleoskeleton and Cytoskeleton (LINC) Complex in Endothelium Homeostasis.

K. DENIS; Virginia Commonwealth University, Richmond, VA.

The linker of nucleoskeleton and cytoskeleton (LINC) complex is localized in nuclear membrane and plays a central actor for forces transmission between nucleus and cytoskeleton. The LINC complex is composed by two major components, SUN proteins and KASH proteins, that making the link between nucleoskeleton and cytoskeleton respectively. In different cellular contexts, this complex is known to play a crucial role in cellular organization, cell polarity, cellular motility and DNA stability.We hypothesized that the LINC complex is important in the physiology of vascular cells. Endothelial cells, as the inner most cell layer in blood vessels, are subject of different mechanical stresses imparted by blood flow, as stretch and pressure. In this study, we investigate the importance of the LINC complex, using dominant negative KASH (DN-KASH) to disrupt the LINC complex in human umbilical vein endothelial cells (HUVEC). Expression of DN-KASH expression alters intercellular junction establishment, as well as the responses of cell-cell contacts to cytokine challenge. In addition, disruption of the LINC complex induces cell detachment under arterial levels of fluid shear stress. Taken together our results show that the LINC complex is necessary for endothelial stability, including cell-cell and cell-matrix adhesions. We are currently investigating the hypothesis that a cytoskeleton-nucleoskeleton disconnection induces an aberrant forces distribution in endothelial cells by a loss of mechanical “feed-back”, leading to an alteration of endothelium stability and associated functions.

P2362/B615

How Adherent Cells Reorient in Response to Cyclic Stretching.

J. Lien, Y. Wang; Carnegie Mellon University, Pittsburgh, PA.

Mechanical stimulation by forces transmitted through the surrounding solid and fluid materials plays an important role in regulating the function of many tissues from the subcellular to organ level. Intriguingly, while cells often respond to non-cyclic mechanical cues along the direction of stimulation, adherent cells often reorient perpendicularly to the direction of uniaxial cyclic stretching. While this phenomenon has been documented for decades, the underlying control mechanism remains poorly understood. To address this question, we have developed a simple on-stage stretching approach that allows programmable stretching-relaxation and synchronized imaging of cells cultured on polyacrylamide substrates. We observed that the reorientation of NRK epithelial cells involves shortening along the direction of stretching (referred to as longitudinal) and extension perpendicularly to the direction stretching (referred to lateral). Using substrates with micropatterned lines to constrain cell shape, we found that these responses are independent of each other such that lateral elongation may take place without longitudinal shortening, and vice versa. By analyzing differences of images collected at the beginning and end of stretching or relaxation phases, we show that lateral elongation takes place predominantly during the relaxation phase, indicative of a global shortening signal that takes effect during both stretching and relaxation phases in conjunction with a lateral elongation signal that takes effect only during the relaxation phase. By systematically varying the duration of stretching or relaxation phases while analyzing the cell orientation parameter, $\cos 2\theta$, we show that optimal lateral elongation requires a specific duration of stretching such that the effect diminishes upon prolonged stretching phase. Similarly, at a given length of stretching, the effect on lateral elongation dissipates upon

prolonged relaxation. Together, these results suggest that stretching generates a transient global retraction signal that takes effect right away, and a latent lateral elongation signal that primarily takes effect during the following relaxation phase. In conclusion, the net effect of reorientation is determined by the interplay of these retraction and elongation signals and their respective kinetics of generation and degradation, in conjunction with the adaptation of cells to a stretched substrate through the formation of new adhesion structures.

Cellular Realignment Upon Applied Stress in Three-dimensional Microtissues.

A. Opathalage[1,2], A. Lammers[1,2], S. Ghilardi[1,2], B. O' Reilly[1,2], C. Huyan[1,2], A. E. Sgro[1,2,3]; [1]Department of Biomedical Engineering, Boston University, Boston, MA, [2]Biological Design Center, Boston University, Boston, MA, [3]Department of Physics, Boston University, Boston, MA.

Multicellular tissue self-assembly at the cell-cell and cell-matrix levels is governed by chemical and mechanical cues. A major mechanical cue that controls tissue integrity and is a probable inducer of cell alignment in processes such as vasculogenesis is stress stimulation. To study the role of stress stimulation, high-throughput mechanical conditioning assays have been developed for systems ranging from centimeter-scale to submillimeter-scale tissues. However, currently these systems are limited to applying uniaxial stresses. To address this limitation, we designed and fabricated a high-throughput and easy-to-implement pneumatically-controlled microfluidic module integrated with square-shaped microtissues formed with 3T3 fibroblasts in type I collagen adapted from Legant, W. R. et al. Proc. Natl Acad. Sci. 2009. This microfluidic system has wells underneath the pillars supporting the tissues and as vacuum is applied, the wells in the device evacuate and the thin membrane between the wells and pillars deflects, stretching the microtissue seeded on it. The placement of the wells controls the direction of the stress, allowing induction of stress in multiple directions. Using this device, we investigate the role stress stimulation plays in cell realignment. We quantify the coarse-grained cell orientation field using the nematic order parameter $Q = (\langle \cos 2\theta \rangle^2 + (\langle \sin 2\theta \rangle^2)^{1/2}$ with Q ranging from 0 to 1 where Q=1 is perfect alignment. Under no stress, square tissues have disordered cells in the center due to the isotropic arrangement of the pillars. Upon cyclic stretch, we observe high cell alignment in the center with $Q = 0.87 \pm 0.02$ as compared to the non-stretched control tissues of $Q = 0.49 \pm 0.04$. Our microfluidic platform provides a robust method to induce stress stimulation in three-dimensional microtissues and permits quantitative studies of fundamental cellular mechanics.

Spatiotemporally Distinct Cell Behaviors Drive Multilayered Tissue Spreading.

H. Y. Kim, S. Jung; Institute for Basic Science (IBS), Daejeon, KOREA, REPUBLIC OF.

Spreading of embryonic tissue plays a critical role to construct various shapes of body parts during development, yet little is known about the cellular mechanisms that drive multilayered tissue spreading. Here we take advantage of the multilayered ectoderm tissue isolated from an early stage of Xenopus embryo that autonomously spreads out on the fibronectin-coated substrate similar to in vivo. Quantification of tissue spreading using particle image velocimetry (PIV) indicates the emergence of directed tissue movements along the edge at around 6 hours after spreading which is coincide with elevated nuclear YAP localization. We begin to dissect the role of cell behaviors including directed cell movement, cell division, and radial intercalation that can contribute to the mechanically distinct phase

of tissue spreading. Quantifying tissue spreading ratio, cell displacements, spatiotemporal patterns of cell behaviors combined with altered F-actin dynamics, cell divisions, and intercalations propose distinct contributions of cell behaviors at different stages of multilayered tissue spreading. Our integrative analysis of spatiotemporally distinct cell behaviors during multilayered tissue spreading will provide fundamental insight for morphogenesis, disease progression, and tissue engineering.

P2365/B618

Tissue Mechanics in Initiation and Propagation of Epithelialization on the Surface of Deep Ectoderm Aggregates.

H. Kang, H. Y. Kim; Institute for Basic Science (IBS), Daejeon, KOREA, REPUBLIC OF.

Cells in our body are highly plastic which can switch their phenotypes in the range from mesenchymal to epithelial as they needed. Our previous study shows that tissue mechanical property and cell contractility play a critical role for epithelialization on the surface of deep ectoderm aggregates generated from early Xenopus laevis embryo. However, it is still vague how local tissue mechanics may direct the initiation and propagation of epithelialization to cover the entire surface of the embryonic aggregates. Using RFP-ZO1 we follow the spatiotemporal dynamics of epithelialization on the surface of the deep ectoderm aggregate and begin to find single or patches of epithelial cells emerge from 2 hours-post-aggregation (hpa). Newly epithelialized cells often laterally added to existing epithelial cells. Groups of epithelial cells merge and expand to cover the aggregate surface. To understand the role of local cell contractility to initiate and propagate the observed epithelialization, we adopted optogenetics using Cry2-RhoA. With blue light Cry2-RhoA clustered and located to the membrane that consequently induce cell contractility and shrinkage of the cell size by ~15%. This in *vitro* system of live embryonic aggregates that can regenerate new epithelium combined with optogenetics provides a platform to interrogate the correlation between local tissue mechanics and epithelialization.

Substratum Stiffness Regulates Erk Signaling Dynamics in Mammary Epithelial Tissues.

P. E. Farahani, J. E. Toettcher, C. M. Nelson; Princeton University, Princeton, NJ.

The Ras/Erk signaling cascade is critical for tissue development and homeostasis, and coordinates the growth, proliferation, and migration of cells. Aberrations in Erk signaling result in developmental disorders and promote uncontrolled cell growth and proliferation, which are hallmarks of cancer. Efforts to understand the dynamics of Erk signaling have largely focused on how growth factor stimulation influences the dynamic output of Erk activity. However, Erk dynamics also appear to be influenced by mechanical stimuli. We investigated the influence of substratum stiffness on Erk dynamics by culturing mammary epithelial cells on substrata of different stiffnesses and monitoring Erk dynamics at the single-cell level using a kinase translocation reporter. Cells cultured under high growth factor concentrations exhibited pulsatile Erk dynamics whose amplitude and frequency increased as substratum stiffness increased. Similarly, stimulating growth factor-starved cells with epidermal growth factor (EGF) on soft substrata resulted in a low-amplitude, transient Erk activation, in contrast to the high-amplitude, sustained Erk activation in cells on stiffer substrata. Using optogenetics to acutely stimulate Ras produced a sustained Erk response irrespective of substratum stiffness, suggesting that the mechanical microenvironment regulates Erk signal transmission at nodes upstream of Ras. Consistently, we found that EGFR expression is significantly decreased in cells cultured on soft substrata, which might account

for the increases in EGFR phosphorylation and downstream Erk activation in cells on stiff substrata. Taken together, our work establishes a framework for how biochemical and mechanical stimuli are combinatorially interpreted by cells to regulate Erk signaling dynamics.

Atomic Force Microscopy Measurements of Lung Tissue.

N. Chada[1], L. Hapach[1,2], S. Schwager[1], P. Massion[3], C. Reinhart-King[1]; [1]Vanderbilt University, Nashville, TN, [2]Cornell University, Ithaca, NY, [3]Vanderbilt University Medical Center, Nashville, TN.

Matrix stiffness is critical for the proper phenotypic behavior of cells. This is also true for cancer cells as cancer cell function is modulated by matrix stiffness. Recent attention has been given to the mechanical properties of the tumor microenvironment, which includes blood vessels, immune cells, and the extracellular matrix, and how it can affect cancer cell proliferation, extravasation, migration, and other processes in the metastatic cascade. Studies have shown that a stiffer tumor microenvironment promotes cancer progression and cell migration in addition to contributing to other microscopic and macroscopic changes in the cell and tissue architecture. Several studies have attempted to quantify the tumor microenvironment stiffness and in doing so, have employed a variety of techniques and methods. However, there exists a wide range of values reported for similar tissues. Thus, accurate and precise ways to measure matrix stiffness must be developed. Here, we find that tissue preparation prior to mechanical testing significantly impacts the elastic modulus value obtained. We use atomic force microscopy to measure the elastic modulus of fresh mouse and human lung tissues. We test samples that are cryopreserved, fixed with paraformaldehyde or infiltrated with sucrose. Our data indicate that time post-mortem and fixation alter mechanical properties. We also find that sectioning the tissue before mechanical measurement as opposed to measurement on the bulk sample affects the measured stiffness values. Further, our data indicate that the method of sample preparation can alter the micromechanical properties of lung, and reproducibility of measurements relies on consistency of preparation protocols.

P2368/B621

Extracellular Matrix Stiffness Regulates Chondrocyte TRPV4 Activity.

N. S. Trompeter[1], R. Skinner[1], M. Griffin[1], C. J. Farino[1], O. A. Banda[1], J. H. Slater[1], J. P. Gleghorn[1], R. L. Duncan[2,1]; [1]University of Delaware, Newark, DE, [2]University of Michigan at Flint, Flint, MI.

Osteoarthritis (OA) is the most common joint disorder in the United States, affecting over 54 million adults. During the development of OA, the stiffness of the extracellular matrix (ECM) of cartilage decreases due to a degradation of both collagen type 2 and proteoglycans. The Transient Receptor Potential Vanilloid 4 (TRPV4) channel plays a crucial role in the development, function, and mechanosensation of cartilage through its conductance of calcium. Whereas altering matrix stiffness changes the function and phenotype of chondrocytes, few studies have investigated the role ECM stiffness has on TRPV4-mediated calcium signaling and chondrocyte function. We postulated that ECM stiffness would modulate TRPV4 activity to alter chondrocyte phenotype and function. Here we show that decreasing the ECM stiffness, modeled by poly(ethylene-glycol) (PEG) hydrogels, reduces the responsiveness of TRPV4 to hypotonic challenge. PEG-diacrylate (PEG-DA) hydrogels were made using weight percentages of 14.1% (350kPa), 9.8% (175kPa), and 5.2% (35kPa) of PEG-DA were used to mimic normal, arthritic, and severely arthritic cartilage, respectively. ATDC5 chondrocytic cells seeded on the

hydrogel surface were loaded with Fluo-4 before recovering in either HBSS or 100nM GSK2193874 (GSK219), a TRPV4 specific antagonist, before challenge with 50% hypotonic swelling (HTS). The normalized intracellular calcium influx of the cells demonstrate significant differences based on the stiffness of the gels. Cells grown on the 350 kPa gels show significantly higher responses to HTS when compared to cells grown on the other gels. Additionally, cells grown on the 175 kPA gels show a significantly greater response to HTS when compared to cells grown on the 35kPA gels. Inhibition of TRPV4 with GSK219 significantly suppressed the response of cells to HTS when they were seeded only on the normal and OA gels. The balance of TRPV4 activity may play a key role in the progression of OA, as other studies indicate ablation or over-activation of TRPV4 cause deleterious effects on the phenotype of chondrocytes. Further studies will explore the role of ECM stiffness on TRPV4 and chondrocyte function and phenotype. Our findings indicate that as the stiffness of the ECM decreases, the response of chondrocytes to HTS is suppressed in a TRPV4-dependent mechanism.

P2369/B622

Substratum Stiffness Regulates TRPV44 4 Activity in Lung Epithelial Cells: Implications for Lung Development.

N. Trompeter, C. S. Millar-Haskell, J. P. Gleghorn; University of Delaware, Newark, DE.

Transient Receptor Potential Vanilloid 4 (TRPV4) is a mechanosensitive non-selective ion channel that is highly expressed in the lung and has been implicated in pulmonary fibrosis, hypertension, and mechanical ventilation barotrauma in premature babies. While implicated in a variety of lung pathologies, the role of TRPV4 in lung development is still unclear. Our lab has previously shown that TRPV4 is present in the embryonic lung and that it regulates airway branching and maintenance of the pulmonary vasculature during development. However, the signaling mechanism through which TRPV4 regulates these functions remain unknown. Given that cell contractility, basement membrane thinning, and correct spatial deposition of extracellular matrix (ECM) proteins are required for proper airway branching morphogenesis, we sought to understand the role of ECM stiffness in altering lung epithelial cell signaling. Whereas Rahaman et al. 2016 have shown that the response to TRPV4 agonism decreases with decreasing ECM stiffness in fibroblasts isolated from fibrotic lung tissue, TRPV4 response has yet to be studied in lung epithelial cells. We hypothesize that decreasing matrix stiffness will alter the responsiveness of lung epithelial cells to TRPV4 agonism. Here we demonstrate that that decreasing the ECM stiffness, modeled by polyacrylamide gels, reduces the responsiveness of TRPV4 to antagonism. Mouse lung epithelial (MLE) cells were seeded on top of polyacrylamide gels of different stiffnesses (2 kPa, 10 kPa, and 40 kPa) and fuctionalized with fibronectin. MLE cells were cultured for 4 days and loaded with Fluo-4 AM to assess intracellular calcium influx. MLE cells were then imaged on a Zeiss AxioObserver Z1 and challenged with 25 µM RN-1747, a TRPV4 specific agonist, and intracellular calcium was measured over a ten minute period. Our results demonstrate that as substratum stiffness decreases, MLE calcium influx decreases with TRPV4 agonism. Cells on the 40 kPa gels had the highest sensitivity to TRPV4 agonism with the largest number of cells responding and the largest transient calcium peaks. Whereas MLE cells grown on both the 2 kPa and 10 kPa responded to TRPV4 agonism, fewer cells responded and the transient calcium influxes were attenuated. These data suggest that ECM stiffness regulates the activity of TRPV4 in mouse lung epithelial cells to modulate epithelial Ca^{2+} signaling. These data, in combination with our previous work, demonstrate an important role for spatial patterning of the ECM and TRPV4 activity in regulating proper lung development.

P2370/B623

Study of Mechanical Response of Hepatic Cell Line C9 to Substrate Stiffness.

L. Cabriales, **M. Hautefeuille**, G. Vazquez-Victorio, D. Martinez-Pastor, N. Vazquez, M. Macias-Silva; Universidad Nacional Autónoma de México, Mexico, MEXICO.

Mechanical interactions are key mediators of cellular processes such as proliferation, differentiation, motility and quiescence. Thus motivating the use of substrate stiffness control for mechanotransduction studies showing that lower stiffness is expected to maintain epithelial phenotype and may induce a modification on mesenchymal phenotype as well. Although the stiffness values for different types of adherent cells vary widely, it is generally true that cell proliferation and differentiation increase with matrix stiffness. For most of these studies, researchers have used a wide variety of immortalized cell lines in order to guarantee experiment reproducibility from one laboratory to another. However, these cell lines were developed to survive and proliferate on commercial dishes and well plates made with very stiff materials, hence restraining their mechanical response. In particular, C9 hepatic cell line is a highly proliferative cell primed on stiff materials and a great substrates adhesion capacity when compared to other lines such as HepG2.In this work, we studied the mechanical response of C9 cells cultured on soft PDMS substrates (Young's Modulus ranging between 24 - 232 kPa) compared to a Petri dish (GPa). It was observed that by decreasing the rigidity of the substrate, it is possible to modulate the proliferation rate without decreasing cell viability. A decrease in phospho-Erk1/2 measured by Western Blot suggested that MAPK signalling pathway may be responsible for proliferation regulation rather than Hippo pathway. In spite of the epithelial morphology presented in these cells, Western blot characterization revealed that C9 presented a mesenchymal phenotype rather than epithelial. Interestingly, when maintaining the line during several passes (up to 10) on soft PDMS, C9 cells unexpectedly acquired an elongated morphology and re-established their proliferation rate as if cultured on rigid substrates. Expression levels of α-SMA in passage 10 showed by Western blot characterization suggested that cells underwent a transdifferentiation to myofibroblast. This results raise important questions regarding the use of cell lines for stiff substrates and priming on soft substrates.

P2371/B624

Effect of Substrate Stiffness and TGF-β Factor on EMT in Primary Rat Hepatocytes.

B. Díaz-Bello[1], M. Macías-Silva[2], G. Vázquez-Victorio[1], M. Hautefeuille[1]; [1]LaNsBioDyT, Facultad de Ciencias, UNAM, Mexico, MEXICO, [2]Instituto de Fisiología Celular, UNAM, Mexico, MEXICO.

Primary hepatocytes are epithelial cells that, when seeded on rigid substrates (like polystyrene Petri dishes or glass coverslips), their phenotype change and undergo an epithelial-mesenchymal transition (EMT)-like, which typically occurs from the third day of culture. The plastic cell culture plates and coverslips have a much greater stiffness (GPa) with respect to the reported pathophysiological values of the liver (<5 kPa). This reported transition on rigid substrates is accompanied by an increase in cortical actin expression, which has been linked to processes such as fibrogenesis; also, there is an increase in cell area spreading, in the mesenchymal phenotype markers such as vimentin and, on the other hand, a decrease in epithelial phenotype markers such as the E-cadherin. Furthermore, while in *vitro* the transforming growth factor beta (TGF-β) provokes the hepatocytes EMT[1], in *vivo* it does not have the same effect. Therefore, we decided to study the influence of this factor on primary rat hepatocytes seeded on softer substrates and assess whether there is the same epithelial-mesenchymal transition

effect. For this purpose, glass coverslides and polyacrylamide hydrogels with a stiffness of 1 kPa and 20 kPa (conjugated with collagen-I on its surface) were used. The hepatocytes were seeded on them and the cell culture was maintained for 5 days, then the cells were fixed and the expression of vimentin, E-cadherin, morphology and cellular area was determined. The results obtained suggest that TGF-β effect in the EMT is affected by the stiffness of the substrate, the rat hepatocytes on the 1 kPa hydrogels do not show their typical in vitro EMT as reported when they are seeded in tissue culture polystyrene plates with TGF-β. This project was funded by PAPIIT, UNAM #IT102017 and BDB thanks the DGAPA-UNAM Postdoc Fellowship. 1) Kaimori A., et al. Transforming Growth Factor-β1 Induces an Epithelial-to-Mesenchymal Transition State in Mouse Hepatocytes in *Vitro* (2007). The Journal of Biological Chemistry. 282:30, 22089 -22101

P2372/B625

Intracellular Molecular Cues Guide Cell Polarization on Geometrically Confined Extracellular Matrix.

D. Kim; KU-KIST Graduate School of Converging Science and Technology, Korea University, Seoul, KOREA, REPUBLIC OF.

Cells recognize and properly respond to diverse biophysical stimuli to maintain mechanical homeostasis that is crucial to control cell behaviors such as cell polarization, proliferation, and migration. Biological aging is the time-dependent deterioration of cell function, resulting in the progression of chronic diseases including cancer, neurodegeneration, and cardiovascular disorders. Accordingly, the ability of cells to mechano-sense their microenvironments diminishes with biological aging. While previous studies on aging have mainly focused on the clinical aspects of tissues and organs, however, underlying mechanism of cellular aging in the context of interaction between cell and micro-environment remains unclear. Here we first identify molecular basis of attenuated cellular mechanosensation. We synthesized collagen-coated polyacrylamide hydrogels with varying stiffness to provide various ranges of mechanical strength mimicking in *vivo* tissue environments. To determine age-dependent differential mechanosensation, human dermal fibroblasts (HDFs) were obtained from differently aged healthy individuals ranging from 2 to 92 years old. For the systematic analysis of cell morphology, automated high-throughput cell phenotyping (HtCP) technique was applied. To identify the role of lamin A/C, a nuclear membrane protein mediating age-dependent functional decline of cells, young cells were lamin-mutated by transient transfection of lamin Δ50, which mimics old cells. We further quantified intranuclear dynamics by analyzing displacement of chromatin centroids with confocal microscope-based live cell imaging and high-speed particle tracking technique. Statistical analysis of mean squared displacement was performed by a customized MATLAB code. This research reveals underlying molecular mechanism of age-dependent progressive decline in single cell resolution. Using not only cellular structural markers but intranuclear protein markers and transcription factors, we estimate the grade of cellular functions when mechanical interplay occurs between cells and microenvironment. Our results reveal underlying subcellular mechanism of how age-induced malfunctioning of nucleus can attenuate mechanosensation of cellular microenvironment. We expect that the relationship between cellular age and mechanosensing ability could determine donor's biological age and health condition. The result of this research will accelerate the development of clinical applications and translational research for designing personalized medicine and recovering health condition against the aging process.

Force-induced Recruitment of Cten Along Keratin Network.

J. Cheah, K. Jacobs, V. Heinrich, S. Lo, S. Yamada; University of California, Davis, Davis, CA.

The cytoskeleton provides structural integrity to cells and serves as a key component in mechano-transduction. Tensins are thought to provide a force-bearing linkage between integrins and the actin cytoskeleton; yet, direct evidence of tensin's role in mechano-transduction is lacking. We here report that local force application to epithelial cells using a micron-sized needle leads to rapid accumulation of cten (tensin 4), but not tensin 1, along a fibrous intracellular network. Surprisingly, cten-positive fibers are not actin fibers; instead, these fibers are keratin intermediate filaments. The dissociation of cten from tension-free keratin fibers depends on the duration of cell stretch, demonstrating that the external force favors maturation of cten-keratin network interactions over time and that keratin fibers retain remarkable structural memory of its force-bearing state. These results establish the keratin network as an integral part of force-sensing elements recruiting distinct proteins like cten and suggest the existence of a novel mechano-transduction pathway.

Surface Topography Modulates Actin Cytoskeleton and Cell Mechanosensing of Extracellular Matrix.

B. Cui, 94305, X. Li, L. Klausen, W. Zhang; Stanford University, Stanford, CA.

The interaction between the cell membrane and the extracellular matrix is crucial for many cellular functions by modulating mechanosensitive signaling pathways. Physical properties of the extracellular matrix such as stiffness and topography affect such interactions. Our recent work reveals that surface topography of tens to hundreds of nanometer scale modulates cell signaling by activating intracellular curvature-sensitive proteins. We use vertical nanoscale structures protruding from a flat surface as a platform to induce high curvatures on the cell membrane. We found that these high membrane curvature induce a drastic reorganization of the actin cytoskeleton, a reduction in the number of focal adhesion, and also a reduction of the cell membrane tension. Mechanistic studies reveal that the effect arises from the activation of curvature-sensitive proteins.

Studies of Polyhydroxyalkanoate Based 3d Substrates for Medical Applications.

T. Witko[1], M. Guzik[1], D. Solarz[2]; [1]Jerzy Haber Institute of Catalysis and Surface Chemistry Polish Academy of Scien, Cracow, POLAND, [2]Faculty of Physics, Astronomy and Applied Computer Science, Jagiellonian University, Cracow, POLAND.

Biopolymers represent one of the leading sectors for bio-based products and their expected growth is foreseen to be significant within the next years. Polyhydroxyalkanoates (PHAs) represent a class of optically active biodegradable polyesters accumulated by numerous bacteria as discrete intracellular granules or as a net like extracellular structures. PHAs are non-toxic materials and biodegrade to harmless products in the environment. The work focused on developing and optimizing manufacturing process of PHA based substrates with porous structure. Additionaly the analysis of impact of PHA based substrates on mammalian cells physiology and morphology has been tested. The cytotoxicity assessment and long-term microscopic studies revealed high biocompatibility level of PHA polymer and no toxic impact on living cells. Further research concerned advanced analysis employing confocal and

fluorescent microscopy. The received data indicates the influence of biopolymer on the structure and morphology of the cytoskeleton and cell shape. The structure of actin filaments suggest a high level of cell adhesion to the biopolymeric substrate while compared with glass. A quantitative analysis was also applied to determine the impact that PHO exerts on both cells' morphology, cytoskeleton architecture and migration velocity. PHAs can be subjected to simple modifications that can change both their biological and chemical properties, as well as their physical properties such as hydrophobicity or hardness. These features make polyhydroxyalkanoates versatile polymers, which applications and commercial use can be dictated by the needs of the market and not by limitations posed by the material itself. Thanks to employment of advanced experimental methods combined with complex data analysis it was possible to precisely elucidate the impact of biopolymeric substrates on living mammalian cells and confirm their suitability in biomedical devices and medical applications.

P2376/B629

Mapping Mesenchymal Stem Cell Heterogeneity Via Single Cell Rna Profiling of Matrix-directed Differentiation Towards Soft and Stiff Tissue Lineages.

S. Brielle, D. Bavli, A. Motzik, O. Ram, A. Buxboim; Hebrew Univ-Jerusalem, Jerusalem, ISRAEL.

Mesenchymal stem cells (MSCs) form a heterogeneous population of multipotent progenitor cells that contribute to tissue remodeling, repair and homeostasis. While differentiation of MSC populations towards soft and stiff tissue lineages is directed by matrix mechanics, single cells differ by their matrix-sensing potential and multilineage differentiation capacity. Here we cultured bone-marrow derived human MSCs on soft and stiff matrices that mimic fat and pre-calcified bone and used a bipotential adipogenic/osteogenic medium to induce differentiation. To study lineage specification heterogeneity, we employed the droplet-based inDrop labeling platform to perform single cell RNA (scRNA) profiling of thousands MSCS at naïve, matrix-conditioned and early differentiating states. At the population level, cell mechanosensitivity was validated by cell and nucleus projected area analyses and functional differentiation assays favoring adipogenesis on soft matrices and osteogenesis on stiff matrices. Yet, scRNA profiling indicated that matrix elasticity directs linage differentiation only in a fraction of cells. Dimensionality-reduced transcriptomes of thousands of cells collected at different time points clustered into distinctive subpopulations linking matrix priming and linage specification. Using machine learning classification tools, we identified surface marker distributions of MSC subpopulations. Diffusion pseudotime reconstruction of naïve states, matrix-priming and lineage specification histories revealed a cell-fate decision-making bifurcation towards fat and bone fates. Adipogenesis was retarded on stiff matrices and soft matrices activated chondrogenic markers in osteogenic cells. Differential gene expression screening between matrix-sensitive cells that differentiated in parallel with matrix mechanics and matrix-insensitive cells that exclusively express stress-associated surface markers revealed tropomyosin isoforms whose signaling functions we validated via knockdown and overexpression experiments. Taken together, our work provides mapping of MSC subpopulations characterized by multilineage differentiation capacity associated with cytoskeletal proteins that mediate mechanical signaling.

P2377/B630

Stiffness Regulation of Transcriptional Cofactors in Hepatocytes.

G. Vazquez-Victorio, A. Rodríguez-Hernández, D. Pérez-Calixto, M. Hautefeuille; UNAM, Ciudad de México, MEXICO.

The liver metabolizes several endogenous and exogenous molecules sustaining homeostasis in the organism. Hepatocytes are the cells that carry out all metabolic processes in the liver. It has been shown that mechanical cues affect hepatic functions because of the gene regulation and the polarity that preserves hepatic phenotype is lost. It is also known that YAP and TAZ proteins take part in regulating hepatocyte proliferation during regeneration and cancer development. However, neither YAP and TAZ nor other cotranscriptional cofactors activation by changes in stiffness has been evaluated. So, we decided to investigate the regulation of YAP, TAZ, MRTF-A and MRTF-B transcriptional cofactors by stiffness. We fabricated polyacrylamide hydrogels from 0.5 to 40 kPa to evaluate nuclear translocation of all cofactors. We also studied protein association among these mechanosensitive proteins. We found out that the main transcriptional cofactors that respond to external mechanical cues can be activated differentially and association can be regulated by stiffness in hepatocytes.

P2378/B631

Structural Relationship between the Putative Hair Cell Mechanotransduction Channel Tmc1, Tmem63/osca and Tmem16 Proteins.

A. Ballesteros[1], C. Fenollar-Ferrer[2], K. J. Swartz[1]; [1]NINDS-NIH, Bethesda, MD, [2]NIDCD-NIMH, Bethesda, MD.

Our senses of touch, hearing, balance, and proprioception depend on mechanically gated ion channels, which transduce mechanical energy into electrical signals that are transmitted to the brain. Previous studies on the mechanisms of hearing have elucidated the biophysical properties of the mechanotransduction (MET) channel essential for hearing, yet its molecular identity and structure remain elusive. The transmembrane channel-like protein (TMC1) localizes to the site of the MET channel, interacts with the tip-link responsible for mechanical gating, and genetic alterations in TMC1 alter MET channel properties and cause deafness, supporting the hypothesis that TMC1 forms the MET channel. We generated a structural model of TMC1 based on the X-ray and cryo-EM structures of the TMEM16 and TMEM63/OSCA proteins, revealing the presence of a large cavity near the protein-lipid interface that harbors the two TMC1 mutations that cause autosomal dominant hearing loss (p.M418K and p.D572N/H), suggesting that it could function as a permeation pathway. We also find that hair cells are permeable to 3kDa dextran labeled with Texas-Red, and that dextran permeation requires TMC1/2 proteins and functional MET channels, supporting the presence of a large permeation pathway and the hypothesis that TMC1 is a pore-forming subunit of the MET channel complex.

P2379/B632

Piezo1-sAC-IP_3R2 Axis Regulates the Adaptive Cellular Responses of Endothelial Cells to Mechanical Cues.

D. Santana, E. Friedrich, D. Rafacz, A. B. Malik, D. Mehta, Y. A. Komarova; University of Illinois at Chicago, Chicago, IL.

Mechanosensitive channels expressed by Endothelial Cells (ECs) are responsible for sensing mechanical cues and converting them into chemical signals to elicit specific cellular responses. The mechanosensitive channel Piezo1 plays an important role in vascular homeostasis by sensing hydrostatic pressure and shear stress in ECs. However, specific cellular mechanisms involved in Piezo1-mediated mechanotransduction remain elusive. Here, we investigated the mechanisms of Piezo1-mediated Ca^{2+} signals in ECs. Using intracellular and endoplasmic reticulum (ER) calcium sensors to respectively monitor the changes in Ca^{2+}_I and Ca^{2+}_{ER} concentrations, we have shown that pharmacological activation of Piezo1 induced an increase in Ca^{2+}_I that was potentiated by Ca^{2+} release from ER stores. Ca^{2+} influx through Piezo1 led to a transient activation of soluble adenylyl cyclase (sAC) which, in turn, activated cAMP-dependent Ca^{2+} release via Inositol Trisphosphate Receptor 2 (IP_3R2), a calcium channel located in the ER. Depletion of either sAC or IP_3R2 markedly reduced the Piezo1-mediated increase in cytosolic Ca^{2+}_I indicating that Ca^{2+}_{ER} release represents a mechanochemical positive feedback loop eliciting Ca^{2+} signals in ECs. Furthermore, depletion of IP_3R2 blocked alignment of ECs in the direction of shear flow suggesting that activation of IP_3R2 downstream of Piezo1 is an essential element of a mechanotransduction response. Our data, for the first time, establish the role of Piezo1-sAC- IP_3R2 axis in regulating the adaptive cellular responses of ECs to mechanical cues.

P2380/B633

Myosin-II Mediated Traction Forces Evoke Localized Piezo1-dependent Ca^{2+}Flickers.

K. L. Ellefsen[1], J. R. Holt[1], A. Chang[2], J. L. Nourse[1], J. Arulmoli[1], A. Mekhdjian[2], H. Abuwarda[1], F. Tombola[1], L. A. Flanagan[1], A. R. Dunn[2], I. Parker[1], **M. Pathak**[1]; [1]University of California, Irvine, Irvine, CA, [2]Stanford University, Stanford, CA.

Piezo channels transduce mechanical stimuli into electrical and chemical signals, and in doing so, powerfully influence development, tissue homeostasis, and regeneration. While much is known about how Piezo1 responds to external forces, its response to internal, cell-generated forces remains poorly understood. Here, using measurements of endogenous Piezo1 activity and traction forces in native cellular conditions, we show that actomyosin-based cellular traction forces generate spatially-restricted Ca^{2+} flickers in the absence of externally-applied mechanical forces. Although Piezo1 channels diffuse readily in the plasma membrane and are widely distributed across the cell, their flicker activity is enriched in regions proximal to force-producing adhesions. The mechanical force that activates Piezo1 arises from Myosin II phosphorylation by Myosin Light Chain Kinase. We propose that Piezo1 Ca^{2+} flickers allow spatial segregation of mechanotransduction events, and that diffusion allows channel molecules to efficiently respond to transient, local mechanical stimuli.

P2381/B634

Myosin-dependent Mechanosensory Adaptation in *Drosophila*.

C. Guan[1], K. Nishi[1], O. Bäumchen[2], M. Göpfert[3], C. F. Schmidt[1]; [1]Department of Physics, Duke University, Durham, NC, [2]Max Planck Institute for Dynamics and Self-Organization, Göttingen, GERMANY, [3]2Department of Cellular Neurobiology, Schwann-Schleiden-Centre for Molecular Cell Biology, University of Göttingen, Göttingen, GERMANY.

Mechanosensory receptor cells detect and convert a diverse range of physical forces such as sound, vibration and stretch into biological (electrical) signals. The fruit fly *Drosophila melanogaster* possesses specialized organs, chordotonal organs (ChOs), to “hear” external sound, feel airflow and keep track of body motions (propiosensing). Mechanoelectrical transduction in these organs is typically controlled by active, force-generating processes (adaptation motors). The nature of those force generators, however, is not known. We have combined electrophysiological analysis with mechanical stimulation, and have correlated mechanical properties and active manipulation with neuronal activity. We show that non-muscle myosin II activity in ChOs of *Drosophila* larvae is responsible for both mechanosensoy adaptation and neuronal responsiveness. Mechanical experiments suggest that elasticity and pretension in the ChO’s depend on the activities of myosin motors.

P2382/B635

Piezo-like Channel Functions as a Mechanosensitive Regulator Governing Reproduction in *Caenorhabditis Elegans*.

X. Bai, 20814; National Institutes of Health, Bethesda, DC.

PIEZOs are mechanosensitive ion channels; the two PIEZO proteins in humans are involved in a wide range of developmental and physiological processes. Dysfunctional alleles of PIEZOs cause at least six diseases. However, the cellular and molecular mechanisms of PIEZOs in these diseases are not well understood. To address this, we investigated the functional roles of *pezo-1*, the sole PIEZO ortholog in *C. elegans*, using CRISPR/Cas9 and other genetic tools. GFP::PEZO-1 widely expresses from embryos to adults in *C. elegans*. Notably, it strongly expresses at several valvular tissues, including the pharynx-intestine and spermatheca-uterine valves. It is also expressed in the somatic gonad and in sperm. Two large deletions and multiple patient-specific loss-of-function and gain-of-function mutants cause severe reproductive deficiency, such as reduced brood size in *C. elegans*. In *vivo* observations show that newly fertilized oocytes undergo a variety of transit defects in and out of the spermatheca. Post ovulation oocytes were frequently damaged during spermathecal contraction. Due to PIEZO channels’ permeability to Ca^{2+} and the importance of calcium signaling in regulating spermatheca contractility, we are imaging the calcium indicator GCaMP in *pezo-1* mutants. Subtle variation of calcium release was observed in *pezo-1* mutants compared with wild type. To test possible genetic interactions between *pezo-1* mutants and cytosolic Ca^{2+} regulators, we performed a candidate RNAi screen to deplete calcium regulatory proteins in *pezo-1* mutants and wild type animals. Depletion of the ER calcium-release channel *itr-1* synergistically reduced brood size in *pezo-1* mutants. In contrast, depletion of the *itr-1* negative regulator, *lfe-2*, partially rescued the smaller brood size in the *pezo-1* mutant. Furthermore, sperm number significantly declined in 2-3 days adults of *pezo-1* mutants compared with wild type. Mating with male worms rescued reproductive deficiency in *pezo-1* mutants, suggesting that the lack of sperm in *pezo-1* mutants contributes to its reproductive deficiency. To test the specificity to sperm, we depleted PEZO-1 in different tissues, including somatic tissues, sperm and germline with auxin-inducible

degradation system (AID). A reduced brood size was observed in each tissue-specific degradation strain. Therefore, our study suggests that *pezo-1* may act in different reproductive tissues to promote proper ovulation and fertilization in *C. elegans*.

Evaluating the Developmental Potential of Oocytes and Preimplantation Embryos Via in Situ Rheological Characterization.

O. Wintner, **S. Brielle**, R. Friedman, D. Kalo, D. Kitsberg, Z. Roth, A. Buxboim; Hebrew University, Jerusalem, ISRAEL.

In vitro fertilization (IVF) treatments account for 1.7% of live births in the USA alone. Early identification of embryos with high implantation potential is required for avoiding clinical complications to the newborn and to the mother that are associated with multiple-embryo pregnancy and for shortening time to pregnancy. Previous studies have demonstrated a correlation between the mechanical properties of the embryos and their developmental capacity to implant in the uterus. We developed the MechanoPLATE - a multiplate-based glass device that facilitates continuous viscoelastic characterization of oocytes during in vitro maturation (IVM) and of embryos during preimplantation development under optimal culture conditions. Stress-strain relationships are obtained via controlled pressue system. Creep compliance measurements are fitted to a linear viscoelastic model. The developmental potential of oocytes is scored based on the capacity to complete second meiosis (MII) stage. Similarly, embryo quality is determined by the capacity to developmentally advance and reach blastulation stage. Using a bovine model, we demonstrate a non-invasive rheological method, which does not compromise the developmental potential of oocytes and embryos. In situ aspiration probes the integrated mechanical properties of the ooplasm and the surrounding zona pellucida. Only high quality Germinal vesicle (GV) oocytes that reach MII soften during IVM whereas poor quality arrested oocytes remain stiff. Changes in embryo mechanics offer means of discriminating between high-potential and low-potential embryos at early stages of preimplantation development. These mechanical profiles are consistent with a decrease in the reproductive potential of aged versus young cows and oocytes obtained from large antral follicles during the cold versus hot season. In situ rheological assessment of oocytes and embryos is compatible with visual evaluation of preimplantation embryo development, which offers non-invasive and accurate means of selecting the oocytes and embryos with the highest developmntal potential for transfer into the uterus. Our assisted reproductive technology has the potential of improving domestic animal breeding schemes and IVF clinical performance in human.

Chemotaxis and Directed Cell Migration 2

P2384/B637

Steering Cytoskeletal Dynamics with Electric Fields.

A. Bull, Q. Yang, M. J. Hourwitz, L. Campanello, J. T. Fourkas, W. Losert; University of Maryland, College Park, College Park, MD.

Endogenous electric fields are present in many biological processes including at the edge of healing wounds. It is known that for many types of cells, including neutrophils, DC electric fields of the same order of magnitude as these endogenous fields direct cell migration to the cathode. In this presentation we determine the effect of DC electric fields on actin polymerization dynamics. We find that actin waves

are guided by DC electric fields for multiple cell types. Giant *Dictyostelium discoideum* cells (produced via electrofusion) allow us to measure electric field response of actin waves located far from the leading or trailing edge of a cell, and thus decouple cell polarity and shape from actin wave responses. We also use nanoridges, fabricated substrate nanotopographies, which alter the actin waves from the broad, two-dimensional waves seen on flat substrates to one-dimensional waves traveling along the nanoridges. We find that the one-dimensional waves on nanoridges respond faster to electric fields and respond by a 180 degree switch in wave direction to changes in field direction. Actin waves on flat substrates, on the other hand, respond to electric fields by a gradual turn in the preferred wave direction. This difference is also notable in the overall migratory behavior of neutrophil-like HL60 cells, which tend to gradually turn toward electric fields on flat surfaces, while switching front and back on nanoridges. When the nanoridges are aligned in competition with the electric field, i.e. In a perpendicular direction, we find that actin waves follow the nanoridges while, on the whole cell scale, migrating cells follow the electric field. This points to the possibility that different guidance signals may dominate cell behavior on different length scales. Together, our data reveal new insights into the mechanism behind cell migration via DC electric fields with actin waves playing a key role in cell response and control.

P2385/B638

Probing the Directional Motile Cue: Quantitative Study of Galvanotactic 3D Migration in Neutrophil-like HL-60 Cells.

N. M. Belliveau, J. A. Theriot; Department of Biology and Howard Hughes Medical Institute, University of Washington, Seattle, WA.

Migratory cells must constantly integrate physical and chemical cues within their environment for effective movement. Among these cues, electric fields have been found to reorient cells along the direction of potential difference (galvanotaxis), with particular relevance to development and wound healing in mammals. While this phenomenon has been studied extensively in a variety of cell types, the underlying mechanism(s) behind this directed movement remain enigmatic. Here we consider galvanotaxis in the context of ameboid immune cell migration. We study migration of the neutrophil-like HL-60 cell in *vitro* using 3D extracellular matrices in order to mimic the complex environment they may encounter within the body. We begin by demonstrating that these neutrophil-like cells indeed show directed motion under an electric potential. This response is rapid, with cells orienting along the potential gradient within seconds of the electric field being generated. Using Cas9-mediated gene-editing, we have constructed an inducible CRISPRi cell line that we then use to perturb gene function through gene knockdown. Single cell tracking data is used to infer quantitative motility characteristics including cellular persistence and we present preliminary results upon perturbation to a number of candidate genes potentially involved in galvanotaxis. We also contrast this migration modality with motile behavior under chemotaxis, as well as characterize the general motility characteristics of these cells in the absence of any directional cue. Due to their amenability to genetic manipulation, these HL-60 cells will provide an important model system to study the molecular basis underlying galvanotaxis in ameboid-type cells.

P2386/B639

Osmolarity-independent Cues Guide Rapid Cell Migration to Injury in Zebrafish Epidermis.

A. S. Kennard[1,2], J. A. Theriot[2,3]; [1]Stanford University, Stanford, CA, [2]University of Washington, Seattle, WA, [3]Howard Hughes Medical Institute, Seattle, WA.

During wound healing cells must respond rapidly to changes in their environment in order to mitigate tissue damage, on timescales too short to be controlled by changes in gene expression. To disentangle the effects of different environmental cues on wound-induced cell migration, we have studied wound healing in larval zebrafish: when the tailfin is lacerated with a needle, basal epidermal stem cells up to 300µm away from the wound polarize their cytoskeleton within tens of seconds and migrate toward the wound over the span of about 15 minutes. One cue that has been suggested to induce cell migration after injury is a sudden shift in osmolarity due to mixing of interstitial fluid and the external medium at the wound (Gault 2014). By changing the composition and concentration of ions in the external medium, we discovered that, although a change in osmolarity did promote cell migration, it was not necessary for actin polarization: cell migration was partially inhibited in all isosmotic media, but the actin cytoskeleton still polarized toward the wound in all media except isosmotic sodium chloride. By measuring cell volume after wound healing we confirmed that changes in cell volume were not sufficient to explain this differential cytoskeletal response in isosmotic media. This suggests that cells can sense tissue damage via non-osmotic, ion-specific mechanisms. Electric fields, arising from short-circuiting ion transport across the epidermis at the wound site, are a possible alternative signal of tissue damage, but it is unknown whether electric fields are able to induce cell polarization or migration towards a wound in *vivo* at short (<30 min) timescales. Consistent with this possibility, we found that applying an electric field in *vivo* is sufficient to stimulate actin polarization and rapid cell migration in the absence of a wound. Work is ongoing to directly measure the transepithelial potential across the epidermis and determine if this could be the source of an electric field that guides cell migration during wound healing. These results suggest that the overall physiology of the epidermis, including the transport of specific ionic species, has an important and unappreciated role in rapidly guiding cells towards damage.

P2387/B640

Durotaxis: 'migration by Feel'.

R. M. Hakeem, J. E. Bear; University of North Carolina, Chapel Hill, NC.

Directional cell motility is indispensable for embryonic development, immune response, wound repair, and cancer metastasis. Cells encounter a variety of cues that can serve as navigational guides, directing the cell where to migrate. While progress has been made understanding the molecular underpinnings of chemo- and haptotaxis, how a cell can sense and respond to changes in the mechanical properties of its microenvironment (durotaxis) remains elusive. Durotaxis is founded on the observation that cells seem to move by ‘feel’ from soft to stiff matrix. We sought to understand the pathways that regulate this phenomenon as little is understood on this front. To address this, we engineered photopolymerizable hydrogels that possess tunable gradients of stiffness. Using our system, we have obtained stiffness gradients that range from 0.5 to 95 kPa. Our preliminary data demonstrates that individual cells can durotax across a rigidity gradient. Our aim is to dissect the key molecular players of durotaxis with the intent of furthering the field’s understanding on how cells navigate their environment. In addition, we

hope that providing mechanistic insight on durotaxis will help bridge the role of physical cues in the development of metastasis and fibrotic diseases, to eventually pave the way for novel targeted therapeutics.

P2388/B641

Leveraging Population-Level Intercellular Variation of 2D Cell Shape for Mechanistic Insight into Cell Migration.

R. D. Labitigan[1,2], A. L. Sanborn[1], C. V. Hao[1], J. A. Theriot[2]; [1]Stanford University, Stanford, CA, [2]University of Washington, Seattle, WA.

Cell shape is a large-scale manifestation of the overall physical and functional state of a cell's cytoskeleton and other structural elements. Dynamic control of cell shape is essential for diverse cell types ranging from neurons to single-celled amoeba. For some well-characterized motile cell types (such as human immune cells and fish skin cells), it has been shown that control of a cell's shape is inherently linked to control of its motile behavior. Understanding the variation in a cell's shape, both through time and across a population of cells, can thus shed light on the molecular mechanisms involved in cell shape determination and motility. We have developed an approach to identify the most important axes of 2D cell shape variation in a population of thousands of fixed cells from a single imaging sample. In contrast to using simple handpicked summary metrics (such as cell area or circularity), our approach uses principal component analysis (PCA) to provide an unbiased, compact representation of cell shape, while maintaining the rich information embedded in the population's cell-to-cell variation. Furthermore, this allows quantitative, biologically-interpretable comparisons upon pharmacologic or genetic perturbation and sensitive detection of differences that would otherwise be obscured using simple metrics. This approach has enabled us to precisely quantify cell shape changes upon systematic perturbation of the actin cytoskeleton and other structural components like organelles. As a case study, we have mapped the shape space of human osteosarcoma U2OS cells (a motile cell type that forms dynamic cell shapes) and then quantified the effect of Rho kinase (ROCK) inhibitor Y-27632 on cell shape. Although individual Y-27632-treated, fixed cells do not show any obviously aberrant cell shapes relative to control cells, a population analysis reveals a striking change in their shape distribution. Upon Y-27632 treatment, U2OS cells exhibit a dose-dependent shift toward more polarized, crescent-shaped morphologies, and a wider range of left-right asymmetry. Along with live cell imaging, this population-level shape analysis of fixed U2OS cells suggests that ROCK inhibition may enable (1) higher migration speeds via enhanced front-back polarization and (2) more robust whole-cell turning via enhanced left-right asymmetry, pointing toward a role for ROCK signaling in limiting U2OS cells' intrinsic migratory behavior.

P2389/B642

Identifying Potential Protein-protein Interactions at the WRAMP Structure to Explore Regulation of Directional Cell Migration.

S. Miller[1], M. Hoh[1], T. Lee[1], M. Connacher[1], E. Witze[2], N. Ahn[1]; [1]University of Colorado Boulder, Boulder, CO, [2]University of Pennsylvania, Boulder, PA.

In multicellular organisms, cells must move in a defined direction for proper development and immune cell function and for the pathological process of cancer cell invasion. The Wnt5a-receptor-actomyosin-polarity (WRAMP) structure is a dynamic protein network marked by the transient polarization of the transmembrane protein melanoma cell adhesion molecule (MCAM). MCAM polarization is accompanied

by enrichment of F-actin and myosin-IIB followed by immediate retraction of the cell rear. During periods when WRAMP structures are present in migrating cells, cells move with increased speed and directional persistence relative to periods when WRAMP structures are absent. This study aims to identify and test possible protein interactors and protein trafficking pathways required for WRAMP structure formation and activation of actomyosin contraction, rear cell retraction, and associated directional migration. We used proximity proteomics to identify potential members of the interaction network around MCAM at the WRAMP structures by fusing MCAM to the biotin ligase BioID or peroxidase APEX2 and purifying biotinylated proteins for identification using mass spectrometry. The results of this experiment show that BioID and APEX2 provide distinct but overlapping interactomes for MCAM. Using Gene Ontology enrichment analysis, we found that many of these proteins are involved in membrane trafficking. In addition, we discuss imaging methods used to validate the presence of these candidates at the WRAMP structure and monitor the role of different membrane compartments in WRAMP structure formation. This study corroborates a role for membrane trafficking at WRAMP structures and will help elucidate specific protein-protein interactions involved in controlling actomyosin activation and directional cell migration at the rear of the cell. More broadly, this work expands on the functional implications of adhesion molecule turnover through membrane trafficking and its impact on cell motility.

P2390/B643

Translation Contributes to Cell Migration in Confined Microenvironments.

R. Moriarty[1,2], K. Stroka[2], S. Mili[1]; [1]National Cancer Institute, NIH, Bethesda, MD, [2]University of Maryland, College Park, MD.

Cancer cells experience confinement in *vivo* during metastasis as they leave the primary tumor and migrate through the surrounding extracellular matrix, intravasate to the bloodstream, travel through capillaries as small as 3 μm in diameter, and as they extravasate into new tissues to form secondary tumors. Cancer cells in high degrees of confinement are able to employ novel migration mechanisms as actomyosin contractility is disrupted. In line with this, we have previously showed that low degrees or loss of actomyosin contractility have promoted differing subsets of RNAs to localize to peripheral regions of both cell protrusions into very narrow pores and cells confined within narrow microchannels. This is relevant as cells are able to direct subcellular RNA localization and local translation for migration purposes in two dimensional environments. Therefore, we sought to understand how global translation patterns may be altered and used for cell migration purposes in confinement. We hypothesized that cells in confinement would display altered patterns of translation due to the geometrical restrictions imposed upon the cell. We model in *vitro* confinement by seeding cells into 3 μm wide by 10 μm tall microchannels and encouraging them to migrate by establishing a chemoattractant gradient. Using pharmacological inhibitors and translation imaging methods, we explore the role of RNA translation during migration in confinement. Interestingly, our current findings point to a role for RNA translation during changes in directionality. We will discuss recent findings and our efforts to delineate the underlying mechanism.

P2391/B644

Mapping the Heterochromatin Changes Upon Induction of Cell Migration and Revealing the Role of H3k27me3 in Determining the Transcriptome of Migrating Cells.

T. Segal, M. Salmon-Divon, **G. Gerlitz**; Ariel University, Ariel, ISRAEL.

H3K9me3, H3K27me3 and H4K20me1 are epigenetic markers associated with chromatin condensation and transcriptional repression. Previously, we found that migration of melanoma cells is associated with a global increase in chromatin condensation that includes a 2-4-fold increase in these markers as detected by immunostaining. This heterochromatinzation is required for efficient cell migration. Our studies together with recent reports by others suggest it is a general signature of migrating cells. In this study, we mapped these markers by ChIP-seq to get deeper understanding of their function. The analysis revealed that induction of migration leads to expansion of these markers along the genome and to an increased over-lapping between them. Significantly, induction of migration led to a higher increase in H3K9me3 and H4K20me1 signals at repetitive elements than at protein-coding genes, while an opposite pattern was found with H3K27me3. Transcriptome analysis detected 182 genes altered in their RNA levels 3 hours after induction of migration. These genes are associated mainly with tumor migration signaling pathways such as TGF-β and ERK5, energy generation and oxidative stress response. Inhibition of H3K27 methylation by an Ezh2 inhibitor revealed that 33% of the migration-associated changes in RNA levels are dependent on H3K27me3. These H3K27me3-dependent genes are less prone to regulation at the RNA stability level than H3K27-indepednt migration-altered genes. Surprisingly, H3K27me3 is also required to prevent changes in the RNA levels of 501 other genes upon induction of migration. Taken together, our results suggest that heterochromatinization in migrating cells covers all genomic elements rather than restricted to specific genomic loci and that H3K27me3 is a key component in executing a migration-specific transcriptional plan as well as to buffer the genome from unwanted transcriptional changes.

Rescuing DNA Damage After Constricted Migration Reveals a Mechano-regulated Threshold for Cell Cycle.

Y. Xia, C. Pfeifer, K. Zhu, L. Dooling, M. Tobin, **M. Wang**, I. Ivanovska, D. Discher; University of Pennsylvania, Philadelphia, PA.

According to the “Go-or-grow” hypothesis, cell migration and cell cycle are mutually exclusive. Transwell pores are widely used to study 3D migration and show that migration through ~2-4 μm channels suppresses cell cycle whereas migration through larger pores relieves contact inhibition and enhances cell cycle [1]. Constricted migration causes nuclear rupture and potentially DNA damage [2]. The latter remains uncertain as the results of damage markers vary. Some remain unchanged in suitably fixed cells (e.g. 53BP1) and others correlate strongly to cell cycle (e.g. BRCA1). Here, various rescuing treatments for DNA damage in constricted migration reveals a cell cycle checkpoint consistent with excess damage. We find myosin-II inhibition rescues rupture and partially rescues DNA damage in terms of the reduced foci counts of γH2AX. Co-overexpression of multiple DNA repair factors or addition of antioxidant lead to partial rescue that is independent of rupture. Cell cycle defects persist with the individual rescuing treatments, but combined treatments fully rescue both DNA damage and cell cycle suppression in constricted migration. The sigmoidal relation between cell cycle and DNA damage is consistent with DNA damage checkpoints that halt cell cycle across both early and late phases. The same sigmoidal

relation was seen for cell migration through pores of varying diameter, confirming the trend. Thus, 3D constricted migration reveals a novel 'go or grow' mechanism in which cells cease to 'grow' if they experience enough DNA damage when they 'go', and a combination of cytoskeletal force reduction and modulation of sources or repair of DNA damage is needed to rescue the damage and the growth. [1] Pfeifer, C.R., Y. Xia, ⋯ D.E. Discher. 2018. Constricted migration increases DNA damage and independently represses cell cycle. *Mol Biol Cell*: mbcE18020079. [2] Irianto, J., Y. Xia, C.R. P2393/B646

The Contractile Vacuole Polarizes and Is Critical for Cell Streaming during Aggregation in *Dictyostelium Discoideum*.

S. Fadil, C. Janetopoulos; University of the Sciences, Philadelphia, PA.

Distinct changes often occur in morphology during the formation of cellular polarity. In the case of directed migration, cells often form a defined front and rear, as they migrate towards or away from migratory cues. In many cell types, the microtubule organizing center and nucleus take up discrete localizations relative to one another. During the directed migration that takes place in cellular aggregation, the early process in fruiting body development, *Dictyostelium discoideum*cells reorganize many cellular components, including their actin and microtubule cytoskeletons. We have discovered that the contractile vacuole (CV) network also polarizes towards the rear of the cell during migration. Observations with light microscopy of retrograde CV movement were confirmed by imaging cells expressing the fluorescently tagged CV marker dajumin. CV diastole is coordinated with propagating cAMP waves during cell streaming. Interestingly, we found that the cAMP transporter ABCC8, which has been shown to be responsible for cAMP secretion, localizes to the CV network. Mutants lacking the huntingtin protein (htt-) lacked a detectable CV in the vegetative state and had smaller than averaged sized CVs. htt- cells made very weak cAMP waves and didn't stream. htt- cells have previously been shown to have an inability to regulate their osmotic pressure, and the loss of this dynamic organelle is likely critical to this phenotype. Our results demonstrate that posterior redistribution of the contractile vacuole in migrating cells plays a critical role in recruiting cells into streams and contributes to cAMP secretion/relay.

P2394/B647

Mechanical Coupling of Epithelial Cell Migration and Actomyosin Cable Formation in the Two-layered Epidermis of Embryonic Zebrafish.

C. K. Prinz[1], A. S. Kennard[2,1], E. C. Labuz[2,1], M. J. Footer[1], J. A. Theriot[1]; [1]Howard Hughes Medical Institute, University of Washington, Seattle, WA, [2]Biophysics Program, Stanford University, Stanford, CA.

During wound healing of the embryonic epidermis, restoration of the epidermal boundary is governed primarily by two cytoskeletal processes: migration of epithelial cells toward the wound and contraction of an actomyosin cable in cells along the wound margin. Previous studies in Drosophila epithelial tissues and in cell culture demonstrated that wound repair proceeds in distinct phases and requires coordination between both processes in mono-layered systems [1]. It remains unclear exactly how these two processes are mechanically coupled or the extent of their interaction during wound healing. In zebrafish embryos, cable formation and cell migration are spatially separated in the two layers of the

epidermis: cable formation in the superficial cell layer and cell migration in the basal cell layer. This separation offers the opportunity of pinpointing the distinct mechanical contributions of each process with cell layer-specific gene expression. Cytoskeletal actin is crucial in both cable formation and cell migration. In each layer separately, we expressed a genetically encoded construct derived from gelsolin-1 (DeAct-GS1) that directly interferes with the polymerization of F-actin by sequestering actin monomers [2]. Fluorescent microscopy and image analysis reveal that cells in the basal layer expressing DeAct-GS1 have fewer protrusions, smaller lamellipodial fronts, and do not polarize towards the wound as much as control cells. They also appear to initiate independent migration more slowly than cells expressing control constructs. Mosaic expression of DeAct-GS1 is not sufficient to inhibit wound closure. In future work, we will compare the effects of our DeAct construct to the effect of a drug with known actin monomer sequestering activity, latrunculin. Additionally, we will compare stoichiometric inhibition of actin with our DeAct-GS1 to more potent catalytic constructs in both basal and superficial layers. This will enable us to investigate the effects of mosaic inhibition of actin in one process to the other. With these findings we hope to improve our understanding of wound healing and how the two distinct actin-dependent processes are coupled. 1. Abreu-Blanco, M. T. et al. J Cell Sci 125, 5984-5997 (2012). 2. Harterink, M. et al. Nature Methods 14, 479-482 (2017).

Algal Mind-control: Phototaxis of the Giant Ciliate *Stentor Pyriformis* Is Mediated by Algal Endosymbionts.

V. Boudreau[1,2,3,4], T. M. Gerbich[3,5], T. C. Fadero[3,5], N. Srinivas[3,6], K. K. Niyogi[2,4,7], W. F. Marshall[1,3];
[1]Department of Biochemistry and Biophysics, University of California, San Francisco, San Francisco, CA, [2]Department of Plant and Microbial Biology, University of California, Berkeley, Berkeley, CA, [3]The Physiology Course, Marine Biological Laboratory, Woods Hole, MA, [4]Howard Hughes Medical Institute, Berkeley, CA, [5]Department of Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC, [6]Department of Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA, [7]Molecular Biophysics and Integrated Bioimaging Division, Lawrence Berkeley National Laboratory, Berkeley, CA.

Photosynthetic algae are responsible for ~50% of global primary production of biomass. Algal endosymbiosis is recognized as a major driver of the evolutionary diversification of eukaryotes, conferring complex cell biological functions such as phototrophy and phototaxis to their hosts. As single cells, ciliates harboring photosynthetic endosymbionts are common in aquatic ecosystems, yet how single cells integrate symbiont-derived light sensing remains mysterious. Here, we describe the first positive phototactic behavior in a Stentor species, *Stentor pyriformis*, a giant single cell harbouring several hundred algal endosymbionts. Tracking single cell swimming behaviors, we have found *S. pyriformis* phototaxis behaves in a circadian rhythm as has been previously described in the green alga *Chlamydomonas reinhardtii*. Using bandpass filters across the visible light spectrum, we show *S. pyriformis* swims preferentially towards yellow-green light, supporting an algal photoreceptor-based phototactic mechanism. Additionally, minimum evolution phylogeny of the algal endosymbiont's 18S rRNA and RbcL genes identify the symbiont as a species of Chlorella most closely related to *Chlorella variabilis*, which has been shown to be sensitive to yellow-green light. Taken together, our results suggest phototaxis in the giant ciliate *S. pyriformis* is mediated by its Chlorella symbionts in a time of day and light quality manner. As an emerging model of cell biological photosymbiosis, *S. pyriformis* provides an excellent system to uncover symbiont-mediated host behavior in an organism lacking a traditional nervous system.

Inter-species Repression of Diatom Light-dependent Motile Responses.

S. A. Cohn, B. A. Timmerman; DePaul University, Chicago, IL.

Diatoms are unicellular siliceous golden algae, crucial to the ecological stability of numerous marine and freshwater ecosystems. Previous studies on light-stimulated direction change in diatoms indicated that *Stauroneis* (*Stauroneis phoenicenteron*) cells had increased response times when in the presence of *Craticula* (*Craticula cuspidata*) cells (*Diatom Res.*, 2016, **31**:173-184). Recent experiments have shown that *Stauroneis* cells have an even greater repression of response when they are in the presence of *Pinnularia* (*Pinnularia viridis*) cells. To determine if direct or near-direct cell-cell contact was responsible for this effect (in contrast to soluble factors in the medium), *Stauroneis* were placed in a slide chamber containing *Craticula* or *Pinnularia* on only one side of the chamber, so that some *Stauroneis* had no nearby other diatom cells, while other *Stauroneis*, immersed in the same medium, were directly surrounded by other *Craticula* or *Pinnularia*. The nearby presence of *Craticula* resulted in significantly longer direction change response times (56 ± 5 s; $P = 0.05$) compared to isolated *Stauroneis* cells in the same medium (38 ± 4 s). The nearby presence of *Pinnularia* resulted in an even greater direction change response times (139 ± 13 s; $P < 0.01$) compared to the isolated *Stauroneis* cells (68 ± 9 s). This response is dependent on living *Pinnularia* cells, and was no longer present when *Stauroneis* were in the presence of dead, ethanol-fixed and rinsed *Pinnularia* (response time of 47 ± 6 s; $P = 0.90$ compared to isolated *Stauroneis*). Interestingly, when motile *Stauroneis* were irradiated along with ethanol-fixed dead *Craticula*, they showed increased response times whether they were directly in the presence of the dead *Craticula* (77 ± 18 s) or just in nearby medium from the treated *Craticula* (105 ± 18 s). These studies suggest that *Stauroneis* response times are repressed in the presence of other species and that *Stauroneis*/*Pinnularia* effects requires direct inter-species interactions with live cells. Ethanol fixation does not remove all of the repressioneffects of *Stauroneis* interaction with *Craticula*, suggesting that some extracellular factors, such as small mucilage components, may still be present in the fixation/rinsing process, and are released into the medium. This work was supported by grants through the DePaul College of Science and Health, the DePaul University Research Council, and equipment purchased previously through NSF Grant IBN-9982897.

An Investigation of the Mechanical and Functional Role of Vinculin in Conjunction with Alpha-catenin at Cell-cell Contacts.

J. Cabe, V. Narayanan, V. Bejar-Padilla, V. Maruthamuthu, D. Conway; Virginia Commonwealth University, Richmond, VA.

Mechanical forces, largely exerted or detected at epithelial cellular contacts, have been indicated necessary for normal cellular homeostasis in events such as collective cell migration, proliferation and glandular organization. Prior studies have implicated vinculin as a potent mechano-sensor, and an effective mechano-coupler of the cytoskeleton to cell-cell and cell matrix proteins. The functional consequences of vinculin as a mechano-transducer across cell-cell contacts, however, is not yet fully understood. Here, we hypothesize that vinculin in conjunction with alpha-catenin, plays a vital role in

regulating normal function and homeostasis in the epithelium. To test this, mutant MDCK II cell lines were generated using CRISPR to produce vinculin knock-out (KO), α-E-catenin KO, and vinculin α-E-catenin double KO cells. α-E-catenin KO cells were rescued with mutants unable to bind vinculin (α-E-catenin L344P) or that were constitutively bound to vinculin (α-E-catenin M319G/R326E). Using these cell lines, 2D assays were conducted that probed the role of vinculin in cellular migration and proliferation. The study concluded that both, collective migration and proliferation, were slower in α-E-catenin L344P and M319G/R326E cell lines compared to the control. Vinculin was further examined in 3D assays to analyze its role in acinar development. Compared to the control that manifested a single lumen morphology, the α-E-catenin KO cells, and the double KO cells, presented disrupted acinar lumens, thereby emphasizing the role of vinculin and α-E-catenin in acinar formation. To further investigate the force dependent role of vinculin and alpha-catenin, traction- force and FRET-force measurements were performed. Traction force showed only a modest, 25% decrease, in force in α-E-catenin KO cells, suggesting that the cell-cell adhesion is still mechanically preserved. Furthermore, measurement with an E-cadherin FRET force sensor showed no significant difference in force across E-cadherin in confluent monolayers, indicating that the adherens junction is still mechanically loaded in the absence of α-E-catenin. We speculate that the adherens junction is still able to remain connected to actin in the absence of alpha-E-catenin. Altogether, these data demonstrate that vinculin in conjunction with α-E-catenin, functions as a regulator of mechanical forces at intercellular junctions and cell-matrix contacts thereby regulating epithelial cellular homeostasis.

Investigating Vinculin's Role in Responding to Locally Applied Mechanical Force at Cell-cell Junctions in Vertebrate Epithelia.

L. van den Goor, A. L. Miller; University of Michigan, an n Arbor, MI.

Cell-cell junctions, including adherens junctions (AJs), which promote cell-cell adhesion, and tight junctions (TJs), which promote epithelial barrier function, are linked to an apical array of F-actin and Myosin-II (actomyosin). This linkage to the actin cytoskeleton is important for maintaining the structure and function of these cell-cell junctions. Vinculin, a scaffolding protein, is recruited to AJs when tension is increased at cell-cell junctions in order to reinforce the connection between AJs and actomyosin[1]. However, how epithelial cells maintain adhesion and barrier function when mechanical force is locally applied on cell-cell junctions – at the cleavage furrow during epithelial cell division or when three cells pull on a single point at tricellular junctions – remains unclear. We have shown that Vinculin is recruited to reinforce AJs at the cleavage furrow during cytokinesis, and expression of dominant negative Vinculin results in a reduction of AJ and TJ proteins at the cleavage furrow[2]. Vinculin also exhibits tension-dependent enrichment at tricellular junctions. Using *Xenopus laevis* embryos, we are knocking down Vinculin to investigate its role in response to both naturally occurring local increases in tension as well as manipulations that globally induce tensile stress. Preliminary experiments suggest that Vinculin acts to counterbalance the locally applied force generated by the contractile ring. Vinculin knockdown cells with one or fewer junctions intersecting with the cleavage furrow divide faster than control cells. However, when two or more intersecting junctions are present at the cleavage furrow, Vinculin knockdown cells divide in a time frame similar to that of control cells. We propose that in this case, the force provided by the intersecting junctions acts to counterbalance the force generated by the actomyosin contractile ring. We hypothesize that Vinculin stabilizes AJs when mechanical force is applied to maintain junction integrity and barrier function. These experiments will help us gain a better understanding of how

epithelial cells maintain cell-cell adhesion and barrier function when cell-scale and tissue-scale forces challenge the connections between cells. 1. Dysfunction of PLEKHA7 Promotes Cell Proliferation and Correlates with the Progression of Pancreatic Ductal Adenocarcinoma.

R. Misra, L. Pence, R. Lu, P. Z. An astasiadis; Mayo Clinic, Jacksonville, FL.

Cell-cell adherens junctions are crucial to the formation and maintenance of epithelial tissues. Their disruption plays a critical role in the progression of epithelial cancers. PLEKHA7 is an integral component of adherens junctions at the apical zonula adherens and has proposed tumor suppressive functions. This study aims to determine the role of PLEKHA7 in the progression of Pancreatic Ductal Adenocarcinoma (PDAC), a lethal cancer with a five-year survival rate of 8%. Endogenous expression of PLEKHA7 was knocked down following infection of BxPC3 cells with lentiviruses expressing PLEKHA7 shRNA. Additionally, PLEKHA7 was ectopically overexpressed in the same cells using PLEKHA7-expressing retroviruses. Subsequent changes to cell growth were measured using an MTT Assay. Next, over 40 human Pancreatic Intraepithelial Neoplasia (PanIN) cores were classified by stage, stained for PLEKHA7 by immunohistochemistry, and characterized for expression phenotype. Finally, over 100 human PDAC cores were stained for PLEKHA7 by immunohistochemistry and characterized for expression phenotype. In the BxPC3 cell line, knockdown of PLEKHA7 led to significantly increased cell growth, compared to a control group. Overexpression of PLEKHA7 in the BxPC3 cell line led to significantly decreased cell growth, compared to a control group. Cell growth was also studied in the PANC-1 and Capan-2 cell lines. As the human PanIN lesions progressed from stage 1A to stage 3, PLEKHA7 was increasingly lost or mislocalized from the zonula adherens. An alysis of the carcinoma cores revealed PLEKHA7 to be lost or mislocalized in the vast majority of cases. These observations are consistent with PLEKHA7's proposed tumor suppressive function and suggest a novel role for the protein in the formation and progression of PDAC.

Potential Role of TNTs in Astrocytic Gliosis.

V. M. Ayres[1], V. M. Tiryaki[2], I. Ahmed[3], D. I. Shreiber[3]; [1]Michigan State University, East Lansing, MI, [2]Siirt University, Siirt, TURKEY, [3]Rutgers, the State University of New Jersey, Piscataway, NJ.

Astrocytic gliosis induced by direct cell-cell communication(s) has been long suspected but its mechanism(s) have not been clearly identified. We present our recent research that indicates a potential role for Tunneling Nanotubes (TNTs) in A1 phenotype astrocyte reactivity. TNT formation has been reported in several cell systems including astrocytes and neurons. A nanoscale-diameter tube originates on one cell and extends freely without substrate interactions for multiple cell body lengths, to establish a physical or secretory connection with another cell [1], as opposed to gap and adherens junctions formed between adjacent somata. TNTs appear to function as communicating junctions, and represent a mechanism that can be hijacked to communicate a diseased state at a level of cell-to-cell granularity. During our studies of astrocyte responses modulated by external nanophysical cue sets [2],

culture surface: poly-l-lysine-functionalized Aclar® (PLL Aclar) was investigated. When primary P1-3 cerebral cortical astrocytes (rat model) were stimulated with dibutyryladenosine cyclic monophosphate (dBcAMP) while modulated by PLL Aclar cues, they became reactive in ways that mimicked scar formation during gliosis, thus providing a model system for the study of A1 phenotype astrocyte reactivity. We now report that atomic force microscopy investigation of dBcAMP astrocytes modulated by PLL Aclar cues at time point 24h revealed extensive coverage of cell surfaces by TNT-like structures. Structures were typically y-shaped with cell attachments on the short branches and a long ~ 80-90 nm diameter branch that extended over one or more cell body lengths. Immunocytochemistry was performed using super-resolution microscopy, revealing long-distance cell-cell connections. The protein constituents were demonstrated to be actin, tubulin and also GFAP. GFAP has not be previously reported as a TNT constituent protein but is well known to be upregulated during astrocytic gliosis. Current investigations using Fluorescent Recovery after Photobleaching (FRAP) to investigate cell-to-cell transmission of Ca2+, up-regulated by mechanical stimulation of one cell in a connected pair, are designed to test if all or only some TNT candidate structures are capable of transmission. [1] HH Gerdes, et al., Mech. Devel. 130:381-387 (2013)[2] VM Tiryaki, et al., Nanomed. 10(4):529-545 (2015)

Micropatterning of EM Grids for Cryo-electron Tomography of Endothelial Cell-cell Junctions.

L. Engel, C. G. Vasquez, E. Montabana, W. I. Weis, A. R. Dunn; Stanford University, Stanford, CA.

Endothelial cell-cell contacts contain adherens junctions, mediated by cadherins, that are important for controlling vascular permeability. While it is known that altered junctional organization can lead to vascular fragility, the detailed macromolecular organization at endothelial cell-cell junctions is poorly understood. Cryogenic electron tomography (cryo-ET) is increasingly being used to investigate macro-molecular protein complex structure and organization inside cells. Recently, extracellular matrix (ECM) micropatterning of electron microscopy (EM) grids via maskless photopatterning has emerged as a method to position and confine cells to specific shapes on EM grids for whole-cell cryo-ET (Engel et. Al., bioRxiv 2019). Here, we report on an EM grid micropatterning approach that improves the efficiency of our cryo-ET workflow by increasing the yield of endothelial cell-cell junctions positioned in areas accessible to the electron beam on the EM grid. We demonstrate compatibility of this EM grid micropatterning technology with vitrification and cryo-ET and aim to apply the technology to resolve the organization and structure of junctional macromolecular complexes.

P2402/B656

The Role of the Desmoplakin-Ect2 Interaction in Cardiac Function: Emerging Roles for Desmosomes as Essential Signaling Hubs.

C. Y. Kam[1], H. Zarkoob[1], **A. Jaiganesh**[1], A. D. Dubash[2], F. Sheikh[3], K. J. Green[1]; [1]Northwestern University, Chicago, IL, [2]Furman University, Greenville, SC, [3]University of California San Diego, San Diego, CA.

Desmosomes (DSMs) are intercellular junctions that anchor intermediate filaments (IF) at sites of cell adhesion in organs that withstand high mechanical forces like the skin and the heart while maintaining tissue integrity. Defects in DSM proteins cause cardio-cutaneous pathologies like Carvajal syndrome. The IF anchoring protein desmoplakin (DP) is essential for DSM integrity and is a frequent target of mutations in disease. While DP's structural role in cells is well established, new roles for DP as a signaling hub are fast emerging. Here, we identify a novel interaction between DP and the Rho Guanidine

exchange factor Ect2 and **hypothesize that DP acts as a scaffold to recruit Rho GTPases, in turn mediating changes in F-actin and cardiomyocyte (CM) contractility. To** address this hypothesis, we first assessed DPs role in recruiting Ect2 and subsequently Rho to cell borders. Using immunofluorescence microscopy in neonatal rat ventricular cardiomyocytes (NRVCMs) and tissue from a CM-specific DP-deficient mouse model (DPcKO), we found that Ect2 and active Rho (Rho-GTP) localized to cell junctions in controls while this localization is abrogated when DP was silenced in NRVCMs or absent in the DPcKO tissue. Re-expression of wild-type DPII in depleted NVRCMs restored Ect2 and active Rho border localization. However, junctional Ect2 was reduced when a DP Carvajal mutant missing the putative Ect2-binding C-terminal region (7901delG) was expressed or cardiac tissue from Carvajal patients was analyzed. These findings support the idea that **DP is required for Ect2 and active RhoA localization at cell borders in vitro and in vivo** and that this interaction is potentially impaired in Carvajal syndrome. Rho stimulation is known to induce actin stress fiber formation and promote actomyosin-mediated contractility, essential for cardiac function. Through a collagen compaction assay, we showed that DP and Ect2 silencing reduced NRVCM contractility and this was partially restored by re-expressing wild-type DPII. Impaired contractility was also confirmed through reduced levels of troponin and myosin light-chain upon DP silencing as well as disrupted F-actin structure. Taken together, our data suggest through its interaction with Ect2, DP governs Rho signaling and actin organization to ensure mechanical integrity and cardiac function. RhoA GTPase and its downstream effectors also contribute to CM identity and differentiation, raising the possibility of an expanded role for DP as an essential signaling hub in tissue morphogenesis.

P2403/B657

Irf6 Regulates Cell Adhesions Independently of RhoA.

A. Antiguas, M. Dunnwald; University of Iowa, Iowa City, IA.

IRF6 regulates cell adhesions independently of RhoA an gelo antiguas, Martine Dunnwald Department of an atomy and Cell Biology Interferon regulatory factor 6 (IRF6) is a transcription factor that belongs to the IRF family of transcription factors. Mice lacking Irf6 exhibit defects of the epidermal barrier including abnormal localization of tight junction components to the upper layers of the epidermis compromising the epidermal integrity. Therefore, we hypothesize that IRF6 positively regulates the formation of cell-cell adhesions. To test our hypothesis, we took advantage of an in vitro system of keratinocyte culture. We performed cellular assays to evaluate the integrity of keratinocyte monolayers after mechanical disruptions. For this, we cultured keratinocytes until confluency, then used Dispase to remove cell-extracellular matrix adhesions, generating a floating monolayer upon which mechanical forces were applied by pipetting. Our data shows that the integrity of IRF6 deficient monolayers is disrupted compared to wild type. To understand the molecular mechanisms underlying this observation, we used immunofluorescent confocal microscopy to follow the pattern of cell-cell adhesions after inducing their formation following addition of Ca^{2+}. We found that components of the adherens junctions and tight junctions where not properly localized to the membrane, while desmosomal components Plakophilin and Desmocolin were absent from the membrane of IRF6 deficient cells. Interestingly, protein levels of junctional components were not altered in IRF6 deficient cells. Increased RhoA activity is a characteristic of cells lacking IRF6. However, the addition of a ROCK inhibitor did not change the pattern of localization of junctional proteins. To further investigate this junctional defect, we evaluated p120 catenin and found this molecule absent from the plasma membrane of IRF6 deficient cells. Overall, our data suggest a role for IRF6 in the proper localization of cell-cell junction components at the cell membrane. Our

preliminary evidence shows no recovery of the cell adhesion defect by using a ROCK inhibitor in IRF6 deficient keratinocytes, suggesting cellular processes downstream of RhoA are not the origin of this defect.

P2404/B658

Accumulation of Intercellular Stress Dictates the Expansion Patterns of the Epithelial Monolayer.

Y. Cho[1], B. Gweon[2], J. Notbohm[3], D. Kim[1], H. Jeong[1], H. Jang[4], D. Helfman[1], Y. Park[4], J. Fredberg[5], J. Shin[1]; [1]Korea Advanced Institute of Science and Technology, Daejeon, KOREA, REPUBLIC OF, [2]Hanyang University, Seoul, KOREA, REPUBLIC OF, [3]University of Wisconsin-Madison, Madison, WI, [4]Korea University, Seoul, KOREA, REPUBLIC OF, [5]Harvard T.H. Chan School of Public Health, Boston, MA.

Dynamic expansion of cellular monolayers occurs during physiological events such as embryogenesis, wound healing, and cancer invasion. The expanding epithelial monolayers often display a tortuous landscape characterized by the collective protrusion, called 'fingering,' or the individual cell scattering, called 'dissemination' at the interface of the advancing front. Until now, the physical mechanism for such diverse expansion patterns remains largely unknown. Here, we established a simple circular monolayer of MCF10A to study the epithelial expansion. Using traction force microscopy (TFM) and monolayer stress microscopy (MSM), we quantified the spatiotemporal distribution of physical forces between the cell and the substrate or between adjacent cells within the expanding monolayer, respectively. During the expansion, we witnessed the accumulation of average intercellular stress near the advancing edge. When the intercellular stresses were decomposed to radial and circumferential components with respect to the center of the monolayer, we found a strong negative correlation between the geometrical tortuosity of the expanding front and the maintenance of local circumferential intercellular stress. The radial intercellular stress component was highly accumulated at the local fingering sites, whereas the stress accumulation was disturbed at the local disseminating sites. Through the downregulation of specific cadherins (E- and P-cadherin) within the epithelial monolayer by siRNA inhibition, we revealed that P-cadherin disruption inhibited the long-range accumulation of both circumferential and radial stress components which resulted in the dissemination of majority of cells at the expanding edge. These data suggest the mechanical role of P-cadherin in physical stress transmission and accumulation within the collective monolayer. Our results emphasize the distinctive contribution of intercellular stress components to the dynamic expansion patterns of the collective monolayer.

P2405/B659

Does the Paracellular Permeability Pathway for Large Solutes, the Leak Pathway, Have a Size Limit?

K. Amsler, A. Monaco, J. Axis, B. Ovryn; New York Inst Tech Coll Osteopathic Med, Old Westbury, NY.

The tight junction is the primary barrier limiting the movement of solutes and water between adjacent epithelial cells (paracellular permeability). Movement of solutes through the paracellular route has been divided into two pathways. The Pore Pathway has a high capacity, mediates the permeation of small solutes (molecular radius $\leq$ ~4 an gstroms), and exhibits charge selectivity. In contrast, the Leak Pathway has a low capacity, mediates the permeation of larger solutes, and does not exhibit charge selectivity. Multiple studies have demonstrated regulation of paracellular permeability via the Leak Pathway but many questions remain about its properties and characteristics. One property of the Leak Pathway that is still unclear is whether it has a size limit for permeating solutes, i.e., is mediated by a "pore" of a

defined size, or is simply a discontinuity of the tight junction that allows the paracellular movement of solutes regardless of their size. To investigate this question, we measured the transepithelial permeation of fluorescein-dextrans of increasing size (4 kDa (Stokes radius = ~13 an gstroms) to 70 kDa (Stokes radius = ~60 an gstroms)) across post-confluent populations of the renal epithelial cell line, MDCK. Since fluorescein-dextrans cannot cross the cell membrane, the paracellular route is their primary, if not sole, pathway to move across the epithelium. Each of the fluorescein-dextrans exhibited a linear rate of transepithelial permeation. As expected, permeation rate decreased as Stokes radius increased. The Stokes-Einstein equation calculates the relationship between free diffusion rate and Stokes radius. The measured flux rates deviate from the expected relationship based on the Stokes-Einstein equation as Stokes radius increases. This argues for the existence of a Leak Pathway that is size-limited, i.e., is a “pore” of defined size. To pursue this hypothesis, we used the measured fluorescein-dextran flux rates to calculate a pore size with the Renkin sieving equation. Using the approach of Adson et al. (J Pharmaceut Sci 83:1529, 1994) we obtained a ‘best-fit” pore size of 362 an gstroms (36.2 nm) for the Leak Pathway. These results support the hypothesis that, at least under our experimental conditions, the Leak Pathway of MDCK cells exhibits a size limit which restricts the paracellular movement of solute molecules as Stokes radius increases. Combined with the ability to regulate the Leak Pathway by various physiological and pathophysiological mechanisms, these results suggest the Leak Pathway may be an important cell physiological mechanism regulating the paracellular movement of large solutes.

Dynamic Endothelial Actin Structures Induce Asymmetrical Junctions That Guide Leukocyte Extravasation.

J. D. Van Buul; University of Amsterdam, Amsterdam, NETHERLANDS.

During an inflammatory response, the activated endothelium, lining the inner layer of blood vessels attracts neutrophils that subsequently cross the vessel wall to resolve, the inflammation, a process referred to as transendothelial migration (TEM). We found that the endothelium actively recruits and guides leukocytes in their exit. Upon TNF-induced inflammation, the endothelial membrane forms dynamic dorsal and lateral protrusions. Typically, we found that actin-mediated junctional protrusions serve as preferred exit sites for neutrophils. Based on a Rac1 FRET-based biosensor, we showed that these junctional protrusions are positive for Rac1 activity and that neutrophils prefer such areas for diapedesis. In an attempt to promote the extravasation of leukocytes by locally induce Rac1 activity, we used the photoactivatable Rac1 probe. Exogenous Rac1 activation leads to local and increased TEM while blocking Rac1 activity perturbed TEM. We hypothesized that for leukocytes to successfully cross cell-cell junctions, such junctions should display asymmetric activity of membrane protrusions. To test this, we transfected one endothelial cell population with the photoactivatable Rac1 probe or constitutively active Rac mutants and cultured them with a control population of endothelial cells. This resulted in an endothelial monolayer that showed asymmetric junctions, where one endothelial cell expressed the probe and the neighboring one not. We found that almost 90% of all neutrophils had a preference to cross through the asymmetric junction by going underneath the protruding cell. These experiments show that endothelial cells generate dynamic actin structures at asymmetrical junctions to support diapedesis and not simply open cell-cell junctions as was suggested before. Our findings highlight the importance of the endothelium in recruitment and guidance of immune cells through the

vessel wall and will have an impact on therapies that are devoted to controlling leukocyte extravasation by targeting the cell-cell junction regions.

Loss of ASPP2 Promotes Cell Invasion and Migration Via LSR and YAP in Human Endometrial Cancer.

T. Konno[1], T. Kohno[1], T. Okada[2], H. Shimada[2], S. Satohisa[2], S. Kikuchi[3], T. Saito[2], T. Kojima[1]; [1]Department of Cell Science, Research Institute for Frontier Medicine, Sapporo Medical University School of Medicine, Sapporo, JAPAN, [2]Department of Obstetrics and Gynecology, Sapporo Medical University School of Medicine, Sapporo, JAPAN, [3]Department of an atomy, Sapporo Medical University School of Medicine, Sapporo, JAPAN.

Apoptosis-stimulating p53 protein 2 (ASPP2) is an apoptosis inducer that acts via binding with p53 and epithelial polarity molecule PAR3. Although downregulation of ASPP2 is observed in endometrial cancer tissues and contributes to migration and invasion of the cancer cells in vitro, the detailed mechanisms remain unclear. Lipolysis-stimulated lipoprotein receptor (LSR) is a unique and an important molecule at tricellular contacts of normal and cancer cells, and loss of LSR promotes cell migration and invasion via upregulation of TEAD1/AREG dependent on Yes-associated protein (YAP) in human endometrial cancer cells. In the present study, to find how loss of ASPP2 promotes cell migration and invasion in human endometrial cancers, we investigated the mechanisms including the relationship with LSR and the regulation using human endometrial cancer cell line Sawano. Loss of ASPP2 by the siRNA promoted cell migration and invasion in Sawano cells. The loss of ASPP2 decrease LSR expression, and induced expression of phosphorylated YAP (pYAP), claudin-1, -4 and -7 as well as those by loss of LSR. Knockdown of YAP by the siRNA prevented upregulation of pYAP, cell migration and invasion induced by loss of ASPP2. Treatment with the specific antibody against ASPP2 downregulated ASPP2 and LSR and affected F-actin at tricellular contacts and upregulated expression of pYAP and claudin-1. The ASPP2 antibody induced cell migration and invasion via YAP. Upregulation of ASPP2 in Sawano cells was observed in high glucose condition and by treatment with HDAC inhibitors. In normal human endometrial epithelial cells, ASPP2 was in part colocalized with LSR at tricellular contacts and knockdown of ASPP2 or LSR by the siRNAs induced expression of claudin-1 and claudin-4. Loss of ASPP2 promoted cell invasion and migration via LSR and YAP in human endometrial cancer cells. The maintenance of ASPP2 plays crucial roles in preventing malignancy of cancer cells.

The Rho-GEF Trio Reinforces Vascular Endothelial Barrier Integrity.

J. Van Rijssel[1], I. Timmerman[2], M. Hoogenboezem[1], Y. Wu[3], R. W. Wubbolts[4], J. Goedhart[5], J. D. van Buul[1,5]; [1]Molecular Cell Biology lab, dept. Molecular and Cellular Hemostasis, Sanquin Research and University of Amsterdam, Amsterdam, NETHERLANDS, [2]Department of Hematopoiesis, Sanquin Research and University of Amsterdam, Amsterdam, NETHERLANDS, [3]Center for Cell an alyses and Modelling, University of Connecticut Health Centre, Farmington, CT, [4]Department of Biochemistry and Cell Biology, Faculty of Veterinary Medicine, Utrecht University, Utrecht, NETHERLANDS, [5]Department of Molecular Cytology, Swammerdam Institute for Life Sciences, University of Amsterdam, Amsterdam, NETHERLANDS.

Endothelial cell-cell junctions maintain a restrictive barrier that is tightly regulated to allow dynamic responses to permeability-inducing factors, inflammatory agents and transmigrating leukocytes. The

ability of these stimuli to remodel endothelial adherens junctions (AJs) and tight junctions (TJs) depends on Rho- and Rap-GTPase-controlled cytoskeletal rearrangements. How activity of Rho and Rap-GTPases is spatio-temporally controlled at endothelial junctions by guanine-nucleotide exchange factors (GEFs) is incompletely understood. Here, we identify a crucial role for the Rho-GEF Trio in stabilizing VE-cadherin-based junctions through indirect activation of Rap1. We show that Trio physically interacts with VE-cadherin and locally activates Rac1 at junctions during nascent AJ formation, as was judged by FRET-based biosensor techniques, resulting in the remodeling of junctional actin from radial to cortical actin bundles, a critical step for junction stabilization and TJ formation. Moreover, our data show that the GEF1 domain of Trio activates the GTPase Rap1 in a Rac1/RhoG-dependent manner. Trio-Rap1 signaling promotes the formation of linear junctions and functionally increases endothelial barrier function, in addition to thick F-actin fibers that, based on super-resolution microscopy, co-localize with active myosin II. We show that myosin-based tensile forces on F-actin bundles tightly pack endothelial cell junctions into linear arrays. By promoting an optimal junctional surface-tension ratio, Trio improves the stability of the vascular endothelial barrier.

P2409/B663

Septinpolymer Interactions with Catenin Complex Determine Epithelial Cell Polaritysite Seletion.

X. Wang[1,2], W. Wang[1,2], X. Liu[1,2], X. Yao[1,2]; [1]Morehouse School of Medicine Keck Center of Organoids Plasticity, Atlanta, GA, [2]MOE Key Laboratory of Membraneless Organelle and Cellular Dynamics, Hefei, CHINA.

Cell polarity is essential for physiological processes in metazoans which depend on the asymmetric organization of cellular components and structures. However, the molecular mechanisms underlying epithelial cell polarity establishment had remained elusive. In particular, how polarity site determination and polarity establishment machinery assembly are poorly illustrated. Here we show that septin complex interacts with catenin machinery to organize a functional domain to divide apical from basal membranes in epithelial cells using 2D and 3D model systems. Using polarized 2D epithelial cell monolayer culture model system and trans-epithelial electrical resistance as functional readout, our siRNA screen revealed the importance of septin integrity in epithelial cell polarity establishment. Our proteomic screen uncovered the dynamic formation of a novel septin-catenin complex during 2D monolayer polarization. The functional relevance of septin-catenin complex was then examined 3D culture in which suppression of septin resulted in formation of immature cyst without lumen, a hallmark seen in catenin-deficient 3D cultures and animals. Mechanistically, septins stabilize an association adherent catenin complex with actin cytoskeleton as, depletion or disruption of septin complex liberates adherent junction and polarity complexes into the cytoplasm. Using spectral imaging analyses coupled with chemical inhibitors, we are currently delineating the order of septin-catein complex assembly and polarity establishment in epithelial cells. Together, these findings reveal a previously unrecognized role for septins in the polarization of the apical-basal axis and lumen formation in polarized intestinal epithelial cells.

P2410/B664

A Novel Desmosome-COP9 Signalosome Interaction.

V. Krajcz, S. Cholak, A. An tonyan, N. A. Najor; University of Detroit Mercy, Detroit, MI.

The epidermis, the outermost layer of skin, serves as a critical barrier against the outside environment. A common feature among epithelial tissues is the proper maintenance and formation of cell junctional protein complexes. Desmosomes are a type of cell-cell junctional protein complex that have been shown to interact with the COP9 signalosome (Constitutively Photomorphogenic). The desmosome-COP9 complex has been shown to downregulated epidermal growth factor receptor (EGFR), which is a known signaling player in cell growth. This subsequently causes the promotion of epidermal differentiation. The mechanism by which the desmosome-COP9 complex regulate EGFR is through the removal of a protein modification called Nedd8 (de-neddylation). Upon the removal of Nedd8, EGFR is destabilized, allowing for a dampening of the growth signaling transduction pathway. While the desmosome-COP9 signalosome super-complex functions have been well defined for the maintenance of skin homeostasis, its potential role in other cytosolic regulatory pathways has not yet been explored. Previous work has lead us to question the extent to which the desmosome-COP9 signalosome can function in additional cytosolic regulator pathways. Through targeted protein analysis in a variety of epithelial cells lines, this research aims to identify and clarify the process by which the desmosome-COP9 Signalosome complex contributes to novel cell signaling.

Novel Insights into Tunneling Nanotube Formation and Function.

S. Dagar, A. Sharma, R. Pergu, M. Rawat, S. V. S. Mylavarapu; Regional Centre for Biotechnology, Faridabad, INDIA.

Abstract Tunneling nanotubes (TNTs) help in intercellular communication over long distances in animal cells and allow for bi-directional transport of cellular cargo between cells. TNTs are functionally important in several physiological processes such as signal transduction, embryonic development, immune responses, apoptosis, cancer, neurodegenerative disease initiation and intercellular pathogen transfer. Despite their established implications in health and disease, there is only a rudimentary mechanistic understanding of the biogenesis and function of tunneling nanotubes. Recently, the protein MSec was reported to be essential for TNT formation. We had hypothesized that MSec interacts with key interaction partners and needs to localize at specific subcellular regions to mediate TNT biogenesis. We describe the morphometrics of TNTs with an emphasis on the subcellular localization of MSec in mammalian cells. We observed the MSec is localized at the cortex of cells along the actin meshwork and inside the nanotubes as discrete and periodic punctae. An alysis of the MSec interactome determined in our group revealed the presence of RNA binding proteins (RBPs) that we show are required for TNT formation. Depletion of the novel MSec interacting RBPs from cells does not appear to affect the cortical enrichment of MSec, but drastically reduces TNT numbers. The strong interaction of MSec with these RBPs suggests that the localized transport to and/or translation of some of their target mRNAs at the cortex and inside TNTs could play important roles in TNT formation, maintenance and function. We further ascertained that there is significant reduction in cortical protein translation levels upon depletion of MSec-interacting RBPs. We have also uncovered a novel role for intracellular molecular motors in ensuring MSec localization to the cortex, thereby enabling TNT biogenesis. We observe a significant reduction in MSec cortical enrichment and also in nanotube numbers upon potent inhibition

of the activity of these motors using small molecule inhibitors. Present efforts are focused on understanding how molecular motors and selected RNA binding proteins regulate the process of TNT formation. Our work highlights novel molecular mechanisms and pathways that are required for tunneling nanotube formation and function and would help to explain the importance these enigmatic structures.

P2412/B666

The Crk Tyr221 Phosphorylation Site by Abl Kinase Is Dispensable for Cell Adhesion.

H. Yu, Y. Mao, X. Zhang; Columbia University, New York, NY.

ABSTRACT: the Crk adaptor proteins play a central role in many cellular processes including cell adhesion, motility and survival. There are two ubiquitously expressed Crk family proteins, Crk and CrkL, which are highly similar in their one SH2 domain and two SH3 domains. Previous studies have shown that Abl phosphorylation of the Tyr221 residue in Crk leads to an intramolecular interaction with the SH2 domain, preventing Crk from binding to other phosphotyrosine proteins. However, this elegant mechanism of Crk regulation by Abl has not been tested in vivo. Here we show that the homozygous Crk^{Y221F} knock-in mouse mutants are viable and fertile with no obvious changes in expression of Crk and CrkL protein. For integrin-mediated cell-matrix interaction, the mutant MEF cells bound normally to fibronectin-coated surface, forming focal adhesion and stress fibers after PDGF activation like wild type controls. Co-immunopreciptation experiment showed that the Y221F mutation did not perturb binding of Crk to phospho-p130Cas, which recruits Crk to the focal adhesion complex. For cadherin-mediated cell-cell interaction, the Y221F mutation also failed to perturb adherens junctions, which were readily disrupted by Abl inhibitors. Together, these results demonstrated that the Y221 phosphorylation site on Crk is not essential for cell adhesion.

Interaction of the Extracellular Matrix with the Cell-cell Junction Associated RNAi Machinery in Colon Cancer.

A. C. Daulagala, C. C. Bridges, J. Yost, L. Rutledge, J. Nair-Menon, M. Yost, A. Kourtidis; Medical University South Carolina, Charleston, SC.

Colon cancer is the third most common and second deadliest type of cancer in the United States. Loss of epithelial tissue integrity is widely observed in colon tumors. Cell-cell junctions are essential for the maintenance of epithelial tissue integrity. The Adherens Junction (AJ) is a cell-cell adhesion complex composed of E-cadherin and the catenin family of proteins. We have shown that the E-cadherin-p120 catenin partner called PLEKHA7 is critical for epithelial integrity. Importantly, we have also shown that PLEKHA7 recruits the core components of the RNAi machinery, such as AGO2, DGCR8 and DROSHA at mature apical adherens junctions to regulate miRNA levels and activity. Loss of PLEKHA7 disrupts the function of the associated RNAi machinery and promotes pro-tumorigenic cell behavior. We hypothesize that PLEKHA7 acts as a sensor of epithelial homeostasis by regulating a junction-associated RNAi machinery. Prolonged wound and fibrosis are key precursors to colon cancer by extensive deposition of extracellular matrix (ECM). Investigation of 2D Caco2 colon epithelial cells grown on different ECM substrates, such as collagen, laminin and fibronectin, showed differences in the localization of PLEKHA7 and the junction-associated RNAi machinery. In addition, investigation of biomechanical effects using stiffness assays and 2D stretch assays resulted in disturbances in the proposed localization model of the

RNAi machinery at high stiffness conditions, which are a feature of fibrotic and tumor tissues. Interestingly, PLEKHA7 depletion also resulted in increased levels of a series of ECM-related proteins, revealing an extensive, bi-directional cross-talk between PLEKHA7 and the ECM. Examination of normal human colon tissues confirmed co-localization of PLEKHA7 and of the core RNAi components at the apical surface of fully differentiated colon crypts. However, this localization is disrupted or lost in colon tumor samples from patients. Together, our data point towards a novel putative tumor suppressor mechanism tethering tissue mechanosensing with cell behavior, of which we are currently investigating its modes of regulation.

Influence of the Endogenous Cardiotonic Steroids Marinobufagenin and Digoxin on the Physiology of Ephitelial Cells.

E. Ogazon, L. Jimenez, L. Hinojosa, J. Martinez-Rend{on, A. Castillo, M. Cereijido, A. Ponce; CINVESTAV Del IPN-44533066, Ciudad de Mexico, MEXICO.

Cardiac glycosides are a group of compounds widely known for their action in cardiac tissue. In the past two decades renewed interest has emerged since some cardiac glycosides were found to be endogenously produced. Endogenous cardiotonic glycosides (ECG) modulate important features of cells. We have previously studied the effect of ouabain, an endogenous cardiac glycoside, on the physiology of Madin Darby Canine Kidney cells (MDCK), and we have shown that in concentrations in the nanomolar range, it modulates key properties of these cells, such as tight junction, apical basolateral polarization, gap junctional intercellular communication (GJIC) and Adherent Junctions. In this work we study the influence of digoxin and marinobufagenin, two other endogenous cardiac glycosides, on GJIC as well as Tight Junctions. We evaluated GJIC by dye transfer assays and tight junction sealing by trans-epithelial electrical resistance (TER) measurements, as well as immunohistochemistry and Western blot assays of expression of claudin 4. We found that both, digoxin and marinobufagenin, increase GJIC, and significantly enhance the sealing degree of the Tight junctions, reflected by increased TER. Immuno-fluorescence assays show that both compounds promote enhanced basolateral localization of claudin-4 but not claudin-2, while densitometric analysis of Western blot assays indicate a significantly increased expression of claudin-4. These changes, induced by digoxin and marinobufagenin on GJIC and TER, were not observed on ouabain resistant MDCK cells, a modified MDCK cell line that has an alfa subunit with reduced ouabain affinity, indicating that Na^+-K^+-ATPase acts as the receptor mediating the actions of both ECG. Plus, the fact that the effect of both cardiac glycosides were suppressed by incubation with PP2, an inhibitor of c-Src kinase, PD98059, an inhibitor of mitogen extracellular kinase-1 and Y-27632, a selective inhibitor of ROCK, a Rho-associated protein kinase, indicate altogether, that the signaling pathways involved include c-Src and ERK1/2 as well as Rho-ROCK. These results show that the studied ECG modulate Tight and Gap Junctions and strengthen our general hypothesis that, a very important physiological role of ECG, is the control of the epithelial phenotype and the regulation of cell-cell contacts.

P2415/B669

Dissecting the Role of the Coxsackievirus and Adenovirus Receptor (CAR) in Intercellular Communication, Hypoxia Response and Cardiac Function.

F. K. Voss, W. Hamann, M. Thakkar, F. Freiberg, R. Jüttner, M. Gotthardt; Max Delbrueck Center for Molecular Medicine Berlin, Berlin, GERMANY.

The coxsackievirus and adenovirus receptor (CAR) is a cell-contact protein that mediates virus uptake and is essential for early cardiac development. It localizes to the tight junctions of epithelial cells and the intercalated disc of cardiomyocytes. CAR expression is low in the adult myocardium but is increased during remodeling following disease or injury. Recently, we have documented an unexpected protective role of CAR in myocardial infarction: in CAR KO mice undergoing coronary artery ligation, infarct size is reduced resulting in improved survival rates. In order to dissect weather the protective role of CAR is connected to its function in mediating intercellular communication or rather to its involvement in hypoxia signaling or cytoskeletal and extracellular matrix remodeling, we have started to generate a comprehensive interaction map and probe the protein environment depending on external stimuli. To this end we use human iPSC derived cardiomyocytes in a proximity proteomics approach with BioID-CAR fusion protein and evaluate the role of CAR in the response to hypoxia and cell death. Thus, we aim to reveal how car integrates endocytosis, cell-contact formation, and signal transduction to provide the mechanistic basis for future CAR directed therapies.

Septin 9 Is Required for Tks5-dependent Formation of Invadopodia.

J. T. Okletey[1], T. Jones[1], C. Montagna[2], E. T. Spiliotis[1]; [1]Drexel University, Philadephia, PA, [2]Albert Einstein College of Medicine, Bronx, NY.

Metastatic cancer cells invade through tissue barriers by forming specialized actin-rich protrusions termed invadopodia. Invadopodia protrude into the extracellular matrix and degrade it by secreting matrix metalloproteinases (MMPs). Formation of invadopodia involves the recruitment and clustering of the scaffold protein TKS5 (Tyr kinase substrate with five SH3 domains) to PI(3,4)P2 membrane domains. Phosphorylation of TKS5 by the Src tyrosine kinase triggers the recruitment of the actin-binding protein Nck1 and a step-wise maturation of invadopodia, which is characterized by the recruitment and phosphorylation of cortactin and secretion of MMPs. A growing number of studies show that over-expression of septin 9, a member of the septin family of GTPases, enhances the migratory and invasive properties of cancer cells. However, the role of septin 9 in invadopodia formation is poorly understood. Here, we show that SEPT9_i1 functions in the early stages of invadopodia formation by affecting membrane recruitment and/or clustering of TKS5. Using SEPT9 isoform-specific shRNAs and gelatin degradation assays, we show that SEPT9_i1 depletion decreases the ability of MDA-MB-231 cells to degrade ECM without impacting overall cell area. Strikingly, SEPT9_i1 depletion results in diminished TKS5 clusters on the ventral membranes of MDA-MB-231 cells. In addition, pTyr421-cortactin puncta are also reduced indicating a loss in invadopodia precursors, which are enriched with phosphorylated cortactin. Consistent with a role of SEPT9_i1 in early stages of invadopodia formation, SEPT9_i1 appears to localize at the base of invadopodia surrounding areas of matrix degradation. On-going work aims at

determining the spatio-temporal role and mechanistic function of SEPT9 in the TKS5 pathway of invadopodia formation.

P2417/B671

Real-time Imaging of Intrinsic and Extrinsic Control Mechanisms in Invasive Breast Carcinoma Cells.

B. Gligorijevic, 19122; Temple University, Philadelphia, PA.

Tumor cell structures that have long been hypothesized as necessary for metastasis are invadopodia, invasive protrusions rich in structural proteins (Tks5, actin), adhesion proteins (eg. Integrin β1), and metalloproteases. Using our unique intravital imaging approaches, we previously demonstrated that invadopodia in vivo are necessary for intravasation and consequent lung metastasis. In primary tumors, we found that cells which assemble invadopodia migrate at slow speeds, in perivascular niches where the ECM is cross-linked. Outside of these niches, no invadopodia were observed and cells migrated at high speeds, via contact guidance along collagen fibers. The invadopodia-driven motility can be switched to contact guidance by reducing the ECM cross-linking or by knocking down Tks5, which in turn reduces intravasation and metastasis. We next deduced that invadopodia-driven motility consists of two oscillating states: i. Invadopodia state, in which a cell is relatively sessile while it assembles invadopodia and degrades ECM; ii. Locomotion state. State balance is regulated by integrin β1 activation levels. Importantly, the Invadopodia state only occurs in early G1, whereas the Locomotion state can be seen throughout the entire cell cycle, suggesting that the cell cycle controls invadopodia assembly. Using FUCCI markers, we next show that Invadopodia state occurs during the G1 phase of the cell cycle. A close look at the regulators of G1 revealed that the cell cycle regulator p27kip1 localizes to the sites of invadopodia assembly and overexpression of p27kip1, but not p21cip1, causes faster turnover of invadopodia and increased ECM degradation. Taken together, these findings suggest that invadopodia function is extrinsically controlled by ECM via integrin β1, as well as intrinsically, via specific cell cycle regulators.

A Synthetic Dysmobility Screen Identified STK40 to Bridge MAPK Signaling and Adhesion-based Cytoskeleton in Kinase-independent Manners.

L. Yu[1], T. Tseng[1], H. Lin[1,2], C. Tsai[3,4], E. Yen[5], W. Huang[6], Y. Wang[7], F. Tsai[1,8]; [1]Dept. Of Pharmacology, College of Medicine, National Taiwan Univeristy, Taipei, TAIWAN, [2]Dept. Of Immunology, College of Medicine, National Taiwan University, Taipei, TAIWAN, [3]School of Integrative and Global Majors, University of Tsukuba, Tsukuba, Japan,, Tsukuba, JAPAN, [4]International Institute for Integrative Sleep Medicine (WPI-IIIS), University of Tsukuba, Tsukuba, JAPAN, [5]Graduate School of Biomedical Science, University of Texas MD an derson Cancer Center, Houston, TX, [6]Institute of Cellular and Organismic Biology, Academia Sinica, Taipei, TAIWAN, [7]College of Pharmacy, Taipei Medical University, Taipei, TAIWAN, [8]Dept. Of Internal Medicine, National Taiwan University Hospital, Taipei, TAIWAN.

Cell migration is important in biological processes but how theses cell migration-related genes crosstalk with each other remain unclear. To resolve this mystery, we conducted a “two-hit” cell migration screen using short hairpin RNA (shRNA) and small molecules inhibitors. Among our candidates, Serine-Threonine Kinase 40 (STK40), a putative serine/threonine kinase, showed potential interaction with MAPK in that suppression of both genes synergistically reduced cell motility. Here we report that STK40 affects migration by altering focal adhesion (FA) dynamics. STK40 knockdown enhanced FA intensity, FA

turnover, increased stress fibers and phospho-myosin light chain (p-MLC). These phenomenon could be rescued by STK40 overexpression even when its kinase domain was truncated, indicating that STK40 might not affect FA dynamics via kinase activity. Our further elucidation of its molecular mechanism revealed that inhibition of MAPK signaling abolished the effect of STK40 on FA dynamics, symbolizing that STK40 cooperated with MAPK signaling in the same pathway. Moreover, literatures and our results showed that both MAPK signaling and STK40 promoted YAP activity, and that YAP changed FA dynamics similar to the effect of STK40. Altogether, our studies demonstrate that non-kinase action of STK40 works synergistically with MAPK signaling, activating YAP pathway to regulate FA dynamics and cell migration.

P2419/B673

Abl-mediated PI3K Activation Regulates Macrophage Podosome Assembly.

C. Yu; University of Hong Kong, Hong Kong, HONG KONG.

Podosomes play critical roles in macrophage adhesion, migration, and matrix degradation. Dot-like F-actin assembly at the plasma membrane is one of the key events of podosome formation. Nevertheless, membrane signals to trigger actin polymerization at the macrophage podosome remain poorly understood. Here, we find that phosphatidylinositol 3,4,5-trisphosphate (PI(3,4,5)P3) lipids are enriched at the plasma membrane of macrophage podosome and serve as the membrane signal to promote WASP and Arp2/3 mediated actin polymerization. We find that phosphoinositide 3-kinase (PI3K) catalytic subunit PIK3CB is distinctly enriched at the podosome core, while PIK3CA, PIK3CD and PIK3CG are not. Knockdown and chemical inhibition of PIK3CB suppress podosome formation. PI3K regulatory subunit p85alpha is recruited to podosome in a Src and c-Abl dependent manner. Inhibitions of c-Abl kinase impede PI3K activation, podosome assembly, and gelatin degradation. Src kinase inhibitions block c-Abl mediated PI3K activation. Transwell migrations of macrophages are suppressed when Src, c-Abl, or PIK3CB is inhibited.Thus, spatiotemporal biogenesis of PI(3,4,5)P3 lipids mediated by Src/c-Abl/PI3K signaling orchestrates podosome assembly, matrix degradation, and chemotactic migration of macrophages.

Coupling between Actin Retrograde Flow and Focal Adhesion Molecules Visualized by Single-molecule Speckle Microscopy.

S. Yamashiro[1,2], Y. Liu[2], N. Watanabe[1]; [1]Department of Pharmacology, Kyoto University Faculty of Medicine, Kyoto, JAPAN, [2]Laboratory of Single-Molecule Cell Biology, Kyoto University Graduate School of Biostudies, Kyoto, JAPAN.

Cell migration is important for many biological processes including development, wound healing and tumor metastasis. At the cell leading edge, the retrograde actin flow, continuous centripetal movement of the actin network, is widely observed in migrating cells. During cell migration, the retrograde actin flow has been thought to promote protrusion via linkage between the lamellipodial actin network and focal adhesions as postulated in the clutch model (Mitchison and Kirschner, Neuron, 1988). However, the role of the interaction between the retrograde actin flow and focal adhesions largely remains unclear. Single-molecule imaging is a powerful approach to directly monitor the mechanics linking actin dynamics and cell adhesion at the molecular level. In this study, we examined molecular motions of focal adhesion components and actin in lamellipodia by using Single-Molecule Speckle (SiMS)

microscopy. Interestingly, several focal adhesion components exhibit flow-associated motion along the retrograde actin flow. Furthermore, in the cell peripheral region between the cell edge and the frontal edge of focal adhesions, the retrograde flow biases toward focal adhesion. Our observations suggest that the retrograde flow streaming into focal adhesions effectively recruit focal adhesion components to focal adhesions. Our findings provide new insights into the physiological roles of the actin retrograde flow in cell migration.

P2421/B675

Mechanisms of Focal Adhesion-based Cancer Cell Migration in *Vivo*.

Q. Xue, J. Carrington, M. Roh-Johnson; University of Utah, Salt lake city, UT.

Cell migration is critical during many biological processes, including embryonic development, immune surveillance, wound healing, and cancer. Cancer cell migration mechanisms in cell culture models have been well characterized. Focal adhesion complexes have been recognized as an important structure that physically link the cell to the extracellular matrix. The dynamic assembly of focal adhesion at the cell front and disassembly at cell rear are tightly coupled with actomyosin contraction force to facilitate cell migration. Cell culture studies have provided a wealth of information regarding focal adhesion biology, however, cell-matrix interactions through focal adhesion complexes during cancer cell migration in living organisms has yet to be clearly established. To address this challenge, we have taken advantage of the optically transparent, genetically tractable zebrafish larvae to manipulate both the environment and our cells of interest, the highly migratory zebrafish melanoma (ZMEL) cells. We expressed fluorescently-tagged proteins to visualize specific components of focal adhesions during cancer cell migration in *vivo*. Strikingly, we discovered that transplanted melanoma cells disseminate to the skin and form punctate structures at the melanoma cell-matrix interface. These punctate structures localize ena/VASP, and a core focal adhesion protein, Paxillin. Thus, we hypothesize that melanoma cells form focal adhesions when they attach to the skin, and this interaction is a critical step during cell migration in *vivo*. We are currently characterizing focal adhesions in *vivo* by analyzing the focal adhesion ultra-structure and quantifying their dynamics in migrating cells. We are also assessing whether melanoma cells transduce a force to the environmental extracellular matrix. These studies will provide significant insight into focal adhesion-based cell migration in *vivo*. It will also help to identify whether melanoma cells utilize focal adhesion-based motility for dissemination and thus we can gain a better understanding on how this poorly understood process contributes to cancer-related deaths.

P2422/B676

Role of Rhoa Binding Protein Slk in Muscle Hypertrophy.

M. Maeda, S. Ueda, M. Yamanoue, Y. Shirai; Department of Agrobioscience, Graduate School of Agricultural Science, Kobe University, Kobe, JAPAN.

Small GTPase RhoA is involved in muscle cell proliferation and differentiation via effector proteins. We identified STE20-like kinase (SLK) as a RhoA binding protein by biotin enzyme labeling (BioID) method. Since SLK is an essential protein for embryonic muscle development, we analyzed the role of the interaction between RhoA and SLK in muscle hypertrophy model. After differentiation, RhoA and SLK protein expression increased in C2C12 myotubes. IGF-1 stimulation of differentiated C2C12 myotubes induced RhoA activation and phosphorylated SLK Ser189 residue, which is dependent on SLK kinase activity. SLK protein has a kinase domain (KD) on the N-terminal side and two coiled-coil domain (CC) on

the C-terminal side. In order to determine the RhoA binding region of SLK, recombinant proteins of GST fusion KD, CC-1, and CC-2 were verified for binding to RhoA by pull-down assay. As a result, binding to RhoA was detected in the CC-2 domain. Besides, recombinant RhoA protein substituted with $GTP_{\gamma}S$ specifically bound to SLK. In the overexpression of constitutively active mutant RhoA (G14V), RhoA (G14V) bound to SLK, and phosphorylated SLK Ser189. On the other hand, constitutively inactive mutant RhoA (T19N) inhibited SLK phosphorylation dependent on IGF-1 stimulation. Pretreatment with the SLK inhibitor erlotinib suppressed IGF-1-induced myocyte fusion and reduced muscle hypertrophy in C2C12 cell. These results suggest that SLK acts as a RhoA effector protein in promoting muscle cells differentiation in IGF-1 muscle hypertrophy.

Bioengineering of Cell-Matrix Interactions

Collective Mechanosensing of Matrix Rigidity Controls Agonist-induced Calcium Oscillations and Force in Multicellular Ensembles of Smooth Muscle Cells.

S. E. Stasiak, R. R. Jamieson, **H. Parameswaran**; Northeastern University, Boston, MA.

The **objective** of this study was to understand specific mechanisms by which pathological alterations in the extracellular matrix (ECM) of airways & blood vessels could be causative of diseases like asthma & hypertension. The binding of a muscle agonist like histamine to a surface receptor on the smooth muscle cell & subsequent rise in cytosolic Ca^{2+} concentration is the universal trigger for force generation in the smooth muscle. The increase in cytosolic Ca^{2+} does not occur in a spatially uniform manner. Rather, agonist exposure induces Ca^{2+} oscillations in SMCs which propagate as waves within the smooth muscle layer. These agonist-induced Ca^{2+} oscillations serve two critical functions in the smooth muscle: (1) the concentration/dose of agonist detected by the surface receptors is transduced into the frequency of Ca^{2+} oscillations with higher concentration of muscle agonist resulting in higher frequency of Ca^{2+} oscillations which can then be detected by downstream Ca^{2+} sensors & translated into dose-dependent increase in smooth muscle force. (2) Agonist induced Ca^{2+} oscillations can be transported from one SMC to its neighboring cell creating a Ca^{2+} wave that propagates around the circumference of the organ & enables synchronized contractions of SMCs necessary to constrict the airway/blood vessels. Agonist induced Ca^{2+} oscillations & long-range Ca^{2+} waves are therefore critical mechanisms that regulate vital parameters such as blood pressure & airway resistance. At present, very little is known about the role of extracellular mechanical factors such as ECM stiffness in regulating agonist-induced calcium oscillations & their transport across the many cells in a smooth muscle cell ensemble. **Findings**: in this study, we demonstrate a collective phenomenon in clusters of human airway smooth muscle, where ECM stiffening alters the intercellular communication between cells in an SMC ensemble causing these cells to increase their Ca^{2+} oscillation frequency & synchronize their Ca^{2+} oscillations. We show the altered intercellular communication causes SMCs in a confluent cluster to falsely perceive a higher dose of agonist & respond by generating a pathologically high level of force in response to a low dose of agonist. In contrast, isolated cells show no change in agonist response with matrix stiffening. We examined intercellular transport of Ca^{2+} in SMC cells & we show that contrary to dogma, the physical mechanism that enables intercellular calcium waves does not involve molecular transport across gap junctions or paracrine signaling through extracellular diffusion, but rather it is enabled by mechanical force-transfer

among cells in the cluster. **Conclusion:** Matrix remodeling in asthma & hypertension could be the cause & not the consequence of the disease progression.

High-precision and Scalable Fabrication of Biomimetic Culture Environments for Enhancing Stem Cell Maturation.

E. C. F. Fisher[1], K. Gray[1], H. Ghazizadeh[1], A. S. T. Smith[2], D. Kim[2], **N. A. Geisse**[1]; [1]NanoSurface Biomedical, Seattle, WA, [2]University of Washington, Seattle, WA.

Stem cell technology holds great promise for properly modeling human biology in *vitro*. Building representative models relies on generating hierarchically organized cells and tissues. In *vivo*, this organization is driven by a complex interplay of cells and their environment, including the extracellular matrix (ECM). Traditional cell culture environments—typically composed of hard and unstructured glass or plastic— fail to fulfill the role of the ECM in development. Consequently, many in *vitro* stem cell models often fall short in correctly reproducing critical in *vivo* phenotypes because cultured cells oftentimes lose type-specific characteristics or express phenotypes indicative of an immature developmental stage. Considerable effort is directed at fabricating biomimetic culture environments that maintain or promote mature phenotypes. However, making biomimetic substrates typically involves costly or hard-to-reproduce techniques that are often incompatible with many standard assays. Our objective is to develop novel surfaces that mimic the mechanical and structural cues of the ECM. The fabrication scheme is based on high-precision photolithography techniques, and is thus highly reproducible, scalable, and amenable to integration with most industry-standard endpoint assays, including high-NA microscopy. We extended this approach to fabricate biomimetic culture surfaces out of elastomers that can be stretched in order to reproduce mechanical cues that are critical in the development and function of certain tissues. Our data demonstrate that various cell types are amenable to this approach. hiPSC-derived cardiomyocytes (CMs) showed in *vivo*-like myofibril alignment, sarcomere spacing and width, and expression of CM-specific proteins that are present in mature myocytes. Furthermore, higher-ordered 2D anisotropic myocyte tissues also showed adult-like structure and electrophysiological responses to drugs in *vitro* when compared to traditional unordered 2D isotropic constructs. Examples of phenotype enhancement of other adherent mammalian cell types will be presented, further demonstrating the utility of the approach for generating more representative cells and tissues. We conclude that our approach is a viable method for re-creating specific aspects of the ECM that are critical for driving the development and maturation of stem cells in culture.

A High-throughput Hydrogel Array Platform for Investigating Stem Cell Mechanobiology.

R. Lei, K. C. Y. Wong, N. A. Repina, K. J. Wolf, G. E. Dempsey, A. Stahl, D. V. Schaffer, S. Kumar; University of California, Berkeley, Berkeley, CA.

Extracellular matrix (ECM) mechanics and adhesivity regulate stem cell behavior in a complex, non-linear, and interdependent manner. To quantify these important regulatory relationships, there is a need for high-throughput matrix platforms that enable parallel culture of cells in many matrix conditions at one time. To this end, we developed a multi-well hyaluronic acid (HA) platform in which cells are cultured on combinatorial arrays of gels spanning a range of elasticities and adhesivities. Our approach is based on an orthogonal photopatterning strategy (Rape et al, *Nature Communications* 6: 8129)

previously developed in our laboratory, with the stiffness gradient implemented by a programmable light illumination system (Repina et al, *bioRxiv,* doi:10.1101/675892). Our new system allows individual treatment and analysis of each matrix environment while eliminating contributions of haptotaxis and durotaxis. Proof-of-principle study on human mesenchymal stem cells (hMSCs) validated that this platform can recapitulate expected relationships between matrix stiffness, adhesivity and cell spreading in hMSCs. C3H10T1/2 (also called 10T1/2) is a mouse embryonic cell line with functional similarities to mesenchymal stem cells with the potency to differentiate into white or brown adipocytes. Previously, we showed that mature white and brown adipocytes generate different degrees of contractility, which is associated with expression of distinct myosin isoforms. (Tharp et al. *Cell Metabolism* 27, 602). This finding raises the broader possibility that adipogenic efficiency may be sensitive to ECM mechanical cues. To test this hypothesis, we cultured 10T/12 cells in our platform and found that matrix stiffness strongly influenced the percentage of cells expressing adipogenic markers. Our work is among the first to quantify the relationship between 10T1/2 fate commitment and matrix stiffness. We anticipate that this platform has broad applications in dissecting molecular mechanisms of stem cell mechanosensing.

2D Confinement Induces Shape Change and Increases Myosin Dependence of Zebrafish Epidermal Keratocyte Motility.

E. C. Labuz[1], A. S. Kennard[1], J. A. Theriot[2]; [1]Stanford University, Stanford, CA, [2]University of Washington, Seattle, WA.

Animal cells rely on actin-based motility in order to respond quickly to damage. Wound-healing fish keratocytes are one of the fastest cell types known, reaching speeds of several hundred nanometers per second. While the efficient motility mechanisms of keratocytes in culture has been studied and modeled extensively, we have recently demonstrated that keratocytes achieve similar speeds during wound healing in zebrafish embryos, despite exhibiting very different motility phenotypes. Compared to *ex vivo*, keratocytes in *vivo* migrate using more dynamic lamellipodia and actin structures, and their cell shapes are diverse and sometimes extremely elongated along the axis of migration. These cells are found basally in a bilayered epidermis during zebrafish development, so we sought to determine how the skin environment influences keratocyte motility, and what biomechanical and molecular processes are uniquely responsible for achieving rapid motility in skin. Keratocyte cell body height in the epidermis (~3 microns) is much smaller than in culture (~8 microns), so we hypothesized that confinement is a large factor in the phenotypic differences between in *vivo* and *ex vivo* keratocytes. Using an agarose overlay to confine isolated keratocytes, we found that confinement is sufficient to restrict keratocyte height to ~3 microns. 2D confinement causes other *in-vivo*-like phenotypes, including elongated cell shape and an increase in the amount and curvature of actin stress fibers. These observations have led us to conclude that physical confinement is likely to contribute significantly to the motility strategies adopted by in *vivo* keratocytes. We are developing genetic methods to directly test the effect of cell-cell interactions on keratocyte shape in the tissue environment. Although isolated keratocytes are still able to move under confinement, they exhibit reduced speed and persistence, as compared to unconfined cells. Keratocytes stop motility completely under dense agarose pads. Furthermore, confined cells, unlike unconfined cells, require activity of non-muscle myosin II for translocation. In the presence of high concentrations of blebbistatin, a myosin inhibitor, confined keratocytes form lamellipodia but cannot move their cell bodies. We are currently investigating models for the importance of myosin in confined keratocyte motility, including for traction force generation, lamellipodial actin turnover, and cell body

deformation.Taken together, our in *vivo and ex vivo* work will identify key interactions between motile cells and the layered epidermal environment.

P2427/B681

Triggering Receptor Expression on Myeloid Cells 1 Mediates Inflammatory Response to Low Shear Stress in a Three-dimensional Co-culture of Coronary Artery Smooth Muscle Cells and Endothelial Cells.

M. Liu[1], R. U. R. Mohammed[1], N. Georgantzoglou[1], S. Samant[1], D. K. Agrawal[2], Y. Chatzizisis[1]; [1]University of Nebraska Med Ctr, Omaha, NE, [2]Western University of Health Science, Pomona, CA.

Objectives: the main objective was to investigate the effect of different flow pattern on the expression of triggering receptors expressed on myeloid cells 1 (TREM-1) and its role in mediating inflammatory response on an in *vitro* model of human coronary artery. **Methods:** Human coronary artery smooth muscle cells (HCASMC) were mixed with neutralized type I collagen and plated on glass coverslips. The human coronary artery endothelial cells (HCAECs) were then plated on top of the collagen gels and cultured overnight. The co-culture was treated with or without low shear stress (LSS, 5 ± 3 dyne/cm^2), medium shear stress (MSS, 15 ± 3 dyne/cm^2), high shear stress (HSS, 30 ± 3 dyne/cm^2) with Flexcell Streamer for 4 h. Expression of TREM-1, cathepsin S and MMP-1 was examined by immunofluorescence (IF) staining, and mRNA of IL-1ß, IL-6, cathepsin S, and MMP-1 were quantified by real time qPCR. **Results:** LSS significantly stimulated TREM-1 expression, cathepsin S, and MMP-1, as evidenced by IF staining and mRNA expression (fold increase vs control) of IL-1ß (2.98 ± 0.11), IL-6 (7.96 ± 1.45), cathepsin S (3.65 ± 0.58), and MMP-1 (3.54 ± 0.85). Suppression of TREM-1 by siRNA resulted in significant inhibition on the IF expression of cathepsin S and MMP-1 proteins as well as mRNA transcripts (fold increase vs control) of the IL-1ß (1.62 ± 0.32, $p < 0.05$), IL-6 (1.25 ± 0.08, $p < 0.05$), cathepsin S (1.12 ± 0.13, $p < 0.05$), and MMP-1 (1.13 ± 0.23, $p < 0.05$). Similar outcomes on the inhibition of the inflammatory cytokines and enzymes were obtained with a pharmacologic inhibitor (LR-12) of TREM-1. Neither MSS nor HSS had significant effect on the expression of TREM-1 or aforementioned inflammatory mediators. **Conclusions:** These findings suggest that LSS promotes inflammatory response through TREM-1 expression in an in *vitro* model of human coronary artery tissue.

P2428/B682

Cell Adhesive Peptide Conjugated Chitosan Hydrogel as Salivary Gland Cell Culture Scaffolds.

K. Hozumi[1,2], C. Takahashi[1], H. Yamada[2], C. Uchiyama[2], A. Kobayashi[1], R. Hiraga[1], M. Nomizu[2]; [1]Kitasto Junior College of Health and Hygienic Science, Minamiuonuma, JAPAN, [2]Tokyo University of Pharmacy and Life Sciences, Hachioji, JAPAN.

The structure is important for proper physical function, and should be replicated during tissue engineering for regenerative purposes. Extracellular matrix (ECM) provides suitable biochemical and structural support to the tissues in vivo and in vitro. The design of biomaterials mimicking the environment of the tissues is useful strategies, and many biomaterials mimic the structural and biological functions of ECM. Chitosan-based biomaterials have been demonstrated to be perform as salivary gland cell culture. Here, we crosslinked chitosan, a polysaccharide with many free amine groups, using dicarboxylic acids and conjugated ECM derived active peptides to the chitosan hydrogel. Ten dicarboxylic acids were examined to obtain the chitosan solution and found that seven liner saturated dicarboxylic acids could solve the chitosan to the water. Then, chitosan was crosslinked by dicarboxylic

acids with direct addition of N-hydroxy succinimide (NHS) and 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide (WSC). As results, glutaric acid ($HOOC(CH_2)_3COOH$), adipic acid ($HOOC(CH_2)_4COOH$), and pimelic acid ($HOOC(CH_2)_5COOH$) effectively generated transparent 3D hydrogels through the chitosan crosslinking. The stiffness of chitosan/dicarboxylic acids hydrogels are correlated with the length of dicarboxylic acids (glutaric acid > adipic acid > pimelic acid). Dicarboxylic amino acids of Glu and Asp were also tested. Chitosan/Glu solution exhibited SOL like liquid by addition of NHS and WSC and chitosan/Asp solution did not show the difference. Chitosan in mixed glutaric acid/Glu generated hydrogels by crosslinking and its stiffness was softened depending on the amount of Glu. These suggest that the stiffness of chitosan hydrogels can control by addition of Glu. Next, we conjugated ECM peptides to the chitosan hydrogel and examined its biological activities. The peptide-chitosan/dicarboxylic acid hydrogel effectively promoted human salivary gland cells (HSGs) attachment, seven days culture of HSGs on the peptide-chitosan hydrogel resulted differentiation and acinar like formation. The biological activities of peptide-chitosan/dicarboxylic acid hydrogel are different depending on the ECM derived active peptide. The peptide-chitosan/dicarboxylic acid hydrogel could use to analyze the cellular functions mediated by specific cell surface receptors and have the potential to use as cell culture matrices of HSGCs.

The Evaluation of Extracellular Matrix Mimetic Elastin-like Polypeptide-laminin α1 Peptide.

A. T. Truong[1,2], K. Hamada[2], Y. Yamada[2], H. Guo[1], Y. Kikkawa[2], C. T. Okamoto[1], J. MacKay[1], M. Nomizu[2]; [1]University of Southern California, Los an geles, CA, [2]Tokyo University of Pharmacy and Life Sciences, Hachioji, Tokyo, JAPAN.

The extracellular matrix (ECM) is comprised of a large network of proteins that are not only essential for providing a physical scaffold but also the necessary biochemical and biomechanical signals for tissue development and repair. Laminins are a major component of the ECM and are responsible for a variety of biological processes such as cell adhesion, migration, proliferation and differentiation. Laminin α1 chain bioactive RGD containing peptide, A99 (AGTFALRGDNPQG), which was previously identified to promote strong cell attachment has demonstrated utility for tissue engineering applications. A variety of biomaterials have been used as scaffolds for these bioactive peptides, but many are not suitable for various reasons such as scalability, harsh reaction conditions or lack of homogeneity. Here, we are the first to describe methods for preparing chemically conjugated and recombinant A99 to elastin-like polypeptides (ELPs) as the scaffold and characterize their behavior as well as evaluate the coating efficiency, cell attachment and spreading activity. Preliminary evidence suggest that the A99-ELP fusion construct has great potential for use as a biomaterial in cell culture applications as they greatly promote cell adhesion and spreading. ELPs are biocompatible protein-polymers that are thermo-responsive and self-assemble in response to heat. Below a lower critical solution temperature (LCST), they are highly soluble but above the LCST, ELPs phase separate, forming coacervates. They provide an excellent structural framework for bioactive peptides and their intrinsic biophysical characteristics allow for simple production with high yields and purity making them an ideal biomaterial for tissue engineering.

P2430/B684

Characterization of Dystroglycan Binding in Adhesion of Human Induced Pluripotent Stem Cells to Laminin-511 E8 Fragment.

Y. Kikkawa[1], Y. Sugawara[1], K. Hamada[1], Y. Yamada[1], J. Kumai[1], M. Kanagawa[2], K. Kobayashi[2], T. Toda[3], Y. Negishi[1], F. Katagiri[1], K. Hozumi[1], M. Nomizu[1]; [1]Tokyo University Pharm/Life Sci, Hachioji, JAPAN, [2]Kobe University Graduate School of Medicine, Kobe, JAPAN, [3]The University of Tokyo, Graduate School of Medicine, Tokyo, JAPAN.

Human induced pluripotent stem cells (hiPSCs) are promising cells for regenerative medicine, similar to human embryonic stem cells (hESCs). These cells have an infinite proliferative potential and capacity for differentiation into all cell types of the body. They are prospective cell sources for applications such as transplantation therapy and drug discovery. The ability to stably expand the stem cells is a fundamental technical requirement for these applications.Stem cells were originally maintained in complex culture systems, comprising a mouse feeder cell layer, media containing foetal bovine serum, an extracellular matrix-rich environment for cell adhesion, and soluble growth factors. Many groups have tried to optimize xeno-free culture conditions for stem cells. In the development of cell culture systems, a fragment of laminin-511 (LM511-E8) was found to improve the proliferation of stem cells. LM511-E8 commercially available as iMatrix-511, is currently used as a culture substrate in combination with various defined medium systems. In human stem cells, integrin α6β1 is a major isoform at cell surfaces. The fragment containing the integrin α6β1-binding site, enables superior adhesion of single cell-dissociated cultures of hESCs and hiPSCs. Therefore, it is well-known that the adhesion of hiPSCs to LM511-E8 is mainly mediated through integrin α6β1. However, the involvement of non-integrin receptors remains unknown in stem cell culture using LM511-E8. In this study, we show that dystroglycan (DG) is strongly expressed in hiPSCs. The fully glycosylated DG is functionally active for laminin binding, and although it has been suggested that LM511-E8 lacks DG binding sites, the fragment does weakly bind to DG. We further identified the DG binding sequence in LM511-E8, using synthetic peptides, of which, hE8A5-20 (human laminin α5 2688-2699: KTLPQLLAKLSI) derived from the laminin coiled-coil domain, exhibited DG binding affinity and cell adhesion activity. Deletion and mutation studies show that LLAKLSI is the active core sequence of hE8A5-20, and that, K2696 is a critical amino acid for DG binding. We furtherexplored the possibility that DG-binding peptides could serve as culture substrata. Our results show that hiPSCs adhere to hE8A5-20-conjugated chitosan matrices. The amino acid sequence of DG binding peptides would be useful to design substrata for culture system of undifferentiated and differentiated stem cells.

Measuring the Inhibitory Effects of *Pseudomonas Aeruginosa* on *Candida Albican*'S Dimorphic Switch.

J. Ou, K. Ly, P. Pham, J. Choy, X. Luo; the Catholic University of America, washington, DC.

Candida albicans (Ca) and *Pseudomonas aeruginosa* (Pa) are commonly found together in polymicrobial lung infections that occur in patients with cystic fibrosis and in immunocompromised individuals. Both microbes are opportunistic pathogens, which display remarkable phenotypic plasticity and are known to have bidirectional antagonistic interactions. Much of what has been learned about Ca and Pa interactions rely on traditional in *vitro* co-culturing methods. While the quorum sensing molecules (QSMs) that mediate Ca and Pa communication were first identified with standard culturing methods, there are still many basic questions about how these two organisms interact and contribute to

infections. For example, liquid cocultures typically have >10^6 cells, which makes it difficult to quantify phenotypic changes (e.g. yeast to hyphal transition) overtime. An other challenge is to differentiate effects that require physical contact between Ca and Pa versus those that solely depend on QSMs. Here, we use a newly developed microfluidic platform that allows for coculturing two or more species permitting cross-communication either in adjacent separate hydrogels or well-mixed within one hydrogel. Ca and Pa cells are grown in hydrogels within a microfluidic device that permits cross-communication (e.g. diffusion of QSMs) under different nutrient and environmental conditions. Simultaneously, we can image both populations of Pa and Ca cells in real-time to quantify phenotypic changes such as the hyphal transition in Ca or changes in Pa motility. As a first test of our system, we are measuring the inhibitory effects of Pa on Ca hyphal development under different nutrient conditions. Our initial results show that nearly 100% of individual Ca cells develop hyphae in the hydrogels at 37°C. When a hydrogel carrying Pa is positioned adjacent to the Ca hydrogel we have not observed an inhibition in hyphal development. Yet, if we mix Pa and Ca together we observe a significant decrease in hyphal Ca cells suggesting that physical contact between Pa and Ca might be required to inhibit the yeast-to-hyphal switch, which will be further investigated. This work sets the stage to measure more complex interactions not only between Ca and Pa but potentially in studies of polymicrobial interactions that far exceed two species.

P2432/B686

Low Adhesive Scaffold Collagen Prepared from Type I Collagen Promotes Neuronal Survival and Neurite Outgrowth.

S. Kunii[1], N. Nakano[2], K. Kanekiyo[2], K. Omae[3], C. Ide[2], **K. Morimoto**[1]; [1]Kindai University, Kinokawa, JAPAN, [2]Aino University, Ibaraki, JAPAN, [3]Foundation for Biomedical Research and Innovation at Kobe, Kobe, JAPAN.

[Objective] the failure of damaged adult CNS axons to regrow results in permanent disabilities with spinal cord injury. In adults, spinal nerve axons rarely regenerate after injury. Pepsin-hydrolyzed type I collagen commonly uses for spinal cord injury repair as a scaffold. However, the transplanted collagen is not the most suitable for spinal cord repair as similar as scar. The poor regeneration of mature axons is attributed to complicated intrinsic and extrinsic mechanisms. Therefore, the repair and regeneration of spinal cord is a very attractive research for tissue engineering and regenerative medicine. Recently, we succeeded in developing low adhesive scaffold type I collagen from porcine skin (LASCol). The cells on the LASCol-coated dish collide each other one after another and get to form spheroid larger. In this study, we report that LASCol has beneficial effects on neuronal survival and axonal outgrowth. [Methods] Culture dish was coated with LASCol, Atelocollagen (Cellmatrix Type I-C, Nitta Gelatin Inc.), or poly-L-lysine. Rat neurons were prepared from the hippocampus of postnatal day 1-2 (P1-2) SD rats. Neurons were seeded and cultured on each coated-dish with Neurobasal Medium including B27 supplement. To investigate neuronal survival, we observed appearance of neurons by a phase-contrast microscope. To evaluate neural regeneration, we stained neurite outgrowth with anti-beta tubulin antibody. Moreover, morphology of regenerated neurite outgrowth was observed by scanning electron microscopy. [Results] Rat neurons strongly adhered on the LASCol coated-dish as comparison with other two coated-dish groups. On the LASCol coated-dish, beta-tubulin of neurons significantly expressed than other experimental group. Moreover, scanning electron micrograph demonstrated that neurite of each neuron form long and fine shape by culturing on LASCol matrix. [Summary and Conclusions] We demonstrated that LASCol supports neuronal survival and axonal regeneration. [Funding and

Acknowledgments] This work was supported by the Adaptable and Seamless Technology Transfer Program through target-driven R&D, JST (AS2715177U to K.M.) and Japan Agency for Medical Research and Development, Translational & Clinical Research (Osaka Univ., A-75 to K.M.). We thank Nitta Gelatin Inc. which provided the collagen materials.

P2433/B688

Characterizing the Biophysical Properties of a Tunable Hydrogel System for 3D Cell Culture.

N. Haruna, A. Ochi, Z. Wang, J. Huang; TheWell Bioscience Inc, North Brunswick, NJ.

The hydrogel-based 3D cell culture model more accurately depicts the microenvironment of cells in *vivo* than the traditional 2D cell culture system, which enables cells to grow, develop, operate, and produce feedback as if they were in a living organism. As we continue to learn more about cell growth in 3D microenvironment, we come to understand that, similar to the 2D cell culture system, the cell-cell communication and cell-matrix interactions rely on many variables of the hydrogel biophysical properties including stiffness, density, porosity, binding ligands, and composition. However, because the current animal-derived hydrogel systems struggle with the batch-to-batch consistency, while the final properties of most hydrogel systems are depended on several key factors such as culture medium, cell density, and supplement compounds; there is a lack of a thorough study on the biophysical properties of current hydrogel-based 3D cell culture products. Here, we used a xeno-free, tunable hydrogel system, VitroGel, to characterize the hydrogel rheological properties in response to ionic molecules, compositions of cell culture mediums, and supplements such as glucose and serum. The tests cover different stages of hydrogel (formation, stable, and injection) at various dilution and mixing ratios. The molecular diffusion properties of hydrogels at different concentrations and formation states were also characterized with phenol red, trypan blue, BSA and IgG. The glioblastoma cancer cells (U87 MG, SNB 75, et al) were cultured in the 3D hydrogel to evaluate the intercellular characters in response to the different hydrogel conditions. The data indicated that the VitroGel system can be a platform with defined and adjustable biophysical properties to support drug screening and toxicology studies, tissue engineering, regenerative medicine, and other basic cell biological studies.

3D Printed Tumor Spheroids for Disease Modeling and Chemotherapeutic Drug Screening.

A. Gebeyehu[1], P. Arthur[1], S. Surapaneni[1], Z. Wang[2], N. Haruna[2], J. Huang[2], M. Singh[1]; [1]Florida A&M University, Tallahassee, FL, [2]TheWell Bioscience Inc., North Brunswick, NJ.

3D Printed Tumor Spheroids for Disease Modeling and Chemotherapeutic Drug Screening Abstract 3D bioprinting is intended for regenerative medicine and disease model development for drug discovery in-vitro. Herein, we evaluated the printability of a series of xeno-free and ready-to-use bioinks, developed from the tunable hydrogel (VitroGel) system. We observed that Ink H4 and Ink H4-RGD hydrogel displayed excellent rheological properties among all screened samples. Ink H4-RGD was printable with less cell destructive extrusion pressure and showed more than 90% cell viability for both tumor and normal cells. Oscillatory rheological measurements of Ink H4-RGD hydrogel showed good printability with a wide temperature range of 20 and 37^{o}C. The constructed cell-laden scaffold maintained its stiffness for more than 20 days of incubation at 37^{o}C. NSCLC PDX (EGFR T790M) cells, which were cultured in 3D printed Ink H-RGD scaffold, showed high cell proliferation with tumor microenvironment and spheroid formation (500 µm in diameter) within 7 days as analyzed by NucBlue/Actin green and E-

cadherin immunofluorescence staining. IC50 values of docetaxel, doxorubicin and erlotinib demonstrated higher resistance in 3D spheroids of NSCLC-PDX, MDA MB231 WT and HCC B-27 cells when compared to 2D monolayers cells, as analyzed by cytotoxicity assay ($P < 0.001$). Our results of the rheological analysis, shape fidelity, scaffold stability and biocompatibility of Ink H4-RGD suggest that it could be considered for cell printing and soft tissue development for high throughput screening of various anti-cancer drugs.

P2435/B690

Ability of Individual Cells to Remodel Local Substrate Fibers Guides Their Polarization and Migration Persistence.

M. Pamonag, A. Hinson, E. Burton, S. Babcock, **K. Kubow**; James Madison University, Harrisonburg, VA.

Directing cell migration is critical for both tissue engineering/regeneration and controlling cancer metastasis. Cell migration has been guided directly via physical structures and gradients. However, cell migration control is also an emergent property of fibrous extracellular matrix (ECM) and scaffolds in which cells can rearrange fibers to generate their own guidance cues. This positive feedback system in which cells simultaneously follow and align fibers has typically been studied in the context of multi-cell masses and large-scale, permanent ECM deformations. However, such systems do not accurately recapitulate single, autonomous cell invasion. Here, we asked whether the positive feedback afforded by flexible substrate fibers influences individual cell migration decisions. HT-1080 fibrosarcoma cells were seeded as spheroids into 3D collagen type I matrices that were photocrosslinked or non-crosslinked ("native"). Cells invaded from the spheroids into the matrix as individuals and their migration paths were tracked over several hours. Cells in crosslinked matrices showed a decrease in fiber reorganization and alignment, and a concomitant decrease in migration persistence relative to cells in native matrices, suggesting that an individual cell's ability to align fibers affects is persistence. Parallel experiments were conducted in which spheroids were instead seeded onto 2D substrates with rigid polycaprolactone (PCL) fibers of varying densities and on glass. Cell persistence increased with increasing fiber density, and was highest on isotropic glass, suggesting that a fibrous substrate structure can limit migration if it cannot be aligned by cells. These findings indicate that the autonomous migration of individual cells in fibrous environments is affected by the fibers' responsiveness to remodeling and suggest a means to influence cell invasion by modulating cells' ability to generate their own contact guidance cues.

Cell Death: Apoptosis

Compulsive Methamphetamine Taking and Abstinence Under Punishment Are Associated with Differential Expression of Atf2-p53 in the Rat Dorsal Striatum.

R. Subu, S. Jayanthi, J. Cadet; National Institute on Drug Abuse, NIH, Baltimore, MD.

Addiction to methamphetamine (METH) affects approximately 25 million people in the world. Our laboratory has focused its attention on deciphering the molecular neurobiology of compulsive METH taking behaviors by using the drug self-administration (SA) model. Towards that end, we have used a reproducible METH SA model accompanied with contingent footshock punishment to dichotomize METH self-administering Sprague-Dawley rats into two phenotypes. Some animals continue to self-

administer METH compulsively (shock-resistant, SR) whereas others decrease their consumption (shock-sensitive, SS) in the presence of punishment. This model thus includes two DSM criteria of addiction, namely escalated drug intake and continuous use in the presence of adverse consequences. In the present study, we have found that compulsive METH taking (resistant) rats exhibited increased striatal abundance of phosphorylated activating transcription factor 2 (ATF2) in comparison to shock-sensitive (sensitive) rats. ATF2 is a histone acetyltransferase that adds acetyl groups to histones H2B and H4. Once active via phosphorylation, ATF2 can homodimerize or heterodimerize with other AP1 transcription factors in responses to a diverse set of cellular responses that are involved in inducing apoptosis. We thus reasoned that downstream death cascades might be activated in the shock-resistant METH rats. To test this idea, we measured the expression of the apoptotic protein, p53, and found significant increases in p53 protein levels in the dorsal striatum of resistant METH SA rats in comparison to other groups. Increased p53 was accompanied by decreased expression of the p53 target protein, Bcl-2. These results indicate that compulsive METH taking may be associated with the existence of neuropathological changes like those reported in post-mortem human brains.

Calpain 1-mediated MST1 Activation Regulates NMDA-induced Excitotoxicity in Cortical Neurons.

J. Lim, R. Lee, Y. Kim, I. Lee, E. Choi; Korea University, Seoul, KOREA, REPUBLIC OF.

Overstimulation of the ionotrophic N-methyl-D-aspartate (NMDA) receptor may cause an excessive influx of calcium that leads to excitotoxic cell death. In this study, we identified MST1 (mammalian sterile 20-like kinase-1), a serine/threonine kinase known to promote apoptosis, as a novel substrate of calpain 1. We showed that induction of excitotoxic stress in primary cortical neurons by treatment with NMDA resulted in the cleavage and activation of MST1, both of which are dependent on calpain 1 protease activity. Calpain 1-mediated cleavage promotes the nuclear translocation of MST1 resulting in the phosphorylation of histone 2B as well as neuronal cell death. Taken together, our findings suggest that NMDA induces the stimulation of MST1 in a calpain 1-dependent manner and that this stimulation is an integral part of the mechanism for NMDA-induced excitotoxicity.

Structural and Spatio-temporal Organisation of Bax and Apaf1 during Apoptosis.

A. C. Borgeaud[1], I. Ganeva[1], J. Chadwick[1], N. R. Ader[1,2], P. C. Hoffmann[1], W. Kukulski[1]; [1]MRC LMB, Cambridge, UNITED KINGDOM, [2]National Institute of Neurological Disorders and Stroke, National Insititutes of Health, Bethesda, MD.

Apoptosis involves a series of highly regulated events towards cell death. Upon apoptotic signals, the protein Bax inserts into the outer mitochondrial membrane (OMM), assembles into clusters and ruptures the OMM. This leads to release of cytochrome c from the intermembrane space into the cytosol, where it interacts with Apaf1 forming the apoptosome complex that activates caspases. Although the sequence of protein functions is known, their spatial organisation remains elusive. The role of Bax clusters, their composition and structure are enigmatic. Apoptosome formation and distribution is also unknown. Here we address the organisation of Bax clusters and the apoptosome component Apaf1, in particular their structure, dynamics and interactions in human cells. By cryo-electron tomography (ET) of focused ion-beam milled cells, we previously showed that Bax clusters are irregular meshwork, similar to sponge-like structures, possibly contributing to OMM rupture formation by

sequestering OMM components. To explore whether Bax clusters serve as compartments for downstream apoptotic events such as apoptosome formation, we used Bio-ID and immunofluorescence. We found that the mitochondrial fission factors DRP1 and MFF are part of Bax clusters, whereas Apaf1 is not. These results suggest that Bax clusters promote mitochondria reorganisation, but do not host apoptosome formation. By fluorescence imaging, we observed that Apaf1 forms transient foci that disassemble shortly before Bax clusters appear. By ET of resin-embedded cells, we found that Apaf1 foci are dense cytoplasmic structures intersected with ribosomes, thereby differing from Bax clusters which are amorphous, ribosome-excluding zones in resin-embedded cells. We are now investigating the structure of Apaf1 foci by cryo-ET. Whether Apaf1 foci are sites of apoptosome pre-assembly remains to be determined. Because of their occurrence before Bax clusters, Apaf1 could potentially be sequestered into foci to avoid apoptosis until cell fate is determined by cytochrome c release. Based on our data, we propose that the apoptotic pathway is not only organised in time, but also uses special environments such as Bax clusters and Apaf1 foci to regulate cell death. This spatial and structural compartmentalisation could allow to locally disturb cell and organelle processes, and help fine-tuning cell fate.

Manuka Essential Oil Decreases the Proliferation of Human Cancer Cell Lines.

J. Jacob, 07764, S. Soni, M. Parekh, D. Lobo; Monmouth University, West Long Branch, NJ.

Since research on the effects of essential oils on human cell lines is limited, the goal of this project was to treat cancer cells lines with manuka essential oil at different concentrations and ascertain the effects on cell proliferation. The two cancer cell lines tested were fibrosarcoma (HT-1080) cells and cervical adenocarcinoma (HeLa) cells. Manuka oil is popular in many skincare products because of its antibacterial and antiinflammatory properties that treat several skin conditions. However, manuka oil also contains an active ingredient that is commonly found in herbicides and is potentially toxic to human cells at certain concentrations. To conduct the experiment, both cell lines were grown on 24-well plates and subconfluent cultures were treated with varying concentrations of manuka oil for 24 hrs. The effect of the oil on proliferation was measured through direct cell counting using trypan blue dye exclusion and through the use of an MTT assay. A trend was found that as the concentration of oil increased, viability of both cell lines decreased. Fibrosarcoma (HT-1080) cells treated with 500 µg/ml manuka oil had significantly decreased proliferation, with a 55% decrease in viable cells compared to the control. MTT assay results also reflected this trend, with a significant decrease in MTT activity seen in cells treated with 250 and 500 µg/ml manuka oil. Increasing amounts of manuka also decreased proliferation of HeLa cells, with 500 µg/ml manuka oil resulting in a 46% decrease in viable cells compared to the control. To determine if the decreased cell number is the result of apoptosis, PARP cleavage assays will be performed. Western blotting will be used to quantify MAPK proteins usually expressed as part of cell stress responses.

P2440/B696

A New Paradigm for Regulation of Cell Death by Intracellular Ph.

B. Grillo-Hill, J. Peralta, B. DuPriest; San José State University, San José, CA.

Regulated cell death is essential during development to precisely pattern tissues and avoid developmental errors. Dysregulation of cell death is associated with pathologies including cancer

(reduced cell death) and neurodegeneration (increased cell death). Dysregulated intracellular pH (pHi) dynamics are also associated with these diseases, where cancer cells have constitutively higher pHi than normal cells, while degenerating neurons have lower pHi. Supporting this, in vitro experiments showed that the apoptotic caspase enzymes showed increased activity at low pH. Together, these observations led to the current view that cell death is enhanced at low pHi, and inhibited at higher pHi. Our objective in these studies is to directly test this prediction in vivo. We used transgenic Drosophila lines that overexpress the Na-H exchanger *DNhe2* specifically in the eye (*GMR>DNhe2*), which increases pHi and resulted in a smaller, mispatterned adult eye. We performed cell counts in pupal eyes midway through metamorphosis. We found a significant decrease in the number of interommatidial lattice cells at the end of pattern formation from an average of 15 cells in control to 11.4 cells in *GMR>DNhe2*. We performed temperature shift experiments to temporally regulate transgene expression, and determined that the critical phase for expression of *DNhe2* is pupal eye development, which coincides with two well-studied waves of apoptotic cell death. We next tested for genetic interactions between *DNhe2* and apoptotic genes. We found that the pH-dependent cell death is p53-dependent but caspase-independent, which is inconsistent with apoptosis, but suggests autophagy. We are currently testing whether molecular markers for autophagy are increased in *GMR>Dnhe2* eyes. Together, our findings will elucidate mechanisms for pH-regulation of conserved, critical developmental processes and provide evidence for new paradigms in growth control.

P2441/B697

Elucidate BaxΔ2-casapse 8 Interaction Using Computational Modeling.

Q. Yao; Illinois Institution of Technology, chicago, IL.

BaxΔ2 is a functional pro-apoptotic Bax isoform. Instead of targeting mitochondria, BaxΔ2 proteins form cytosolic aggregates and activate caspase 8. Previous experimental studies indicated that the C-terminal helix α9 structure of BaxΔ2 is critical for caspase 8 recruitment. However, the interaction between these two proteins at the molecular level is unknown. In this study, molecular dynamics (MD) simulations were performed on BaxΔ2 and caspase 8 binding-deficient mutant (L164P, located in the helix α9). Protein-protein docking was also used to estimate the binding affinities of BaxΔ2 and L164P mutant with caspase 8. We observed that the movements of BaxΔ2 and L164P mutant were different during MD simulations. The results from protein-protein docking showed that helices α9 of both BaxΔ2 wild type and mutant were near the caspase 8 binding site. However, only wt H9, but not mt H9, forms hydrogen bonds with caspase 8. These results suggest that BaxΔ2 is more favorable for binding to caspase 8 than L164P mutant. Together, these data provide a structure basis for explaining the BaxΔ2 function in Caspase 8-dependent cell death.

High-glucose Diet Reduces Fertility in *C. Elegans*: a Role for Apoptosis.

C. Dressel, A. K. Engstrom, K. Guilbo, M. A. Mondoux; College of the Holy Cross, Worcester, MA.

The amount of sugar in the average human diet has increased dramatically over the past several decades. Increased dietary sugar is correlated with increases in metabolic diseases such as Type 2 diabetes and obesity; these diseases, in turn, affect a range of biological processes, including fertility. C. elegans is an excellent model organism for studying the effects of high-sugar diet on fertility: 60-80% of genes in the human genome have an ortholog in C. elegans. Among these conserved genes are those

that control processes such as insulin signaling, glucose storage, and oocyte aging. Data from our lab and others has shown that a high-glucose diet leads to decreased fertility in *C. elegans* hermaphrodites, but the mechanisms that cause this decrease are unknown. Many types of stressors, including starvation, DNA damage, and pathogen exposure, decrease fertility by increasing germline apoptosis. We hypothesized that a high-glucose diet may also act as a stressor that decreases fertility via an increase in germline apoptosis. We find that in the absence of the core apoptosis proteins CED-3 (caspase 9 ortholog) and CED-4 (Apaf1 ortholog), high-glucose diet does not significantly reduce fertility, consistent with our model. Next, we investigated whether cellular pathways that are known to activate apoptosis are implicated in the fertility decrease seen on a high-glucose diet. We find that the CEP-1 (p53) DNA damage pathway is not required for the response to high-glucose diet: in the absence of CEP-1, a high-glucose diet reduces fertility to the same extent as it does in wild-type animals. We are currently investigating whether other known pathways, like the EGL-1 pathogen response pathway, are activated by a high-glucose diet to reduce fertility. Through this work we hope to understand the cellular consequences of a high-glucose diet for gamete survival and quality and the genetic pathways that regulate those responses.

P2443/B699

The Role of the C-type Lectin Receptor DC-SIGN in the Survival of Lymphoblastic B Cells.

A. J. Valentin-Acevedo; Universidad Central Del Caribe, Bayamon, PR.

C-Type Lectin Receptors (CLR) are soluble or membrane associated proteins capable of binding to carbohydrate ligands such as beta-glucans and mannans. While membrane-associated CLR can function as cell adhesion molecules, in immune cells they also function as a Pattern Recognition Receptors (PRR) mediating innate immune responses. Due to their high avidity for glycoproteins and glycolipids-associated carbohydrates, CLR recognize many pathogens including bacteria, fungi and viruses. DC-SIGN is a type-II transmembrane CLR expressed primarily dendritic cells (DC) and to a lesser extent in other antigen presenting cells like macrophages and activated B cells. DC-SIGN recognizes mannose and fucose bearing glycans and it functions as a receptor for several viruses (e.g. Zika, Sindbis, Dengue and HIV-1). In dendritic cells, DC-SIGN ligation leads to the recruitment and activation of scaffolding and signaling proteins LSP1, KSR1, CNK and Raf-1 modulating cytokine expression and cell function. Similar to DC, activated B cells also express DC-SIGN, however, the role of this CLR in B cell function is still elusive. In B cells, DC-SIGN binds to the HIV-1 envelope protein gp120 and while this interaction promotes T cell trans-infection, the signaling events triggered in response to gp120 binding and their outcome in B cell function is unknown. Our main goal is to identify and characterize signaling pathways in human B cells in response to DC-SIGN activation. To this end, we used two different lymphoblastic cell lines that constitutively express DC-SIGN as a model to study DC-SIGN-mediated signaling. Our preliminary observations showed that DC-SIGN expression sensitizes these cells to apoptosis and DC-SIGN activation using the HIV-1 protein gp120, mannan or an anti-DC-SIGN specific antibody reduced this phenotype. By using an antibody array and immunoblotting, we identified changes in the expression of proteins involved in cell survival and apoptosis including BclXL, Bcl-2 and Bim. Interestingly, treating lymphoblastic B cells with cytarabine in the presence of mannan or anti-DC-SIGN reduced the pro-apoptotic effect observed with cytarabine alone confirming our observations of DC-SIGN-mediated survival. Finally, RNA sequencing analysis of lymphoblastic B cells treated with the DC-SIGN ligand mannan showed the transcriptional upregulation of genes involved in lipid biosynthesis and mitochondrial metabolism. Our study suggest that activation of DC-SIGN in lymphoblastic B cells causes

the upregulation of anti-apoptotic genes promoting cell survival, which correlates with changes related to mitochondrial biology and lipid metabolism. These results suggest a novel role for DC-SIGN in the physiology of lymphoblastic B cells and potentially B cell lymphomas.

Autophagy

Molecular Mechanisms of Atg-9 Localization at Synapses.

S. Yang[1], S. E. Hill[1], L. Manning[1], D. A. Colón-Ramos[1,2]; [1]Program in Cellular Neuroscience, Neurodegeneration and Repair, Departments of Neuroscience and Cell Biology, Yale University School of Medicine, New Haven, CT, [2]Instituto de Neurobiología, Recinto de Ciencias Médicas, Universidad de Puerto Rico, San Juan, PR.

Autophagy is an evolutionarily conserved cellular degradation process in which cytosolic components are engulfed by double membrane structures known as autophagosomes. ATG-9 is the only known transmembrane protein that is a core component of the process. It is thought to cycle between immature autophagosomes and other organelles, and is important for autophagosome formation. Previous work from our lab demonstrated that ATG-9 localizes to presynaptic regions and is associated with autophagosome biogenesis at the synapse (Stavoe and Hill et al., 2016). How ATG-9 localizes within presynaptic regions and traffics between membranes to regulate autophagy is not well understood. To identify molecules required for ATG-9 localization to synapses, we performed candidate screens in AIY. We have identified four endocytic mutants, *unc-26/Synaptojanin 1*, *unc-57/Endophilin A*, *unc-11/AP180* and *dyn-1/dynamin-1*, which display highly penetrant redistribution of ATG-9 to purported subcellular compartments at presynaptic regions. We found that mutants of exocytosis regulators unc-13/Munc13 and unc-18/Munc18 suppressed the ATG-9 phenotype in *unc-26/Synaptojanin 1* mutants, suggesting a role for exocytosis in mediating ATG-9 localization at the synapse. To identify ATG-9 subcellular compartments, we have performed candidate screen looking for mutants that phenocopy endocytic mutants and colocalization study. We tested candidate autophagy mutants and found that mutants defective for early stages of autophagy phenocopied endocytic mutants, suggesting that ATG-9 subcellular compartments can be early autophagic structures. In addition, ATG-9 colocalizes with clathrin heavy chain in both wild type and *unc-26/Synaptojanin 1* mutants, and partially colocalizes with synaptic vesicle proteins, suggesting that ATG-9 accumulates to clathrin-coated structures in the mutants. We hypothesize that ATG-9 cycles between plasma membrane and immature autophagosomes at synapses, and that this process is regulated by clathrin-mediated endocytosis.

Ipmk Mediates Activation of Ulk Signaling and Transcriptional Regulation of Autophagy Linked to Liver Inflammation and Regeneration.

P. Guha, 21075; Johns Hopkins University, Baltimore, MD.

Autophagy plays a broad role in health and disease. Here, we show that inositol polyphosphate multikinase (IPMK) is a prominent physiological determinant of autophagy and is critical for liver inflammation and regeneration. Deletion of IPMK diminishes autophagy in cell lines and mouse liver. Regulation of autophagy by IPMK does not require catalytic activity. Two signaling axes, IPMK-AMPK-Sirt-1 and IPMK-AMPK-ULK1, appear to mediate the influence of IPMK on autophagy. IPMK enhances

autophagy-related transcription by stimulating AMPK-dependent Sirt-1 activation, which mediates the deacetylation of histone 4 lysine 16. Furthermore, direct binding of IPMK to ULK and AMPK forms a ternary complex that facilitates AMPK-dependent ULK phosphorylation. Deletion of IPMK in cell lines and intact mice virtually abolishes lipophagy, promotes liver damage as well as inflammation, and impairs hepatocyte regeneration. Thus, targeting IPMK may afford therapeutic benefits in disabilities that depend on autophagy and lipophagy-specifically, in liver inflammation and regeneration.

P2446/B703

Molecular Crosstalk between Autophagic and Endo-lysosomal Pathways Regulates Cellular Clearance in the Retinal Pigment Epithelium.

L. Tan, N. La Cunza, C. Germer, A. Lakkaraju; University of California, San Francisco, San Francisco, CA.

Interactions between photoreceptors and the retinal pigment epithelium (RPE) - including the visual cycle, outer segment phagocytosis and glucose transport - are essential for maintaining vision. Efficient lysosomal degradation of phagocytosed outer segments and other cellular debris is critical for RPE health. Autophagy proteins participate in LC3-associated phagocytosis of outer segments and in classical autophagic degradation within the RPE. We have found that hierarchical recruitment of autophagic machinery to outer segment phagosomes modulates membrane dynamics and leads to transcriptional activation of lysosome biogenesis. Our work reveals a highly coordinated process that links LC3-associated phagocytosis to scaling RPE degradative capacity to ensure efficient clearance of cellular debris and phagocytosed outer segments.

P2447/B704

ALS/FTD Mutations in UBQLN2 Impede Autophagy Due to a Reduction in Autophagosome Acidification.

J. J. Wu, A. Cai, J. E. Greenslade, N. R. Higgins, M. J. Monteiro; University of Maryland-Baltimore, Baltimore, MD.

Missense mutations in UBQLN2 cause X-linked dominant inheritance of amyotrophic lateral sclerosis with frontotemporal dementia (ALS/FTD). UBQLN2 is one of four UBQLN proteins expressed in humans that regulate proteostasis. The proteins facilitate clearance of misfolded proteins through the proteasome and autophagy degradation pathways. Interestingly, immunostaining of neuronal tissue from human UBQLN2 cases and UBQLN2 mouse models of ALS/FTD have revealed major disturbances in the autophagy marker p62, suggesting ALS/FTD mutations in UBQLN2 may disturb autophagy. However, neither the role of UBQLN2 in autophagy nor how ALS/FTD mutations affect autophagy is known. Here we describe results of the effects of CRISPR/Cas9 inactivation of UBQLN2 on autophagy and of the effects of expression of wild-type and ALS/FTD mutant UBQLN2 proteins in cells and mouse. Cells disrupted in UBQLN2 expression had major defects in autophagic flux, including reduction in acidification of autophagosomes. This acidification defect was discovered through use of a dual split-Venus reporter system comprising tandem-tagged C-Venus-mCherry-LC3 and N-Venus-UBQLN2 reporters. Transfection of these constructs into cells resulted in labeling of autophagosomes with both Venus and mCherry fluorescence, whereas autolysosomes were labeled only by mCherry fluorescence. The reconstitution of Venus fluorescence in autophagosomes demonstrates UBQLN2 can localize to autophagosomes. We next determined whether the autophagosome acidification defect in UBQLN2 knockout cells could be rescued by expression of WT or ALS/FTD mutant UBQLN2 proteins. Our results

show that the acidification defect can be rescued by expression of WT UBQLN2, but not by any of the 5 different ALS/FTD mutant UBQLN2 proteins tested, suggesting the ALS mutations causes loss-of-function. To identify the underlying reason for the acidification defect we examined the proteome of neuronal tissue from ALS/FTD mutant mice to determine whether expression of any subunit of the vacuolar ATPase pump was altered. This analysis revealed a specific reduction in ATP6v1g1, a subunit of the vacuolar ATPase pump, only in transgenic mice expressing a P497S UBQLN2 mutation but not in mice expressing WT UBQLN2. Diminished accumulation of the same subunit was also found in cells and mice disrupted of UBQLN2 expression, suggesting that the reduction of the subunit stems from loss of UBQLN2 function. Taken together our results suggest that ALS/FTD mutations in UBQLN2 drive pathogenesis through loss of function in autophagy through a reduction in expression of the catalytic ATP6v1g1 subunit. Efforts to restore proper expression of the subunit may provide therapeutic opportunities to treat ALS/FTD caused by UBQLN2 mutations.

P2448/B705

Cytotoxicity of Arginine Deprivation to Acute Myeloid Leukemia Cells Is Mediated by Autophagy.

F. Taki[1], N. Assaf[2], H. Noureldine[2], **R. J. Abi-Habib**[1]; [1]Lebanese American University, Beirut, LEBANON, [2]

A large number of tumor types have been shown to be auxotrophic for arginine, secondary to the loss of expression of the urea cycle enzyme argininosuccinate synthetase-1 (ASS1), hence sensitive to arginine deprivation using arginine degrading enzymes. We and others have shown that Acute Myeloid Leukemia (AML) cells are auxotrophic for arginine and sensitive to a recombinant, cobalt-substituted human arginase I [HuArgI (Co)-PEG5000]. However, the impact of arginine deprivation on the flux of autophagy, in addition to the potential contribution of autophagy to the observed cell death in AML have not been investigated yet. In this study, we assess the activation of autophagy following arginine deprivation, in five AML cell lines, and determine the impact of autophagy on cell cytotoxicity through its inhibition using the downstream autophagy inhibitor chloroquine (CQ). [HuArgI (Co)-PEG5000]-induced arginine deprivation led to a marked and sustained activation of autophagy, in AML cell lines, starting at 12 hours and lasting up to 120 hours following arginine deprivation. Addition of exogenous L-citrulline, which reverses arginine dependence in partially auxotrophic cells, led to the complete reversal of the activation of autophagy in partially auxotrophic cell lines, demonstrating that the activation of autophagy is induced by arginine deprivation. Inhibition of autophagy led to a significant decrease in cell death, reaching complete resistance at late time points (between 72 and 120 hours), indicating that cell death following arginine deprivation is mediated by the activation of autophagy (death by autophagy). Addition of the ROS scavenger N-acetylcysteine (NAC), repressed the autophagic response and reversed cytotoxicity of arginine deprivation in AML cells, indicating that the activation of autophagy, and subsequent cell death, following arginine deprivation, occur secondary to ROS generation.We have shown that [HuArgI (Co)-PEG5000]-induced arginine deprivation in AML cells leads to extensive and sustained activation of autophagy which, in turn, leads to the induction of cell death under prolonged arginine deprivation.

P2449/B706

Glyceraldehyde-3 Phosphate Dehydrogenase Bridges the Host Defense Peptide Autophagic Activity to Limit Intracellular Pathogen.

A. Asmita, S. chaudhary, A. Patidar, G. chaubey, R. dilawari, S. talukdar, R. Modenwal, M. Raje; CSIR - Institute of Microbial Technology, Chandigarh, INDIA.

Antimicrobial peptides (AMPs) are major effectors of the innate immune system. They are mainly expressed by epithelial and immune cells. Involved in many critical cellular functions like their ability to kill pathogens via autophagy and immunomodulation, reflects their anti-infective mode of action. *Mycobacterium tuberculosis* (*Mtb*), the causative agent of human tuberculosis (TB), has bedeviled humans for many years. Inside macrophages, *Mtb* resides within phagosomes, where its survival is subjected to the way it alters the phagosomal environment by inhibition of phagolysosome fusion and acidification and thereby getting ingress to the cytosol. Host-directed therapy (HDT) for TB treatment is a passable concept under which host response is targeted, like alteration of host inflammatory pathways or augmentation of cellular anti-microbial defense system. Successful host cell strategy against *Mtb* is its clearance during early stages of infection. During these initial stages, pulmonary TB patients showed upregulation of glycolysis gene glyceraldehyde-3 phosphate dehydrogenase (GAPDH) and an enhanced glycolytic flux in host immune cells. Host cell metabolic reprogramming occurs to mount effective host antimicrobial and immune response against *Mtb* infection. The present study thus attempts to explore cellular and molecular effects of GAPDH on host defense peptide antimicrobial actions. We investigated the host cell GAPDH dependent roles of LL-37 peptide in *Mtb* infected macrophages. We found that peptide activates autophagy and promote the co-localization of *Mtb*-containing phagosomes with lysosomes. We initially determined that silencing GAPDH abrogated LL-37 mediated decrease in intracellular viability of *Mtb*. GAPDH knockdown cells also failed to induce autophagosome machinery upon peptide treatment. Finally, we assessed that GAPDH knockdown cells were inefficient to activate LL-37 mediated P38 MAPK and calcium/calmodulin-dependent protein kinase cascade in infected macrophages. In our current work we also investigated the role of cell surface recruited GAPDH as a putative receptor for LL-37 peptide. Co-immunoprecipitation analysis revealed this peptide interacts with GAPDH localized in membrane of macrophages. Using confocal microscopy based analysis we found specific colocalization of LL-37 peptide with GAPDH on cell surface and also in the same endocytic compartment inside cell. Collectively our findings suggests that anti-infective activities of the antimicrobial peptide against intracellular *Mtb* were dependent on the host cell moonlighting glycolytic enzyme glyceraldehyde-3 phosphate dehydrogenase (GAPDH) where it functions as a bridging molecule.

P2450/B707

Pseudo-phosphatase Mk-styx Reduces Stress Granules When Autophagy Is Inhibited.

T. Prioleau, S. D. Hinton; College of William and Mary, Williamsburg, VA.

Pseudo-phosphatase MK-STYX Reduces Stress Granules When Autophagy is Inhibited Tatiana Prioleau and Dr. Shantá D. Hinton the Biology Department, College of William and Mary, Williamsburg, VA, 23185 **ABSTRACT:** Mitogen activated protein kinase phosphoserine/threonine/tyrosine-binding protein (MK-STYX) is a pseudo-phosphatase, which lacks the essential amino acids cysteine and histidine in the signature motif (HCX5R) that ensures proper phosphatase-enzymatic activity. This renders MK-STYX catalytically inactive; however, this does not render the protein useless. Even though it is unable to hydrolyze phosphorylated residues, MK-STYX is still able to bind phosphorylated substrates. Because of

this, MK-STYX as well as other pseudo-phosphatases serve as signals in important signal transduction pathways. We reported that MK-STYX reduces stress granules, the cell's protective response to environmental stressors. Stress granules are cytoplasmic aggregations comprised of stalled mRNA and proteins. They serve as temporary sites of mRNA modification, sorting, and translation of essential proteins during cellular stress. Stress granules have a life cycle that consists of assembly, coalescence, and disassembly. If stress granules persist after the stressors cease, they may become toxic, affecting major cellular pathways such as the cell cycle and protein synthesis. MK-STYX is involved in reducing these stress granules, but it remains unknown how MK-STYX accomplishes this. The aim of this project is to determine whether MK-STYX reduces stress granules through the autophagy pathway; previous research shows that autophagy clears stress granules. Human embryonic kidney (HEK/293) cells were co-transfected with G3BP-GFP (stress granule nucleator) and mCherry or mCherry MK-STYX or mCherry MK-STYX (active) and analyzed with fluorescence microscopy. Cell co-expressing G3BP-GFP and mCherry (control) showed stress granule formation whereas G3BP-GFP and mCherry MK-STYX co-expressing cells showed stress granule reduction, which was expected. To investigate whether MK-STYX clears stress granules through the autophagy pathway, chloroquine, a drug that inhibits autophagy, is used on all transfection conditions, which is juxtaposed with no treatment placed on all transfection conditions. In the presence of chloroquine, HEK/293 cells co-transfected with G3BP-GFP and mCherry MK-STYX showed the reduction of stress granules. This suggests that MK-STYX reduces stress granules independently of the autophagy pathway.

P2451/B708

Involvement of Atg5 in Apoptotic Nuclear Disassembly.

R. Shimizu, S. Tone; Department of Life Science and Engineering, Graduate School of Tokyo Denki University, Saitama, JAPAN.

[Introduction] We have previously reported that nuclei were condensed from stage 0 to 3 in apoptosis by an in *vitro* system using isolated nuclei (Toné *et al. Exp. Cell Res.* 2007, **313**, 3635-3644). Stage 0 means that the nucleus of the cell is in a normal state, while Stage 1, nuclei become a ring. Stage 2 is a state in which the ring of stage 1 becomes a necklace, and stage 3 is a state in which the beads of necklace aggregate interiorly. In addition to Stage 1~3, we found final stage, Stage 4 in apoptosis, in which the beads of necklace aggregates scattered outward. In this study, in order to reveal the role of autophagy, especially ATG5, one of the important factors in autophagy in executing apoptotic nuclear condensation, we examined nuclear condensation would be induced normally in the absence of ATG5. Moreover, we examined the behavior of ATG5 during apoptotic execution after UV irradiation using anti ATG5 antibody. [Methods] Immortalized MEF derived from wild type (WT) or ATG5 knockout (KO) mouse (Kuma *et al. Nature* 2004, **432**, 1032-1036) were irradiated with UVC (100 J/m^2) or treated with 50 μM etoposide, and cultured till appropriate time. [Results] Nuclear condensation of Stage 1 to 4 occurred and many scattered nuclei (nuclear condensation stage 4) were found in WT. But almost ATG5 KO nuclei were not scattered and arrested at Stage 3. We found that ATG5 protein was gathered around the nucleus at early days after UV irradiation by immunofluorescent staining. As for phagocytosis by, WT cells were successfully phagocytosed by macrophage (MΦ), but ATG5 KO cells failed. [Discussion] in conclusion, ATG5 would be involved in transition from stage 3 to stage 4 of nuclear condensation. We also found that ATG5 selectively recognized the nucleus when MEF cells were apoptotic and ATG5-KO was not phagocytosed by MΦ. It can be speculated that the presence of dead cells not phagocytosed by MΦ due to nuclear abnormality would lead to autoimmune diseases. In addition, a significant decrease

in ATG5 has been reported as a risk factor for SLE (Xiao *et al. Int. Immunopharm*. 2016, **40**, 351-361). It would be interesting to know whether cells derived from SLE patients would perform normal apoptosis, especially nuclear condensation.

P2452/B709

Selective Autophagic Clearance of Neurodegeneration-associated Protein Aggregates Is Mediated by the Autophagy Receptor, TAX1BP1.

S. A. Sarraf[1], H. V. Shah[1,2], G. Kanfer[1], A. M. Pickrell[3], L. A. Holtzclaw[4], M. E. Ward[1], R. J. Youle[1]; [1]Biochemistry Section, Surgical Neurology Branch, National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MD, [2]University of Maryland, College Park, MD, [3]School of Neuroscience Science, College of Science, Virginia Tech, Blacksburg, VA, [4]Microscopy and Imaging Core, Office of the Scientific Director, Intramural Research Program, Eunice Kennedy Shriver National Institute of Child Health and Human Development,National Institutes of Health, Bethesda, MD.

Misfolded protein aggregates can disrupt cellular homeostasis and cause toxicity, a hallmark of numerous neurodegenerative diseases. Protein quality control by the ubiquitin proteasome system and autophagy is vital for clearance of aggregates and maintenance of cellular homeostasis. Autophagy receptor proteins bridge the interaction between ubiquitinated proteins and the autophagy machinery, allowing selective elimination of cargo. Aggrephagy, the selective elimination of protein aggregates, is critical to protein quality control, but how aggregates are recognized and targeted for degradation is not well understood. Using CRISPR-mediated gene editing, we examined the requirements for 5 autophagy receptor proteins: OPTN, NBR1, p62, NDP52, and TAX1BP1 in proteotoxic stress-induced aggregate clearance. Endogenous TAX1BP1 is both recruited to and required for the clearance of stress-induced aggregates while overexpression of TAX1BP1 increases aggregate clearance through autophagy. Furthermore, we found that TAX1BP1 is highly and specifically expressed in the brain compared to other autophagy receptor proteins, suggesting a potential protective role in neurodegenerative disease. In addition, TAX1BP1 depletion sensitized IPSC-derived neurons to proteotoxic stress and toxicity due to expression of Huntington's disease-linked polyQ proteins, whereas TAX1BP1 overexpression clears cells of polyQ protein aggregates by autophagy. TAX1BP1 knockout mice exhibited increased accumulation of ubiquitin conjugates in various brain regions compared to wildtype mice, further supporting a role for TAX1BP1 in prevention of aggregate accumulation. We propose a broad role for TAX1BP1 in the clearance of cytotoxic proteins, thus identifying a new factor with therapeutic potential in clearance of protein inclusions.

Ph.D.

I. Jang, 305-333, H. Jang, K. Yang; Korea Basic Science Institute, Daejeon, KOREA, REPUBLIC OF.

Cordycepin, the major active component from Cordyceps militaris, has been reported to significantly inhibit some types of cancer; however, its effects on ovarian cancer are still not well understood. In this study, we treated human ovarian cancer cells with different doses of cordycepin and found that it dose-dependently reduced ovarian cancer cell viability, based on Cell counting kit-8 reagent. Immunoblotting showed that cordycepin increased Dickkopf-related protein 1 (Dkk1) levels and inhibited β-catenin signaling. Atg7 knockdown in ovarian cancer cells significantly inhibited cordycepin-induced apoptosis, whereas β-catenin overexpression abolished the effects of cordycepin on cell death and proliferation.

Furthermore, we found that Dkk1 overexpression by transfection downregulated the expression of c-Myc and cyclin D1. siRNA-mediated Dkk1 silencing downregulated the expression of Atg8, beclin, and LC3 and promoted β-catenin translocation from the cytoplasm into the nucleus. These results suggest that cordycepin inhibits ovarian cancer cell growth, possibly through coordinated autophagy and Dkk1/β-catenin signaling. Taken together, our findings provide new insights into the reatment of ovarian cancer using cordycepin.

Uncovering Active Modulators of Native Macroautophagy through Novel High-content Screens.

N. Safren, E. Tank, N. Santoro, S. Barmada; University of Michigan, an n Arbor, MI.

Autophagy is a critical, evolutionarily conserved pathway mediating the breakdown and recycling of cellular proteins and organelles. Emphasizing its pivotal nature, autophagy dysfunction contributes to neurodegenerative conditions, cancer, infectious diseases and cardiac disorders. Development of effective autophagy modulating drugs to treat these diseases has been hampered by fundamental deficiencies in available methods for measuring autophagic activity, or flux. To overcome these limitations, we created a unique human reporter cell line and a non-invasive imaging assay to measure autophagic flux in living cells, without the need for potentially confounding drug treatments or protein overexpression. The photoconvertible protein Dendra2 was introduced into the endogenous *MAP1LC3B* locus of human cell lines via CRISPR/Cas9 genome editing, enabling accurate and sensitive determinations of autophagy activity via optical pulse labeling. High-content screening of 1,200 tool compounds and FDA-approved drugs using this assay showed that many reported autophagy stimulators either fail to enhance autophagy, or conversely inhibit autophagy flux, reaffirming the importance of measuring pathway dynamics rather than the steady state abundance of intermediates. Within an expanded library of 24,000 compounds sampling a wide diversity of chemical space, we identified novel active compounds with profound effects on autophagy, validated by comparison with alternative methods. Further, we demonstrate that NVP-BEZ235, one of the most prominent autophagy activators identified herein, exhibited significant neuroprotective properties in a neuronal model of frontotemporal dementia and amyotrophic lateral sclerosis. These studies thus confirm the utility of the high-content autophagy assay we developed, while simultaneously highlighting new autophagy-modulating compounds that display promising therapeutic effects.

Autophagic Flux in Oocytes from Pre-pubertal and Peri-ovulatory Rats during Follicular Atresia.

M. L. Escobar, O. M. Echeverría, A. Castro, N. Torres, G. Vázquez-Nin; Facultad de Ciencias, UNAM, Ciudad de México, MEXICO.

Autophagy is a regulated and evolutionarily conserved catabolic process that implies the degradation and recycling of cytoplasmatic content (1). Autophagy is present at low levels in normal cells with the aim to maintain the intracellular homeostasis by eliminating damaged organelles and proteins. Identification of diverse proteins involved in the initiation (mTORp and Beclin-1), elongation (Atg8/LC3) and degradation (Lamp1 and p62) can be used to monitor the autophagic flux (2).The follicular atresia is a normal event into mammal's ovary to select the oocyte capable to be fertilized. It has been described the presence of the autophagic cell death process in oocytes of atretic follicles from rats in different ages. Although increased levels of LC3 and Lamp1 in oocytes from rats have been reported (3), the

complete degradation levels of this process have not been studied during oocyte elimination. To explore the autophagic flux, the presence and abundance of pro-autophagic proteins involved in each step of the autophagy were observed in pre-pubertal (19-day old) and peri-ovulatory (28-day old) rats. The results indicate that increased levels of mTORp were presents in oocytes from antral atretic follicles of both stages pre-pubertal and peri-ovulatory oocytes. Differently, mTORp was lower in the secondary and primary follicles. The marker to nucleation of autophagic vesicle Beclin-1 was increased in altered oocytes in all the phases of follicular development, as well as LC3 and Lamp 1. However, the marker to the degradation of the vesicles content p62 was decreased in oocytes from atretic follicles. Our results allowed us to identify that the oocytes from antral atretic follicles are more advanced in the autophagic process, and this is more evident in the oocytes of 19-day old. The increased levels of autophagy-related proteins Beclin-1, LC3, and Lamp 1, and decreased levels of p62 indicate the promoting of autophagy in atretic oocytes. In addition, we further show the activation of autophagic flux during oocyte elimination. These results allow us to conclude that the increased autophagic levels in the atretic oocytes is conducted until the complete degradation of the sequestered cytoplasmic content, indicating that autophagy drives to the oocytes toward an elimination process more than a survival pathway. Mitophagy Receptor Nix Mediates Cd-induced Mitophagy in Absence of Parkin in Hela Cells through Phosphorylation.

S. Naeem; Lanzhou University, Lanzhou, CHINA.

Cadmium (Cd), a non-essential heavy metal, when exposed to cells causes damages to mitochondria. Cell has evolved mechanisms to selectively remove damaged mitochondria known as mitophagy. Just like other heavy metals, Cd induces mitophagy mainly through PINK1/Parkin pathway. However, whether Cd exposure can trigger other mitophagy pathways when PINK1/Parkin is abolished remains elusive. We employed HeLa cells, which lack fully functional Parkin, as a cell model to study Parkin-independent mitophagy pathway induced by Cd. Our results showed that NIX could provide an alternate pathway for Cd-induced mitophagy in HeLa cells where the most potent PINK1/Parkin pathway in heavy metals-induced mitophagy is compromised due to mutations in Parkin gene. Specifically, 10 μM Cd for 12 h induced mitophagy in GM00637 and HeLa cells, which was assessed by mitochondrial fusion to lysosomes and decreased expression of mitochondrial markers such as COX-IV and HSP60. Notably, in GM00637 cells, Cd induced mitophagy was still dominantly mediated by PINK/Parkin pathway as evidenced by translocation of Parkin to mitochondria and co-localization with COX-IV. However, increased expression of NIX was observed in mitochondria of HeLa cells only. Moreover, NIX phosphorylation at serine-81 significantly increased in cells treated with Cd, implying that phosphorylation of NIX plays an important role in NIX-mediated mitophagy. These findings reveal a novel mechanism of Cd toxicity and suggest a compensatory role of NIX in Cd-induced mitophagy.

Regulation of the Unlipidated LC3/GABARAP Pool in Mammalian Autophagy.

S. Yu, T. Melia; Department of Cell Biology, Yale School of Medicine, New Haven, CT.

Macroautophagy is a conserved degradation pathway, featured with the *de novo* formation of double-membrane organelles called autophagosomes (AVs). AV formation requires a critical ubiquitination-like lipidation reaction, that covalently attaches the conserved glycine residue in LC3/GABARAP family proteins to phosphatidylethanolamine (PE) on growing AVs. Like ubiquitin and most ubiquitin-like proteins, LC3/GABARAP family is first translated to produce a pro-form, with an extension of amino acids downstream of the conserved glycine. Normally the extension is cleaved by a cysteine protease family of ATG4 rapidly after translation, to expose the glycine residue to allow for lipidation. However, it is not known why LC3/GABARAP and other ubiquitin-like proteins contain the carboxyl(C)-terminal extension, and thus need to be primed first for conjugation. Here we report novel regulation on the unlipidated, glycine-exposed LC3/GABARAP pool. We found a new LC3/GABARAP form when LC3/GABARAP is expressed with the C-terminal extension removed, thus ending with the conserved glycine residue. We observed similar effects with both LC3B and GL1, and in multiple cell lines. By SDS-PAGE electrophoresis, the new form migrates slightly slower than the endogenous ATG4-primed LC3/GABARAP-I form, or pre-primed recombinant LC3/GABARAP proteins purified from bacteria. In addition, a glycine to alanine mutation in LC3B completely abolishes this new form, strongly suggesting the C-terminus as the modification site. We are currently using mass spectrometry to determine the molecular identity of this new form. In summary, we discovered that non-natually primed LC3/GABARAP with the C-terminal glycine exposed is susceptible to other modifications, suggesting the priming step for ubiquitin and ubiquitin-like proteins may coordinate with other mechanisms to protect the reactive glycine residue at the C-terminus.

P2458/B715

Mutations in Atg11's Coiled-coiled 2 Region Disrupt Binding of Multiple Autophagic Partners.

A. S. Kilgore, **M. Gilruth**, S. K. Backues; Eastern Michigan University, Ypsilanti, MI.

Selective autophagy is a cellular process crucial to cellular health and function. This process involves the sequestration and transport of specific cytosolic material such as malfunctioning organelles and protein aggregates to the lysosome / vacuole for degradation and recycling. Patients with perturbed autophagic pathways are often subject to neurodegenerative diseases such as Alzheimer's and dementia. Selective autophagy is mediated by a cascade of specialized proteins referred to as 'autophagy related proteins' (Atg proteins). Many Atg proteins have been shown to interact with Atg11, leading to a model where Atg11 functions as a scaffolding protein and a critical link in the selective autophagic process. These interactions are thought to be mediated through several predicted coil-coil (CC) domains, each of which has a unique set of binding partners. Previous literature has suggested that at least five of these partners, including Atg1, Atg9 and Atg11 itself, bind at Atg11's CC2. The objective of this study was to identify which amino acids within the CC2 are crucial for the binding of each of these partners using directed mutagenesis and a yeast two hybrid screen. We found that mutations at Y565 disrupted binding between Atg11 and each of these partners. However, mutations at Y565 were also found to disrupt binding of Atg11 with Atg32 and Atg19, which are known to bind to the CC4 region of Atg11. This result suggests that mutations at Y565 caused misfolding of the entire Atg11 protein. Consistent with this, western blotting showed that mutations at Y565 caused a significant reduction in Atg11 protein

levels. These results are in contrast to previous reports that removal of the CC2 region does not block interaction with Atg19, and suggest that the previously published mapping of the Atg1, Atg9 and Atg11 interactions to the CC2 may not be reliable.

Autophagy in Germline Proliferation and Maintaining Genomic Stability.

K. Kosinski[1], J. Yanowitz[2], A. Meléndez[1]; [1]Queens College, the City University of New York, Flushing, NY, [2]Magee-Womens Research Institute, University of Pittsburgh School of Medicine, Pittsburgh, NY.

Autophagy is a conserved cellular recycling process crucial for homeostasis. In this multistep process, cellular material destined for degradation is enclosed in the autophagosome, a double-membrane bound organelle that fuses with the lysosome for degradation. BECN1 is crucial for the initial nucleation step of autophagosome formation and is a haploinsufficient tumor suppressor in mammals (Liang et al., 1999; Yue et al., 2003; Qu et al., 2003). The role of autophagy in cellular homeostasis is well documented, but its function in stem cell proliferation and genomic stability, remains not well understood. We recently described a role for BEC-1, the *C. elegans* ortholog of mammalian BECN1, and several other autophagy genes in germline stem cell proliferation (Ames et al., 2017). Specifically, we found that BEC-1*,* ATG-18 (in mammals, WIPI1/2), ATG-16.2 (ATG16L) and ATG-7 (ATG7), are required for the late larval expansion of germline stem cell progenitors during development. We demonstrated that BEC-1/BECN1 functions non-cell autonomously to promote germline stem cell proliferation, which may have implications for the understanding and development of therapies against malignant cell growth in the future. A role for BECN1 in the DNA damage response (DDR) to UV, where it exhibits crosstalk with CEP-1, the *C. elegans* ortholog of p53 was also reported (Hoffman et al., 2014). CEP-1 is well known for its roles in promoting genomic integrity through the DDR, including cell cycle control, apoptosis, and DNA repair. CEP-1 was recently shown to act in meiosis, suppressing nonhomologous end-joining (NHEJ), to commit repair of double-strand breaks (DSBs) to the error-free homologous recombination (HR) pathway (Mateo et al., 2016). We are now investigating the mechanism(s) by which BEC-1 and other autophagy genes promote DNA damage repair. Our preliminary data indicate a role for autophagy in promoting meiotic fidelity. Meiotic crossover events are initiated by induction of DSBs, which are faithfully repaired by homologous recombination to maintain genomic stability. The major hallmarks of meiosis include pairing of homologous chromosomes, synapsis, DSB formation, and crossover repair. A defect at any of these steps can result inchromosomal abnormalities and lethality. Our current work seeks to elucidate the steps of meiosis that require autophagy gene activity. To this end, we are examining the role of different autophagy genes, including *bec-1/becn1 and atg-7, in* the promotion of faithful pairing, segregation, crossover formation and resolution of chromosomes in the germline during meiosis.

Regulation of Atg4 Family Proteases by the C-terminal LIR Motif.

N. Nguyen[1], J. Jin[2], S. Yu[1], A. Valdez[3], T. Olivas[1], K. Kauffman[1], S. Nag[1], T. Melia[1]; [1]Yale University, New Haven, CT, [2]Lanzhou University Second Hospital, Lanzhou, CHINA, [3]Universidad Nacional Agraria La Molina, La Molina, Lima, PERU.

During macroautophagy in mammalian cells, the LC3 and GABARAP subfamilies of proteins undergo two essential proteolytic cleavage events. The first is a constitutive processing of these proteins from a “pro-

“ form to an activated form-I protein, in which a COOH-terminal glycine is exposed by proteolysis (priming). This glycine is subsequently used in the conjugation of these proteins to lipids on the growing autophagosomal membrane. Later, when the autophagosome is fully formed, these proteins are released from the conjugated lipid by a second ATG4-dependent proteolysis event (delipidation). We recently established that the COOH-terminal LC3-interaction region (LIR) on ATG4B contributes specifically to the deconjugation from lipids but not to proteolysis in solution, suggesting this motif is essential for establishing the temporal release of LC3 from autophagosome membranes. This motif is also conserved in the other three mammalian ATG4 proteins, thus here we test whether delipidation is generally regulated at this motif. We find that although the LIR is needed to maintain wildtype-like activity in both ATG4B and ATG4A, the apparent specificity for delipidation and not priming is limited to ATG4B proteins. In addition, phosphorylatable serines in the immediate vicinity of the LIR only modestly alter the functionality of ATG4B and ATG4A in either fully in vitro or cell-rescue experiments, even as broad manipulation of kinase pathways shifts the form-I/form-II balance. Together, these results suggest that this LIR motif is not a major site of regulation but rather is an integral component of the proteolysis mechanism. We also discover that within our ATG4A rescue experiments there is a very strong suppression of the delipidation activity: GABARAP proteins accumulate in the lipidated form when only ATG4A is available and we do not detect any form-I proteins. This surprising result suggests that removal from the autophagosome either absolutely requires ATG4B in *vivo*, or requires a maturation event that is missing when ATG4B is absent.

Hyperthermia Triggers ER Resident Protein Secretion.

K. Trychta, L. Fortuno, E. Wires, B. Harvey; National Institute on Drug Abuse, NIH, Baltimore, MD.

Increased body temperature is often associated with infection and injury; however cancer, blood disorders, and genetic disorders (e.g. malignant hyperthemia) can also result in elevated body temperature. At a cellular level, hyperthemic conditions cause the accumulation of misfolded proteins, trigger endoplasmic reticulum (ER) stress, activate the unfolded protein response, and can ultimately cause cell death. Hyperthermic disruptions to ER homeostasis can affect intrinsic ER functions like protein processing and trafficking, lipid and carbohydrate metabolism, and drug detoxification. The ER also serves as the main intracellular calcium reservoir and, in fact, many ER functions depend on the maintenance of a steep calcium gradient with ER luminal calcium concentrations being much greater than those in the cytoplasm. The connection between hyperthermia, ER calcium, and ER proteostasis remains to be fully elucidated. Our lab previously designed and characterized a *Gaussia* luciferase (GLuc) reporter protein, GLuc-ASARTDL, which contains an ER retention sequence that confers secretion specifically in response to ER calcium depletion. Moreover, the behavior of GLuc-ASARTDL also reflects the behavior of other proteins with ER retention sequences. We demonstrate that increased temperature triggers the redistribution of normally ER resident proteins into the extracellular space. This represents a drug targetable molecular mechanism of ER dysfunction underlying hyperthemic conditions.

Chemogenomic Profiling Identifies the Hsp70 Co-chaperone Hdj2 as a Hub for Anticancer Drug Resistance.

.Nitika, 28223, J. Blackman, A. W. Truman; University of North Carolina Charlotte, Charlotte, NC.

Hsp70 is an important molecular chaperone that is elevated in a variety of tumors and regulates the stability of oncoproteins including Ras, Muc1, p53, Cdk2, and Rb. Attempts to develop anti-chaperone drugs for clinical use in the treatment of cancer have been hampered by toxicity issues. Hsp70 is regulated by a suite of co-chaperone molecules that transport unfolded protein "clients" to Hsp70 for folding and stimulate the intrinsic ATPase of Hsp70. Rather than targeting Hsp70 itself, in this study we examine the feasibility of inhibiting of the Hsp70 co-chaperone Hdj2 as a novel anticancer strategy. Bioinformatic analysis revealed that Hdj2 is upregulated and/or mutated in a variety of cancers such as prostate cancer, breast cancer, and stomach cancer. To assess whether inhibition of Hdj2 may sensitize cells to validated anticancer drugs, we screened compounds present in the NIH Approved Oncology collection for chemical-genetic interactions with the loss of Hdj2 in cancer cells. 41 compounds showed strong synergy with the loss of Hdj2, and 3 of these hits are validated in combination with a unique Hdj2 inhibitor (116-9e) for synergy in Castration-resistant prostate cancer cell lines. Interestingly, 18 molecules from the NIH Approved Oncology collection displayed reduced potency in the knockout cell line, 3 of these hits displayed antagonism in combination with 116-9e. Finally, we used a three-dimensional cell culture model, (spheroids) in order to test the efficacy of the drug combination in an environment that replicates the native tumor environment. Taken together, these results suggest that Hdj2 is a hub for anticancer drug resistance and that Hdj2 inhibition may be a potent strategy to sensitize cancer cells to current and future therapeutics.

P2463/B720

Transient Intracellular Acidification Regulates the Core Transcriptional Heat Shock Response.

C. Triandafillou, A. R. Dinner, D. Drummond; University of Chicago, Chicago, IL.

The cellular response to heat involves dramatic changes in the regulation of fundamental cellular processes, including the induction of a conserved stress-associated transcriptional program regulated by Heat Shock Factor 1 (Hsf1). Canonically, this activation is thought to be triggered by accumulation of misfolded proteins generated by thermal denaturation. However, temperature increase triggers many physical changes in cells, including transient intracellular acidification which, by unknown mechanisms, is broadly associated with increased stress resistance in eukaryotes. Despite decades of research that have characterized the heat shock response, how and whether acidification influences stress-associated changes in transcription, translation, and growth is largely unknown. Here we demonstrate that intracellular acidification triggered by heat shock in the budding yeast S. cerevisiae is adaptive and promotes rapid activation of Heat Shock Factor 1 (Hsf1). Using multiple methods to measure and control intracellular pH during stress, we demonstrate that acidification universally promotes induction of stress-responsive gene. Furthermore, we have found conditions in which prevention of intracellular acidification suppresses the heat shock response following a physiologically-relevant increase in temperature. Finally, we show that heat-associated acidification specifically promotes the induction of genes controlled by the canonical transcription factor Hsf1, even under conditions where classic models of Hsf1-activation would predict a suppressed response. Our findings reveal a decisive causal role for intracellular pH changes in the eukaryotic transcriptional stress response. In light of our findings, we

consider the possibility that Hsf1 may be activated by non-canonical means that are not the direct result of protein misfolding.

P2464/B721

Role of Hsp70 in Protein Aggregation of Sialic Acid Deficient Cells: Pathological Relevance to Neuromuscular Rare Genetic Disorder.

R. Yadav, R. Arya; Jawaharlal Nehru University, New Delhi, INDIA.

Sialic acids are a family of nine carbon acidic amino sugars that are found on terminal position of most glycans structure of glycoproteins. They are involved in stability, turnover and function of glycoproteins primarily affecting immune responses, cell adhesion, cell migration, cell to cell interactions, cell surface receptor stablility, signal transduction, tumor metastasis, wound healing etc. The deficiency of sialic acids in the cell leads to sialic acid metabolism disorders like GNE myopathy (GNEM) and sialuria. Mutations in sialic acid biosynthetic enzyme GNE (UDP-N-acetylglucosamine 2-epimerase/N-acetylmannosamine kinase) cause neuromuscular rare autosomal recessive disease, GNEM, where muscle weakness slowly progresses the patient towards wheel chair bound state. Although hyposialytion is considered to be the major cause of the disease, recent studies indicate other alternate roles of GNE in cell apoptosis, adhesion, cytoskeletal network and ER stress. No treatment or cure is available that reverse the defect and reduce muscle degeneration, still, some compounds under clinical trials include sialic acid itself and its precursors like N-acetylmannosamine (ManNac), sialyllactose. Pathologically, muscle biopsies of patient reveal occurrence of rimmed vacuole which are protein aggregates of misfolded proteins. In order to understand pathomechanism of protein aggregation in sialic acid deficient cells, HEK cell based model for GNEM was generated where pathologically relevant GNE mutations from Indian subcontinent were over-expressed and stable cell lines were generated. The GNE mutant cell lines were established for hyposialylation, reduced enzymatic activity as well as restoration of phenotype after sialic acid supplementation. The levels of key molecular chaperone, HSP70, was found to be altered in sialic acid deficient cells as observed by immunoblotting and confocal microscopy. p-Tau and β-amyloid proteins showed differential expression in GNE mutant cells compared to wild type control cells. The overall protein aggregation was found to be increased in sialic acid deficient cells compared to control cells using Thioflavin S in FACS analysis. Downstream effect of HSP70 malfunction activates stress kinases, JNK and BAG3 leading to apoptosis. Further, HSP70 function is regulated by cytoskeletal network controlling actin dynamics via cofilin and RhoA. We observed activation of p-cofilin and Rho a in sialic acid deficient cells as compared to control cells. Our study indicate role of HSP70 in protein aggregate formation in sialic acid deficient cells. Further study in GNE knock out muscle cells would validate role of HSP70 in GNE deficient cells. Our study offers HSP70 as potential therapeutic target for drug design for GNEM.

P2465/B722

Gene Knockout of Calnexin Or Calreticulin Could Not Halt Human Prothrombin Secretion.

Y. Kimura; Tokyo Denki Univ, Hiki-gun, Hatoyama-cho, Saitama pref, JAPAN.

Most of secretion proteins are N-glycosylated in lumen of the endoplasmic reticulum (ER). It is generally accepted that lectin chaperone, calnexin (CNX) and calreticulin (CRT) which can bind to a type of N-glycans, promote folding of secretion proteins, and that unfolded proteins are transported back to the cytoplasm, where they are degraded by ubiquitin/proteasome system. Only properly folded proteins are

transported to Golgi apparatus. In order to investigate the quality control of secreted protein mediated by CNX/CRT, we have studied the effects of mutations in secreted proteins and gene disruption of CNX or CRT on their secretion. We chose human prothrombin (FII) as a model of secretion protein and generated all 7 possible mutants on 3 positions of the N-glycosylation motifs on FII and 16 mutants on single amino-acid substitution of prolyl residue. The expression and secretion of the mutants were examined by transient transfection to HEK293 or COS-7 cells. All the mutants in N-glycosylation motifs were secreted into medium, even if the triple mutant which has no N-glycan was secreted, although the amount of secretion was decreased. The secreted mutant FII had the similar specific activity to that of wild FII, after treatment with the snake venom Ecarin. In contrast, two mutants on 137Pro or 376Pro residue were never secreted into medium in the prolyl residue substitution. To examine the effects of CNX or CRT gene disruption on secretion of FII, we established two independent CNX or CRT knockout HEK293 cell lines, respectively. Transfection of wild-type FII into the knockout cells showed efficient secretions, whereas secretion of the single mutation FII, P376L was completely halted in CNX or CRT knockout cells as well as in parent HEK293 cells. Taken together, these facts suggest that lectin chaperone, CNX and CRT could bind directly unfolded proteins without N-glycan. It is noteworthy that ER associated degradation (ERAD) of FII would be unusual. Inhibition of the 26S proteasome by Epoxomicin did not affect the intracellular accumulation of FII in the wild-type and the knockout HEK239 cells. On the other hand, intracellular FII was accumulated by lysosomal suppression with Chloroquine. This suggests that the degradation of unfolded FII may not be mediated by the 26S proteasome but by lysosome.

P2466/B723

Elucidation of Er Stress and Upr Pathway in Sialic Acid Deficient Cells: Pathological Relevance to Gnem.

P. Chaudhary, R. Arya; Jawaharlal Nehru University, New Delhi, INDIA.

UDP-GlcNAc 2-epimerase/ManNAc kinase (*GNE*) is the key enzyme involved in sialic acid biosynthesis. Point mutations in the GNE gene are linked to a rare genetic disorder known as **GNE Myopathy** characterized by slowly progressive distal muscle weakness that begins in the late teens to early adult years. Various studies have shown the role of GNE other than biosynthesis of sialic acid and affecting targets not linking with sialic acid biosynthesis. Pathologically, rimmed vacuole formation due to accumulation of misfolded proteins has been observed in muscle biopsies of patients. In order to understand the phenomenon of protein misfolding in sialic acid deficient cells, a HEK cell based system overexpressing GNE mutations of Indian origin was generated. Ultrastructure study by TEM revealed dilation of ER lumen in GNE mutant cells compared to wild type cells indicative of ER stress. Upregulation of GRP78, ER chaperone, indicated accumulation of misfolded proteins which may elucidate ER stress via UPR pathway through any of the three mechanisms: IRE1, PERK or ATF6 pathway. Activation of IRE-1 branch of UPR in GNE mutant cells was ascertained by increased XBP1 splicing via quantitative real time PCR. PERK and its downstream molecule, eIF2α, showed increased phosphorylation in GNE Indian mutants indicating translational attenuation. Further, ER-redox state as measured by MERO-GFP (Mammalian Endoplasmic reticulum-localized RedOx-sensitive GFP) ratio indicated increased oxidized versus reduced ER state suggesting ER stress in GNE mutant cells. This ER stress may cause activation of UPR pathway leading to cell apoptosis in GNE deficient cells. Interestingly, treatment of GNE deficient cells with cell survival molecules such as IGF-1 reverses the defect due to GNE mutation in the cell. Upon IGF-1 treatment, ER stress is reduced in GNE deficient cells as observed

by XBP1 splicing, PERK/eIF2α phosphorylation and MERO-GFP redox state. IGF-1 could rescue the cell apoptosis of GNE mutant cells, thereby, offering a potential therapeutic target for genetic disorders associated with sialic acid metabolism. Future studies on skeletal muscle cells with GNE knock out would validate the pathomechanism of misfolded protein accumulation and potential drug molecules in GNEM.

Overexpression of Perilipin-2 Protects Against Endoplasmic Reticulum Stress-mediated Fatty Liver Disease in Zebrafish Hepatocytes.

C. S. Palmer[1], A. R. Nair[1], S. A. Farber[2], M. H. Wilson[2], J. Teo[3], K. C. Sadler[1]; [1]New York University Abu Dhabi, Division of Biology, Abu Dhabi, UNITED ARAB EMIRATES, [2]Carnegie Institution for Science, Department of Embryology, Baltimore, MD, [3]New York University Abu Dhabi, Division of Engineering, Abu Dhabi, UNITED ARAB EMIRATES.

Fatty liver disease (FLD) is the most common hepatic pathology worldwide and is characterized by an accumulation of lipid droplets in the hepatocytes. Stress signaling pathways in response to unfolded protein accumulation in the endoplasmic reticulum (ER) are mediated by the unfolded protein response (UPR). This network can be accompanied by morphological changes in ER structure either as a sign of dysfunction or as a mechanism to enhance ER capacity. We investigated the relationship between ER morphological changes, UPR target gene expression and fatty liver using zebrafish expressing a transgenic fluorescent marker of the ER in hepatocytes (*Tg(fabp10a:ER-tdTomato)).* Intravital confocal imaging in 5 days post fertilization (dpf) transgenic zebrafish was performed across 6 genetic and pharmacological interventions that induced ER stress in the liver, including two environmental risks factors for fatty liver (ethanol and arsenic). We developed a quantitative approach to measure ER morphology, and found that in untreated livers, hepatocytes had a static and highly reticular ER whereas all stressors caused extensive loss of reticular ER, with tunicamycin and arsenic causing the most dramatic changes characterized by motile punctae which retained the fluorescent ER label. To assess the correlation between ER structural changes and lipid accumulation, we used a transgenic zebrafish line overexpressing the cytoplasmic lipid droplet protein Perilipin-2 (PLIN2, *Tg(fabp10a:EGFP-hPLIN2)*). Surprisingly, overexpression of PLIN2 blocked ER morphology changes in response to tunicamycin, suggesting that this lipid droplet protein protects against ER stress in the liver.

P2468/B725

Nucleation and Growth of a Phase-separated Huntingtin Inclusion.

L. Emtage; York College CUNY, New York, NY.

All major neurodegenerative disorders are characterized by the accumulation of large aggregates of unfolded protein in the nervous system. Among neurodegenerative disorders, the etiology of Huntington's Disease (HD) is uniquely simple: the sole cause of HD is a class of dominant mutations in the HTT gene, which lead to the expansion of a polyglutamine repeat region in the huntingtin protein (Htt). Expanded polyglutamine tracts cause instability, unfolding, and aggregation of mutant Htt protein. Although Htt protein is widely expressed in most tissues throughout life, only a subset of cells degenerate; most cells are able to tolerate mutant Htt without significant ill effect. How do cells cope with large quantities of unfolded protein? Many studies have found that the presence of large inclusions of aggregated protein correlates poorly with cell death, and that the concentration of small oligomeric aggregates is more predictive of cell death. Similarly, in the budding yeast *S. cerevisiae*, cells that form a

single ovoid mutant Htt-GFP inclusion grow normally, whereas numerous widely distributed Htt-GFP aggregates are toxic to the cell. Our goal is to elucidate the mechanisms by which inclusions are initiated and material is incorporated into them. We have used quantitative confocal microscopy to show that the mutant Htt-GFP inclusion in yeast is a mobile, gel-like compartment that releases huntingtin protein. Particle tracking of small aggregates indicates that they move randomly, suggesting that the inclusion body (IB) grows through coalescence with small aggregates that diffuse through the cytoplasm. The formation of an IB may be nucleated and occurs even when the ubiquitin-proteasome system has excess capacity. While the Htt-GFP inclusion in *S. cerevisiae* is often viewed as a deposit of insoluble protein which is associated with the vacuole and receives new material through active transport, our high-resolution imaging studies indicate that the Htt-GFP IB is a mobile, gel-like compartment that most likely grows through collision and coalescence with small particles.

The Ufm-1 Ligase Ufl-1 Regulates the Unfolded Protein Response (upr) and Polyq Aggregation In*C. Elegans*.

B. Ortiz Bido, P. Juo; Tufts Univ-55675894, Boston, MA.

The expansion of polyglutamine (polyQ)-encoding CAG tri-nucleotide repeats in specific genes can lead to age-related neurodegenerative diseases, such as Huntington's disease. PolyQ expansions can result in protein misfolding and aggregation leading to cellular toxicity. However, the molecular mechanisms that regulate polyQ protein aggregation in *vivo* are not well understood. We are using the genetic model *Caenorhabditis elegans to* identify novel genes and mechanisms that regulate polyQ aggregate formation in *vivo and to* analyze their effects on behavior. Expression of YFP-tagged polyQ proteins with different numbers of polyQ repeats in neurons or muscle in *C. elegans* results in the formation of aggregates and cellular dysfunction that increases with age and number of repeats. Here, we tested whether UFL-1, the E3 ligase for Ubiquitin-fold Modifier-1 (UFM-1), affects polyQ aggregates in *C. elegans*. Ufm1 is one of the least well-understood ubiquitin-like proteins. Although the UFM-1 pathwayhas been implicated in erythroid differentiation and protein homeostasis, the specific roles in vivo are not understood. We found that loss-of-function mutations in *ufl-1* results in increased number of polyQ aggregates of *C. elegans* muscle. An imals treated with the proteasome inhibitor Bortezomib also results in an increase in polyQ aggregates, however, this effect is not further enhanced by *ufl-1* mutants, suggesting that the protein folding stress triggered by Bortezomib acts in the same pathway as *ufl-1*. Using a UPR reporter consisting of the BiP/*hsp-4* promoter driving GFP, we found that loss-of-function mutations in *ufl-1* results in increased activation of the UPR. Our results are consistent with a model whereby loss of the UFL-1/UFM-1 pathway causes increased protein folding stress in cells, resulting in increased polyQ aggregation, and activation of the UPR. This study identifies a novel role for the UFL-1/UFM-1 pathway in regulating polyQ aggregation. Future studies will be focused on testing whether other genes in the UFL-1/UFM-1 pathway regulate polyQ aggregate formation, and if the UFL-1/UFM-1 pathway acts cell autonomously in muscle to regulate the UPR and protein aggregation.

The Role of Calnexin in Regulating ER Proteostasis of RESET Substrates.

N. Sharma, N. M. Lott, D. Mandal, **P. Satpute-Krishnan, 20817**; Uniformed Services University, Bethesda, MD.

RESET is a protein quality control pathway that clears diverse misfolded GPI-anchored proteins, including human disease mutants of prion protein (PrP) [1], and select transmembrane proteins out of the endoplasmic reticulum (ER) to the Golgi. RESET contrasts with ER associated degradation and autophagy pathways that retain misfolded proteins for degradation at the ER. During RESET, misfolded proteins are released by the ER-resident chaperone, calnexin (CNX), and bound by p24-family members for vesicular transport to the Golgi. The misfolded proteins subsequently transit the cell surface en route to lysosomes where they are destroyed. Thus, steady-state turnover of RESET substrates is concomitant with ER-export. However, physiological and chemical ER stressors dramatically enhance ER-export and consequent lysosomal degradation. Here we address the questions (i) what are the mechanisms regulating constitutive ER-export of RESET substrates during steady-state conditions and (ii) how do ER-stress conditions enhance ER-export of RESET substrates for subsequent degradation? for these studies, we combined imaging with biochemical analysis, including pulse-chase and pull-downs, using a previously characterized misfolding variant of PrP (PrP*[1]) as a model substrate. Our results suggest that the flux of RESET is regulated by competition of other unfolded/misfolded proteins for CNX-binding under steady-state conditions. Chemically blocking new expression of CNX substrates dramatically inhibits steady-state ER-export and degradation of CNX substrates. Conversely, an increase of competitor binding interactions with CNX during physiologically induced ER-stress conditions, such as during the upregulation of specific secretory pathway proteins, increases the rate of ER-export and degradation of RESET substrates. We present a new model that displacement from CNX by newly synthesized CNX substrates regulates the constitutive and stress-enhanced turnover of RESET substrates. [1] Satpute-Krishnan, *et al*. ER stress-induced clearance of misfolded GPI-anchored proteins via the secretory pathway. Cell. 2014; **158**:522-533

Ufmylation of Rpl26 Links Translocation-associated Quality Control to Endoplasmic Reticulum Protein Homeostasis.

L. Wang, Y. Xu, **Y. Ye**; National Institute of Diabetes and Digestive and Kidney Diseases, NIH, Bethesda, MD.

Protein biogenesis at the endoplasmic reticulum (ER) in eukaryotic cells is monitored by a protein quality control system named ER-associated protein degradation (ERAD). While there has been substantial progress in understanding how ERAD eliminates defective polypeptides generated from erroneous folding, how cells remove nascent chains stalled in the translocon during co-translational protein insertion into the ER is unclear. Here show that ribosome stalling during protein translocation at the ER induces the attachment of UFM1, a ubiquitin-like modifier, to two conserved lysine residues near the COOH-terminus of the 60S ribosomal subunit RPL26 (uL24). Strikingly, RPL26 UFMylation enables the degradation of stalled nascent chains, but unlike ERAD or previously established cytosolic ribosome-associated quality control (RQC), which uses proteasome to degrade their client proteins, ribosome UFMylation promotes the targeting of a translocation-arrested ER protein to lysosomes for degradation. RPL26 UFMylation is upregulated during erythroid differentiation, which helps cells to

cope with increased secretory flow, and compromising UFMylation impairs protein secretion, and ultimately hemoglobin production. We propose that in metazoan, co-translational protein translocation into the ER is safeguarded by a UFMylation-dependent protein quality control mechanism, which when impaired causes anemia in mice and abnormal neuronal development in humans.

Mechanism of a Memory-enhancing Inhibitor of the Integrated Stress Response.

A. A. An and[1], L. R. Kenner[2], J. C. Tsai[1], L. Miller-Vedam[2], H. C. Nguyen[2], P. Jaishankar[2], A. G. Myasnikov[2], C. J. Klose[1], L. A. McGeever[1], A. Frost[2], P. Walter[1]; [1]UCSF, Howard Hughes Medical Institute, San Francisco, CA, [2]UCSF, San Francisco, CA.

The integrated stress response (ISR) is an essential signaling network that enables cells to respond to intrinsic and extrinsic stresses by tuning mRNA translation. The ISR acts through the phosphorylation of the GTPase eIF2, a rate-limiting translation initiation factor. Phosphorylation converts eIF2 from a substrate into an inhibitor of its dedicated guanine nucleotide exchange factor, eIF2B, blocking translation. A drug-like eIF2B activator called ISRIB reverses the effects of eIF2 phosphorylation and restores translation during stress. Remarkably, in rodents, ISRIB enhances cognition and corrects cognitive deficits after brain injury without overt toxicity. To determine its mechanism of action, we solved by cryo-electron microscopy an atomic-resolution structure of ISRIB bound in a deep cleft within a decameric human eIF2B. Formation of fully active, decameric eIF2B holoenzyme depended on the assembly of two identical tetrameric subcomplexes, and ISRIB promoted this step by cross-bridging a central symmetry interface. Structures of eIF2B bound to eIF2 in the phosphorylated and dephosphorylated state revealed eIF2B to be a static platform upon which substrate, inhibitor and drug bind to modulate nucleotide exchange. Based on these structures, an interrogation of the ISR in living cells provides a compelling explanation for both ISRIB's mechanism of activating eIF2B and its lack of toxicity. From this work, eIF2B assembly emerges as a paradigm for translational control and as a promising target for therapeutic intervention for a range of neurological diseases.

P2473/B730

ALS-Linked Mutations in UBQLN2 Alter Stress-Induced Puncta Behavior.

J. F. Riley, T. Dao, S. Hewett, H. Hehnly, C. A. Castañeda; Syracuse University, Syracuse, NY.

Neuronal longevity is dependent on effective protein quality control (PQC), and aberrant protein inclusions are pathological hallmarks of many neurodegenerative diseases. Mutations in the proteasome shuttle factor ubiquilin-2 (UBQLN2), which participates in PQC mechanisms in cells, cause some types of familial amyotrophic lateral sclerosis (ALS). The protein also localizes to inclusions in motor neurons of patients with sporadic ALS. We recently showed that UBQLN2 forms puncta with liquid-like characteristics and co-localizes to stress granules (SGs), a type of membraneless organelle whose formation and persistence is hypothesized to precede protein inclusions. However, detailed characterization of UBQLN2 incorporation into SGs is lacking, and the cellular mechanisms impaired by ALS-linked mutations in UBQLN2 remain enigmatic. To address this, we provoked the formation of SGs and UBQLN2 puncta in either HeLa or U2OS cells by inducing oxidative stress with arsenite. We found that arsenite-induced SGs assemble within 10-13 minutes, with UBQLN2 incorporating into these SGs between 25-35 minutes. The late incorporation of UBQLN2 into SGs suggests that the exchange of PQC

proteins between SGs and the cytoplasm plays a role in SG persistence. UBQLN2's participation in stress response appears localization-driven, as increases in expression level were not detected via western blot. Live imaging the response of UBQLN2 with ALS-linked mutations (MT UBQLN2) to arsenite-induced cellular stress demonstrate that these mutations may result in differences in number and timing of formation of phase-separated UBQLN2 bodies compared to wild-type (WT). Collectively, these data suggest a decrease in adaptability of and propensity for puncta formation behavior as vehicles by which mutations in UBQLN2 contribute to ALS pathology. Fluorescence Recovery After Photobleaching (FRAP) is underway to determine differences in protein mobility in both WT and MT UBQLN2 stress-induced puncta. STORM microscopy is being utilized to observe behavior of both UBQLN2 and SG-related protein Ataxin-2 on a molecular level. Our results characterize UBQLN2 incorporation into SGs, and suggest differential stress response behaviors of MT UBQLN2 as a potential disease mechanism. These findings will inform future research that will further elucidate mechanisms by which mutations in UBQLN2 contribute to ALS pathology.

P2474/B731

The Lon Protease's Impact on Bacterial Iron Maintenance.

K. Massenat, R. Zeinert, P. Chien; the University of Massachusetts Amherst, Amherst, MA.

Proteases are conserved enzymes that are responsible for removing proteins from the cell. In bacteria, such as Caulobacter Crescentus, the Lon protease is essential for degrading misfolded proteins. It is a part of normal protein quality control. This research involves the use of serial dilution spot assays and microscopy to show how cells lacking the Lon protease are sensitive to hydrogen peroxide, more filamentous, and lack a pink coloration. It has also been observed that varying the concentration of PYE media conditions changes the degree of pink coloration present in the cell. Thus far, the addition of iron to the media has proven to have an inhibitory effect on coloration. A Soret absorbance and emission spectra of the pink color suggests the presence of a heme molecule. Heme is critical for detoxification of oxidative stress and could potentially explain the sensitivity to hydrogen peroxide. Given this, the objective of this research is to discover the origin of the pink phenotype and the Lon protease's role in regulating its expression. We will use a combination of both forward and reverse genetics to identify pathways that influence both oxidative stress and pink coloration. Using this approach, we have isolated mutants that restore pink coloration to our Lon deletion strain. Future work will characterize these mutants in relation to other Lon phenotypes in particular oxidative stress. These studies will enhance our understanding of how the Lon protease influences growth and stress responses in Caulobacter crescentus.

P2475/B732

Propagation of Prions in Yeast by Chimeric *A. Thaliana* Chaperones.

S. J. Cole, R. E. Hayward, **J. K. Hines**; Lafayette College, Easton, PA.

Prions are highly organized protein aggregates that are known to cause a multitude of neurodegenerative diseases in mammals. Prions are also present in baker's yeast, *Saccharomyces cerevisiae*, but they do not result in the death of the cell. Yeast is a highly useful organism to model prion behavior due the multitude of prions present in the yeast cell and the ability of the prion to be propagated through populations; a phenomenon that is reliant upon the fragmentation of these prions by the chaperone machinery. Sis1, an Hsp40, is specifically essential for prion propagation, but different

prions rely upon distinct parts of Sis1. Recently, we identified six functional orthologs of Sis1 in the model plant *Arabidopsis thaliana* which could replace Sis1 to maintain both cell viability and propagation of strong variants of the prion [*PSI*$^+$]. Here we show that these orthologs vary in their ability to maintain the prion [*RNQ*$^+$] and weak variants of [*PSI*$^+$]. Sequence analyses revealed significant differences in the glycine-rich regions among orthologs. This region of Sis1 has previously been shown to be specifically required for [*RNQ*$^+$] maintenance, and may play some role in the propagation of weak [*PSI*$^+$]. To test this, the glycine-rich regions of two orthologs were swapped, and the chimeric proteins were tested for maintenance of [*RNQ*$^+$] as well as weak and strong [*PSI*$^+$] variants. Preliminary results support the notion that the glycine-rich region dictates the ability of variants to propagate [*RNQ*$^+$] but not weak [*PSI*$^+$]. Additional experimentation should provide useful information on the specific parts of Sis1 needed for weak [*PSI*$^+$] propagation in addition to a better understanding of interactions between Sis1 and yeast prions.

P2476/B733

Analyzing Amino Acid Content of Yeast Prion-forming Domains and Its Effect on Hsp104-mediated Prion Curing.

S. F. Schock, A. MacElroy, **J. K. Hines**; Lafayette College, Easton, PA.

Yeast prions are self-propagating protein aggregates that act as non-Mendelian genetic factors. In *Saccharomyces cerevisiae,* at least 12 proteins are known to form prions. We have previously noted significant correlations among the amino acid content of the prion-forming domains (PrDs), chaperone sensitivities, and formation rates of the yeast prions [*URE3*], [*SWI*$^+$], [*RNQ*$^+$], [*PSI*$^+$], [*MOT3*], and [*ISP*$^+$]. Among these prions, N-rich PrDs correlated with high levels of specific aliphatic hydrophobic residues and low amounts of glycine and tyrosine. Those prions were also the most sensitive to alterations in chaperone activity. Thus, we hypothesized that prions with N-rich PrDs are less stable in the population than Q-rich prions because their aggregates are less frangible, and likewise that these prions should appear more frequently. Alberti and colleagues in the Lindquist group used an algorithm to identify additional potential prion-forming proteins in yeast; 21 of their most successful candidates together with Sfp1 were later defined by the Ross group as the “Alberti dataset”. Here we present a statistical analysis testing a new hypothesis, based on recent work by Ross and colleagues, that N-rich PrDs are more able to house strongly amyloidogenic, aliphatic hydrophobic residues, whereas Q-rich PrDs will contain more aromatic residues, particularly tyrosine. The relationship between Q/N content, percentage of specific aliphatic hydrophobic residues, and percentage of aromatic residues in the PrDs of these six yeast prions and in the full Alberti dataset were examined. Within the set of six prions previously considered, a strong positive correlation was found between Q/N ratio and %(Y+F+W) and a negative correlation was found between Q/N ratio and %(I+L+M+V), though these correlations disappeared in the full Alberti dataset. Additionally, the effect of Hsp104 overexpression on some prions of the Alberti dataset has been tested with the long-term goal of analyzing the potential effect of amino acid content on this chaperone-prion interaction. These experiments also test the hypothesis that the M-domain of Sup35 is absolutely necessary. These prions are being analyzed using [cPrD-Sup35C] chimeric prions from the Lindquist Lab to ensure only the PrD is causing changes in Hsp104 interaction. Unfortunately, most aggregates were undetectable using SDD-AGE due to the instability of the aggregates, likely due to the lack of the Sup35 M-domain. Successful gels identified no Hsp104-mediated curing of chimeras [Asm4-Sup35C], [Nrp1-Sup35C] or [Gln3-Sup35C], supporting the hypothesis that the

M-domain of Sup35 is responsible for the specific genetic interaction between Hsp104 overexpression and the [*PSI*$^{+}$] prion.

P2477/B734

Hsp70 Independent Role of Nucleotide Exchange Factor Fes1 in Degradation of Gluconeogenic Enzyme and Cell Wall Integrity.

S. Kumar, D. C. Masison; NIDDK/NIH, bethesda, MD.

Cellular protein homeostasis is maintained by regulated protein biosynthesis and degradation of proteins by a protein quality control system (PQC). The PQC is composed of Hsp70, Hsp90 and other co-chaperones (Fes1). The PQC facilitates protein folding, prevents protein aggregation, helps to refold misfolded proteins or stimulates degradation of terminally misfolded proteins. Fes1 is one of the three cytosolic nucleotide exchange factor (NEF) in yeast that requires for growth at high temperature, prion propagation, repression of the stress response and proteasomal protein degradation in association with Hsp70. All known functions of Fes1 are thought to require its ability to regulate Hsp70. The Hsp70 Ssa2, but not its paralog Ssa1, is essential for vacuole import and degradation (Vid) of gluconeogenic enzymes including Fbp1. Fbp1 follows two different degradation pathways depending on the length of glucose starvation. In order to determine if Ssa1 and Ssa2 are regulated differentially by nucleotide exchange factors in yeast, here we find only Fes1 is essential for vacuole import and degradation (Vid) of gluconeogenic enzyme Fbp1. Interestingly differences in Fes1 interaction with Ssa1 and Ssa2 did not account for Ssa2 specificity in the vid pathway. We also find Fes1 mutant (Fes1A79R/R195A) that did not interact with or regulate Hsp70 still retained activities that allowed support of the Vid pathway. Fes1 bound to Vid substrate Fbp1 in vitro independent of Hsp70. Our genetic approaches allowed us to link *fes1Δ* cells thermo-sensitivity with cell wall defects. We also found that Fes1A79R/R195A mutant defective in Hsp70 interaction support growth at high temperature in agreement with this finding, we observed increased phosphorylation of cell wall integrity (CWI) protein Slt2 even at the permissive temperature indicating Fes1 is linked to the CWI pathway. Our study has found the interaction of Fes1 with CWI protein Slt2, increase the possibilities of nucleotide exchange factor Fes1 to work in other cellular events way beyond as cochaperone for Hsp70. These unexpected findings challenge current assumptions in the field about this class of Hsp70 regulatory factors.

P2478/B735

Organelle-targeted Small Heat Shock Proteins in Growth and Stress Tolerance.

P. Patel, T. Liu, M. Kim, E. Vierling; University of Massachusetts Amherst, Amherst, MA.

Molecular chaperones are proteins found in all kingdoms of life and are essential to cell survival. Small heat shock proteins (sHSPs) are one class of ubiquitous molecular chaperones that are upregulated during heat stress. They are proposed to act as the first line of defense by binding to heat-sensitive proteins and preventing their irreversible aggregation. Many details of sHSP function remain to be discovered, and exactly what proteins they protect is unresolved. In addition to the cytosolic sHSPs found in other organisms, during heat stress higher plants produce nuclear-encoded sHSPs targeted to chloroplasts and mitochondria, organelles essential to energy metabolism. In *Arabidopsis thaliana* the four sHSPs found in these organelles are: HSP23.5-M/C and HSP23.6-M/C, which are proposed to be dual-targeted to both organelles, HSP25.3-P, which is targeted to the plastids only, and HSP26.5-MII, which is specific to mitochondria. We have found that plants carrying single, double, triple, or quadruple

mutants of these sHSPs appear to grow normally in the absence of stress. Assays of mutant heat sensitivity indicate that the triple mutant of HSP23.5-M/C, HSP23.6-M/C, and HSP26.5-MII shows heat-sensitivity, though the mutant is more tolerant than a mutant of HSP101, the Arabidopsis homologue of yeast chaperone HSP104. The mutants are being tested for other stress phenotypes, and confirmation of the dual-localization of HSP23.5-M/C and HSP23.6-M/C is in progress. Understanding the phenotypes of these sHSP mutants and determining what proteins they protect will bring us closer to defining their mechanism of action, and the mutants will provide a platform for further studies of sHSP structure and function.

Bax Inhibitor-1 (bi-1) Deficient Mice Develop Hepatic Steatosis by Modulating Aberrant Er Stress during the Aging Process.

K. Bhattarai[1], H. Kim[2], H. Chae[1]; [1]Department of Pharmacology, Chonbuk National University Medical School, Jeonju, KOREA, REPUBLIC OF, [2]College of Dentistry, Dankook University, Cheonan, KOREA, REPUBLIC OF.

Aging-associated ER stress occurs due to declined chaperoning systems of the ER. Persistent stress in the ER reduces cellular functions, induces apoptosis, and leads to age-related diseases. The main objective of our study was to investigate the effect of BI-1 on aging-associated fatty liver. We categorized wild-type (WT) and BI-1 knockout (KO) mice into young, middle and old groups, and observed the effect on hepatic lipid accumulation in normal food diet condition. We observed that the BI-1 deficient aged mice gained body, and liver weight, and high hepatic triglyceride level when compared with its WT counterparts. The increase in lipid peroxidation level and ROS-induced oxidative stress was observed in BI-1 KO aged liver. Loss of BI-1 induced excessive ER-mitochondria interactions and high molecular weight complexes of protein disulfide isomerase (PDI) during the aging process. Furthermore, the impaired UPR function was observed in BI-1 KO mice in advanced age. The canonical UPR arms proteins were aberrantly expressed where we observed that the expression of ER chaperone proteins like GRP78 and PDI; ATF6 alpha, p-PERK, and p-eIF2 alpha were downregulated and IRE1-mediated JNK signaling was activated in BI-1 KO aged liver. CHOP was highly expressed and the nuclear level of sXBP1 was suppressed in BI-1 KO aged mice. ER-associated degradation was highly impaired in BI-1 deficient aging mice as compared to its comparable group. In addition to TUNEL positive cells, caspase 7 and caspase 12 were highly activated in BI-1 KO mice from the middle to advanced age, suggesting the protective effect of BI-1 on aging-induced apoptosis. Collectively, these results suggest that aging-induced fatty liver is regulated by BI-1 through the regulation of ER stress and proteostasis. **Keywords:** BI-1; aging liver; steatosis; ER stress, chaperones; apoptosis

P2480/B737

Investigating the Ribosome-associated Regulation of Stress Induced Prion Formation and the Physiological Impact of [PSI+] in S. *cerevisiae*.

C. Kelly, S. Beck, R. Wike, D. M. Cameron; Ursinus College, Collegeville, PA.

In yeast, the [*PSI*$^+$] prion results from a self-propagating amyloid form of the translation termination factor Sup35 and results in elevated levels of nonsense suppression. The rate of *de novo* Sup35 conversion into the prion conformation is known to increase in response to environmental stressors and can produce beneficial phenotypes for [*PSI*$^+$] strains. Thus, the presence of the prion may serve as an

epigenetic switch to allow the heritable propagation of [*PSI*$^+$] acquired changes. Understanding the mechanisms that control prion formation and the resulting physiological consequences is a critical area of research towards furthering the understanding of amyloid biology. Previous work by our lab and others has shown that the ribosome-associated complex (RAC) suppresses prion formation in yeast. The Hsp40 RAC chaperone Zuo1 anchors the RAC to the ribosome and stimulates the ATPase activity of the Hsp70 chaperone Ssb. Unfolding of the C-terminal domain of Zuo1 facilitates its dissociation from ribosomes, where it can activate a transcription factor for the pleiotropic drug resistance (PDR) pathway. Thus, through this mechanism, some environmental stress conditions may decrease the occupancy of RAC on ribosomes, thereby increasing prion formation. In order to study the mechanisms by which cells regulate prion formation in response to environmental stressors, we conducted a large-scale screen looking for factors that promote Zuo1 dependent activation of PDR. We have identified Btt1, a component of the nascent chain associated complex NAC, as a mediator of Zuo1 dependent PDR activation. The increase in the acquisition of prion conformations under stress conditions has been shown to confer in many cases an increased resistance to those environmental stressors. In order to investigate the observed difference in survival, we previously used SILAC (Stable Isotope Labeling by Amino Acids in Cell Culture) to identify changes in the proteome between [*PSI*$^+$] and *[psi*$^-$] isogenic strains. One group of proteins showing marked prion-dependent differences in abundance are members of the Hxt family of glucose transporters. Thus, we are currently examining the physiological consequences of the [*PSI*$^+$] prion on yeast metabolism by utilizing glucose uptake assays and growth competition assays to measure the functional differences between isogenic [*PSI*$^+$] and [*psi*$^-$] strains exposed to a variety of growth conditions.

Quantitative Proteomics Identifies $GABA_A$ Receptors Proteostasis Network Components.

Y. Wang, 44106, X. Di, T. Mu; Case Western Reserve University, Cleveland, OH.

GABA type a receptors bind GABA and inhibit neuronal firing. Maintenance of $GABA_A$ receptor protein homeostasis (proteostasis) in the cell utilizing its interacting proteins is essential for the function of $GABA_A$ receptors. How the proteostasis network orchestrates $GABA_A$ receptor biogenesis in the endoplasmic reticulum (ER) is largely unexplored. To address this systematically, we employed a proteomics-based approach to identify the interactomes of $GABA_A$ receptors in HEK293T cells by carrying out a quantitative immunoprecipitation-tandem mass spectrometry (MS) analysis by stable isotope labeling by amino acids in cell culture (SILAC). To enhance the coverage and reliability of the identified proteins, we performed comparative proteomics by using both wild type (WT) α1 subunit and a well-characterized misfolding-prone α1 subunit carrying the A322D mutation as the bait proteins. The WT α1 interactome contains 114 proteins, the α1(A322D) subunit interactome contains 103 proteins, and 52 proteins overlap within two interactomes. Bioinformatics analysis enabled us to identify chaperones, folding enzymes, and ER-associated degradation (ERAD) factors. We identified major chaperone networks, including Hsp70/Hsp40 systems both in the ER (BiP and ERdj3) and in the cytosol (Hsc70, DNAJA1 and DNAJA2), Hsp90 systems both in the ER (Grp94) and in the cytosol (Hsp90β, AHSA1, and UNC45A), N-glycoprotein folding systems (calnexin and UGGT1), Hsp47, and folding enzymes (ERp57 and PDIA1). In addition, we identified ERAD factors, including a number of ubiquitin E3 ligases (HUWE1, UBR5, LTN1, and TRIM21), and retrotranslocation proteins (SEL1L and VCP). To evaluate whether such an interaction network is utilized in the mammalian central nervous systems, we used mouse brain homogenates to carry out co-immunoprecipitation assay. Indeed, we demonstrated endogenous

interactions between α1 and selected WT α1 interactors as mentioned above. Manipulating the GABAA receptor proteostasis network components is a promising strategy to enhance GABAA receptor function to ameliorate related neurological diseases.

Non-uniform Distribution of Myosin-mediated Forces Governs Red Blood Cell Curvature through Tension Modulation.

H. Alimohamadi[1], A. Smith[2], V. Fowler[3], P. Rangamani[1]; [1]University of California San Diego, San Diego, CA, [2]Scripps Research Institute, La Jolla, CA, [3]University of Delaware, Newark, DE.

The biconcave disk shape of the mammalian red blood cell (RBC) is unique to the RBC and is vital for its circulatory function. Recent experiments have demonstrated that the biconcave shape of the RBC relies not only on the physical properties of the membrane but also depends on the molecular constituents of the membrane cytoskeleton, including the contractile activity of the nonmuscle myosin IIA (NMIIA) motor protein. Here, we use the classical Helfrich model for the RBC membrane and incorporate heterogeneous force distributions along the membrane to mimic the contractile activity of NMIIA. We find that the biconcave shape of the RBC depends on the ratio of forces per unit volume in the dimple and donut regions of the RBC. Experimental measurements of NMIIA densities at the dimple and donut validate our prediction that (a) membrane forces must be non-uniform along the RBC membrane and (b) the force density must be larger in the dimple region than the donut region to produce the observed membrane curvatures. Furthermore, we find that the tension of the RBC membrane plays an important role in regulating this force-shape landscape. Our findings of heterogeneous force distributions on the plasma membrane for RBC shape maintenance have implications for shape maintenance of many cell types.

Machine Learning Predicts States of Aging and Disease Based on Emergent Single-cell Mechanical Phenotypes.

S. Hinz[1], M. Miyano[1], J. C. Lopez[1], J. Kim[2], L. L. Sohn[2], M. L. LaBarge[1]; [1]City of Hope, Duarte, CA, [2]UC Berkeley, Berkeley, CA.

The mechanical properties of cells are continuously subject to change in the context of differentiation, chronological age, and malignant transformation. Thus, our work is poised to demonstrate that these mechanical properties can be exploited and may present novel label-free biomarkers of clinically relevant functional cell states. We have implemented the use of a novel mechano-node-pore sensing (mechano-NPS) method, which is a powerful tool in multi-parametric single-cell analysis that simultaneously measures cell diameter, resistance to compressive deformation, transverse deformation under constant strain, and recovery time after deformation. Based on these measurements we have defined a new dimensionless parameter, the whole-cell deformability index (wCDI), which can be utilized to discriminate between different cell types. Mechano-NPS measurements were shown to be remarkably sensitive to pharmacologically induced alterations of the cytoskeleton. We are now utilizing machine learning algorithms to identify distinguishing mechanobiological features of different cell types in a non-biased manner. Indeed, using this approach we are now generating a database of the

mechanical phenotypes of normal human mammary epithelial cells (HMEC) derived from primary tissue from women age 16 to 91, whose cells are in a range of states from normal to malignant, and with a number of defined signaling pathway alterations. Our machine learning model predicts the chronological age of tested HMECs with high accuracy and can predict pathways that differ between cell types based on patterns of mechanical measurements. Further, we are investigating the molecular underpinnings of the age dependent mechanical phenotypes. Knockdown experiments of the intermediate filament of keratin 14 (KRT14) partially restored a young mechanical phenotype in HMECs isolated from post-menopausal women. Thus, suggesting a role for KRT14 and the cytoskeletal network in cellular aging. Mechano-NPS has effectively identified mechanical phenotypes that can be exploited to detect and predict cellular properties and its potentially clinically-relevant implications in bias-free disease detection are powerful.

Active Matter Self-organization Simulator (AMSOS): Combining Biophysics and Mechanics on HPC.

W. Yan[1], A. Lamson[2], M. Betterton[2], M. Shelley[1]; [1]Flatiron Institute, New York, NY, [2]University of Colorado, Boulder, Boulder, CO.

We have developed a simulation package to study the large-scale behavior of biofilament/motor-protein assemblies. Each motor-protein is explicitly tracked in space and its interactions with filaments are described by a two-stage explicit kinetic Monte Carlo model. Binding-unbinding events of a motor are based on free-energy changes between unbound, singly-bound, and doubly-bound states, in a way that preserves detailed balance. Motor-protein binding two filaments walk and diffuse along the filaments thus moving the filaments relative to each other. We use a new numerical method based on geometrically constrained optimization to guarantee that steric interactions between filaments are properly and efficiently handled. We further extended the virial stress formula from classical point-mass systems to rigid bodies with finite volumes. These developments are integrated into a massively parallel software package - AMSOS -- whose application we demonstrate by a self-contracting microtubule-motor assembly of more than 100,000 microtubules.

P2485/B743

Decoding the Variance in Intracellular Organization of the Undifferentiated hiPS Cell.

M. P. Viana, S. M. Rafelski,.Allen Institute for Cell Science; Allen Institute for Cell Science, Seattle, WA.

The Allen Institute for Cell Science is developing a state space of structural signatures of the undifferentiated human induced pluripotent stem cell (hiPSC) to understand the principles by which cells organize and transition between states (cellular morphogenesis). To do this we take advantage of the ~35 endogenous fluorescently tagged hiPSC lines in the Allen Cell Collection (www.allencell.org), each expressing a monoallelic EGFP-tagged protein representing a particular organelle or structure. We develop image-based assays and segmentation algorithms for quantitative analyses, taking advantage of thousands of replicate high resolution 3D images for each structure. We are investigating biological sources of cellular variation to identify the basis functions of a dimensionally-reduced, interpretable parameter space that represents integrated intracellular organization. We prototyped an analysis workflow based on the nucleus, using lamin B1, as our first key cellular structure. We used the Allen Cell Structure Segmenter to create accurate 3D segmentations of the nuclei in multi-hour 3D timelapse movies. We fit these extracted nuclear shapes using spherical harmonic functions. We analyzed the

contributions of the spherical harmonic coefficients to the variations in nuclear shapes and found that nuclear shape could be well described by five coefficients representing three distinct shape modes. Each nuclear shape mode represented a different source of biological variation in hiPS cell colonies and occurred on a distinct timescale. The mode represented nuclear volume, which increases throughout interphase, occurring over a one day timescale. The second mode represented how flat (vs. round) a nucleus appeared in the apical-basal axis (Z-direction). This nuclear 'flatness' was linked to differences in cell packing in distinct regions of the colony, i.e., more densely packed regions were composed of taller cells with rounder nuclei, when compared to the less densely packed, shorter cells with flatter nuclei that were often found in the center of colonies. Individual nuclei exhibited little variation in flatness over a multi-hour time period, consistent with the longer timescale of cell packing within colonies that occurs over several days. The third mode represented how 'squeezed' a nucleus appeared in the XY plane; this arose from constant interactions between neighboring cells occurring at timescales of minutes or less. We are now applying these analyses to develop biophysical models of nuclear shape and colony dynamics. This general analysis framework will be extended to cell shape and to each of the key intracellular structures in an integrative fashion.

Mathematical Modelling of Gliding Motility and Its Regulation in *Myxococcus Xanthus*.

Y. Chen[1,2], J. Chen[1]; [1]Department of Biological Science, Virginia Tech, Blacksburg, VA, [2]Genetics, Bioinformatics and Computational Biology program, Virginia Tech, Blacksburg, VA.

Myxococcs xanthus manages "social" behaviors, such as cooperative feeding and fruiting-body formation, through intercellular communication and coordination. A particular intriguing intercellular coordination lies in coordination of motility between cells with physical contacts. Specifically, *M. xanthus* cells glide on substrate with periodic reversals, and physical contacts with opposite-moving colony mates regulate the reversal frequency. This contact-dependent motility coordination is known to be necessary for intriguing population patterns, such as rippling waves. Frz proteins, regulators that control the periodic reversals in *M. xanthus*, exhibit subcellular dynamics that are highly correlated with that of the gliding motility motors and change in response to cell-substrate and cell-cell contacts. To understand how control and coordination of *M. xanthus* motility works, we developed a mathematical model to capture the coupling between the Frz regulators and the gliding motility machinery in cell reversal control. Using the model, we identified several possible mechanisms through which cell-cell contacts can induce proper responses in cell reversals required for generating the rippling waves. Interestingly, we found that both phase advance and phase delay in the cell reversal upon cell-cell contact were able to generate rippling waves. Our model has proposed a new mechanistic explanation for contact-dependent motility coordination in *M. xanthus.*

Substrate Selectivity of DNA Dependent DNA Polymerases Is Controlled by Free Energy Barriers.

A. Nyporko, K. Tokarenko, B. Motrunich, V. Peretyatko, A. Sosedko; Taras Shevchenko National University of Kyiv, Kiev, UKRAINE.

The interaction of regular dNTPs with their natural cell targets DNA Dependent DNA polymerases (DNA pols) is multistage process. It includes primary recognition dNTP and DNA-bounded enzyme, nucleotide incorporation into active site. The next milestone is close complex or excluding dNTP from active site.

The excluding of dNTP can be mentioned by structural inconsistency. Furthermore, the existing kinetic models do not completely explain the process of transition from open to close enzyme form after binding of non-complementary dNTP. Thus, it seems to be necessary evaluate the changes of free energy during dNTP migration from cytoplasm/karyoplasm to DNA pol active site. For studying we applied the umbrella sampling which accurately describes the states of molecular system and the free energy changes alone reaction coordinate. Free energy profiles were calculated for ternary complexes of *E. coli* DNA Poll II and human DNA Pols β and λ (high fidelity B and middle fidelity X DNA pol families). These complexes contained one of four regular dNTP or oxidized 8-oxo-dGTP. Matrix nucleotides in DNA pol active center also were differ. The umbrella sampling calculations were performed with GROMACS software using Charmm27 force field and 1320 trajectories in 30 ns each were computed. The weighted histogram analysis method was used for PMF extraction and free energy calculation. It was established, that in most cases (in exception some cases with incoming dTTP) for fittinng of the incoming nucleotide into the polymerase active center it's necessary to overcome free energy barrier, the value of which varies from 2 to 10 kcal /mol. The magnitude of the barrier depends on both incoming and matrix nucleotides. In the case of complementary incoming and matrix nucleotide the energy barrier is not more than 2.5 kcal/mol and it can be overcome due to the energy of thermal fluctuations. In opposite, the non-complimentary binding demands at least 4 kcal/mol of additional energy and forming of such complex is thermodynamically improbable. In the case with incoming 8-oxo-dGTP, the least free energy barrier is shown for its pairing with the matrix dA, that is fully consistent with experimental data. Thus, the difference of free energy barriers required for dNTP fitting into DNA pols active sites seems to be one of the **key factors** controlling the level of their mismatched incorporation in grow DNA chain.

P2488/B746

Propagation of Forces in Epithelial Monolayer Is Highly Dependent on Substrate Stiffness.

A. Tervonen, S. Nymark, J. Hyttinen, T. O. Ihalainen; Tampere University, Tampere, FINLAND.

Mechanics and physical forces influence many epithelial processes, including epithelial formation and migration, as well as cell signaling via a process known as mechanotransduction. Many pathological conditions lead to changes in the epithelial mechanical homeostasis. For example, in tumors both the cells and the extracellular matrix become stiffer. Unfortunately, it is not well understood how these mechanical changes affect the signaling between cells. To study this, we used a computational approach to see how mechanical disturbances in the epithelia spread and how the stiffness of the substrate under the cells affects the force propagation. Our cellular modeling approach uses a so-called boundary-based method, where the cells are represented by closed boundary polygons and the various cellular cytoskeletal components and processes are described by springs between or forces affecting the polygon vertices. The substrate is modeled as a mass-spring model, described by a hexagonal spring network. We mechanically disturbed the system by moving one cell to describe local micromanipulation of the epithelial monolayer. We simulated the micromanipulation for the epithelium-substrate system as well as for only the substrate. We found that there is a dramatic difference on how the cell deformation spreads in the epithelia and in the substrate depending on the substrate stiffness. When the substrate is softer than the cells, the deformations caused by micromanipulation of a cell propagate across all the cells in the simulated area and the underlying substrate. However, with stiffer substrate, the deformations in both the other cells and substrate are local; only a few nearest neighbor layers deform and there is very little deformation in the substrate itself. We also simulated the deformation of only the substrate without the cells with similar micromanipulation and found that deformations in the

soft substrate are local whereas the stiff substrate has more global deformations. Our results indicate that the distance traveled by the mechanical deformations, and thus mechanical forces and signals, is highly dependent on the stiffness of the cell substrate. There is a major change in force propagation behavior as the substrate becomes stiffer than the epithelial monolayer, which may be extremely relevant especially in tumors due to the changes in mechanical properties.

P2489/B747

Mathematical Modeling of Centrosome Clustering.

X. Li[1,2], N. Baudoin[1,2], D. Cimini[1], J. Chen[1]; [1]Department of Biological Science, Virginia Tech, Blacksburg, VA, [2]BIOTRANS Graduate Program, Virginia Tech, Blacksburg, VA.

Centrosome clustering is strongly implicated in cancer cell mitosis. Most tumor cells have extra centrosomes, which would be expected to induce multipolar cell division and consequently fatal, massive chromosome aberrations in daughter cells. However, cancer cells often evade this fatal outcome through clustering the centrosomes and undergoing pseudo-bipolar divisions. Centrosome clustering is mediated by mechanical interactions between microtubules and microtubule-associated motors. To understand the process and necessary conditions for centrosome clustering, we built a model which characterizes the mechanical interactions between centrosomes in a simplistic manner. Our result shows that attractive interaction between centrosomes alone leads to either nearly no clustering or a high frequency of monopolar clustering. After including a repulsive interaction between centrosomes in the model, we are able to avoid monopolar clustering and reproduce the experimentally observed frequencies of bipolar, tripolar and tetrapolar divisions in cells with four centrosomes. This result indicates the importance of forces that push centrosomes away from each other, which likely stems from anti-parallel alignment and sliding between microtubules associated with different centrosomes.

P2490/B748

Modeling Growth-mediated Motility in *Clostridium Perfringens*.

S. McMahon[1], S. B. Melville[2], J. Chen[2]; [1]Department of Physics, Virginia Tech, Blacksburg, VA, [2]Department of Biological Sciences, Virginia Tech, Blacksburg, VA.

Many bacteria species are able to expedite colony expansion through motility of the cells. *Clostridium perfringens*, the primary cause of lethal gas gangrene, exhibit a unique mode of colony expansion. Chains of cells continuously grow outward from the bacterial colony and curve. These bacteria appear to lack a direct motility mechanism in individual cells and are hypothesized to rely on bacterial growth to push adjacent cells in the strongly connected cell chains. Interestingly, these cell chains tend to curve as they grow. Using a “rigid-rod” model we simulate the growth dynamics of these bacteria chains. Our preliminary results suggest that the cell chain curvature cannot result from the growth of the cell chain and its interaction with the substrate. Motivated by the observation that multiple chains growing side-by-side appear to curve more than single chains, we hypothesize that chain curvature may be a result of lateral interactions between cell chains. An expanded version of the rigid-rod model is used to include these lateral interactions and also implements collision dynamics between cells in adjacent chains. Ultimately, we will use these mathematical models to investigate if this expansion mode of *C. perfringens* could be advantageous for spreading and surviving on different substrates and environments the bacteria may encounter during their opportunistic life cycle.

P2491/B749

Robust and Automated Detection of Subcellular Morphological Motifs in 3D Microscopy Images.

M. K. Driscoll, E. S. Welf, A. Jamieson, K. M. Dean, T. Isogai, R. Fiolka, G. Danuser; University of Texas Southwestern Medical Center, Dallas, TX.

Rapid developments in live-cell 3D microscopy enable imaging of cell morphology and signaling with unprecedented detail. However, tools to systematically measure and visualize the intricate relationships between intracellular signaling, cytoskeletal organization, and downstream cell morphological outputs do not exist in 3D. Here we introduce u-shape3D, a computer graphics and machine learning pipeline to probe molecular mechanisms underlying 3D cell morphogenesis and to test the intriguing possibility that morphogenesis itself affects intracellular signaling. u-shape3D includes a generic morphological motif detector that automatically finds 3D subcellular surface structures. It does so by decomposing the cell surface into convex patches, optionally merging these patches, and then classifying them by motif. Merging and classification is performed via support vector machines, a machine learning algorithm. Training data is generated in part by presenting users with the segmented cell surface and asking users to click on examples of motifs. We demonstrate the robustness of this motif detector by applying it to diverse systems, including blebs on melanoma and U2OS cells, filopodia on bronchial epithelial and melanoma cells, lamellipodia on dendritic and T cells, microvilli on breast cancer cells, extensions on microglial cells, and spines on neurons. These cells were imaged via various imaging modalities including high-resolution light-sheet microscopes, such as the lattice light-sheet, a standard commercial light-sheet microscope, and a laser scanning confocal microscope. In addition to motif detection, we also provide 3D tools to measure molecular localization near the cell surface, surface motion, and spatial statistics. All of these tools, as well as the motif detector, are accessible via a graphical user interface. As an application, we measure the differential association of PIP_2 and $Kras^{V12}$ with blebs on melanoma cells. Both signals polarize with blebs and associate with bleb edges, as expected for membrane-localized proteins, but only PIP_2 is enhanced on blebs. That $Kras^{V12}$ and PIP_2 spatially segregate with blebs, suggests that blebs may modulate intracellular signaling. Overall, our computational workflow enables the objective, automated analysis of the 3D coupling of morphodynamics with cytoskeletal dynamics and intracellular signaling.

P2492/B750

Quantifying Cell Biology: Beyond Human Vision.

A. E. Carpenter; Broad Institute of Harvard and MIT, Cambridge, MA.

Microscopy images contain tremendous information about the state of cells, tissues, and organisms. Often, biomedical researchers use software to identify biological structures and extract metrics of interest from cell images; they quantify phenomena in conventional microscopy experiments as well as high-throughput screens to test drugs in disease model systems. We have developed computational approaches and open-source software, including CellProfiler, for this, bridging the gap between biologists' needs and the latest computational science. Here, we describe going beyond human vision and biologists' existing hypotheses in a strategy called image-based profiling. Instead of measuring individual phenotypes that biologists already know are relevant to a particular disease, we stain many cellular components and extract thousands of morphological features from each cell's image, often using an assay called Cell Painting and computational approaches such as deep learning. We then

harvest similarities in these “profiles”, analogous to transcriptional profiling but less expensive and, surprisingly, more information-rich. Through this approach, we discover that unlabeled cells can be classified for their cell cycle and mitotic stage without any DNA labeling. We find that leukemia can be detected in unlabeled cells, eliminating the need for specific biomarker-based reagents. We find that degradation of red blood cells during blood bank storage can be detected, eliminating the need for tedious expert counting. We find that similarities in images of cells that overexpress genes contain sufficient information to determine unstudied genes' pathway identity and relationships. We identify cell biological impacts of rare disease alleles and mental illnesses. We find that cancer-associated alleles can be classified based on their functional impact without creating individual functional assays for each gene. Overall, cell images should now be considered a source of powerful data about cell state.

P2493/B751

On the Transmission of Spatial Information Via a Physicochemical Channel.

Z. Wang, M. Thomson; California Institute of Technology, Pasadena, CA.

Environmental stimuli are non-uniformly distributed across space. Living things must represent these distributions in order to use this spatial information about the stimuli to compute an appropriate behavioral response. Biological systems often represent and transmit information through chemical channels where information is represented using diffusible molecules. However, spatial information is challenging to represent and transmit through chemical channels because diffusion promotes spatial information loss. In this work, we introduce an information theoretic framework to identify fundamental limits associated with transmitting spatial information in biological reaction-diffusion systems. To analyze the representation and transmission of spatial information by cellular signal transduction pathways, we construct a minimal reaction-diffusion channel capable of transmitting spatial information across a cell membrane. Our channel model consists of a cell membrane and a membrane-bound, diffusible response molecule. The membrane separates the cytosol from the environment. Given inducer molecules in the environment, our physical channel allows for the spatial distribution of the inducer to be transmitted to the cytosol via the arrangement of response molecules on the inner membrane surface. From this simplified model, we obtain a channel transition function that maps the inducer distribution (input) to a set of possible response molecule arrangement on the membrane, with their associated probabilities (output). The transition function allows us to establish bounds on channel performance, and characterize trade-offs between the rate and accuracy of spatial information transfer, for different signal transduction architectures. We show that receptor clustering is important for information transmission in temporally stable environments, whereas uniform distributions of receptors are more beneficial in highly dynamic environments. In conclusion, we establish a theoretical framework for studying trade-offs of spatial information transmission via a biochemical communication channel. Our results offer insights into the functions of natural biological channels such as transmembrane signal transduction in immune sensing, and the designs of novel nanosensors.

P2494/B752

Emergence of Multicellular Calcium Synchronization by Information-transfer between Individual Cells.

A. Zamir[1], B. Vischer[2], R. Moskovitch[1], B. Sun[2], **A. Zaritsky**[1]; [1]Ben-Gurion University of the Negev, Beer-Sheva, ISRAEL, [2]Oregon State University, Corvallis, OR.

We combined a unique experimental system with a data-driven modeling approach as a platform to quantitatively evaluate how noisy heterogeneous behavior of individual cells is integrated across a population toward multicellular calcium synchronization. We used live calcium imaging to collective chemosensing monolayers of fibroblasts in response to periodic external ATP stimuli and found that the cells formed a multicellular communication network that gradually evolved and reinforced collective synchronization. We used information-theory to quantify the asymmetric information-transfer between pairs of cells and defined quantitative measures to how single cells receive or transmit information in the multicellular network. We found that cells take different roles in intercellular information-transfer. Initially short-range communication dominates where cells tend to influence and to be influenced by nearby cells. However as the collective become synchronized long-range communication takes the dominant role, when cells are more likely to influence and to be influenced by cells located further apart. We hypothesized that this can be explained by gradual integration of spatial cues that reinforce the roles that cells take in collective synchronization. Indeed, cells maintained their roles in the communication network between consecutive stimuli cycles and reinforced them over time suggesting the existence of a cellular “phenotypic memory”. We identified a subpopulation of cells characterized with higher probability of both receiving and transmitting information. These “communication hub” cells tend to be most stable - not switching to other roles, thus leading to gradual enrichment in communication hubs that is associated with the gradual establishment synchronization. These results suggest that information is spreading more effectively in the multicellular network by gradual enrichment in “communication hubs” to establish effective collective synchronization. An d thus we propose that synchronization emerges from division of labor of the individual cells that gradually reinforces synchronized calcium signaling from the local to the global scale.

P2495/B753

Visualizing Biological Simulations to Improve Access to Simulation for Research and Learning.

B. Lyons; Allen Institute, Seattle, WA.

Simulation is a powerful tool for investigating physical and chemical mechanisms that are difficult or impossible to directly observe *in vivo*. However, existing biological simulation software is unintuitive for most researchers to use, does not provide a robust way to visualize and communicate results, and generally does not interoperate. This software often requires access to high performance computing resources and secondary knowledge of technology, including usage of command line interfaces and software development tools and processes. These requirements serve to discourage users who may otherwise be able to use simulation as a tool for research and learning, and result in the exclusion of valuable domain expertise from this field. To fill these gaps, we are building software tools to empower users with domain expertise in biology to build, run, analyze, and share simulations. These tools include a web-based graphical user interface (GUI) for defining and analyzing models, a 3D viewport that visualizes spatial simulation results in real time (when possible) alongside plots of quantitative measurements, and a software layer that integrates existing software packages from prior work in computational biology. To inform the design of these tools, we have conducted expert interviews with

dozens of labs involved in projects combining experimental approaches with computational modeling. A needs analysis of their feedback has informed the design of our first user interfaces and has guided the construction of initial models for nucleating branched actin and growing microtubules. These models will serve as starting points for users to build custom models of cytoskeletal systems with their favorite actin-binding proteins or microtubule-associated proteins. We plan to continue to add more systems to eventually enable multiscale modeling of whole cells. To simulate these models at multiple scales, we are currently using the computational software packages ReaDDy and CytoSim, but plan to add more packages to support other systems. This project, codenamed AgentViz, aims to make biological simulation software easier to access and use in order to facilitate collaboration between experimental and computational biologists, and to provide easy visualization and sharing of results. Tackling this problem requires an interdisciplinary team approach, including expertise in usability, visualization, and software development in addition to domain knowledge in biology.

P2496/B754

The Utilization of Multivariate Data an alysis to Assist in the Production and Scale Up of a Live Virus Based Vaccine.

N. Templeton; Merck & Co, West Point, PA.

The utilization of multivariate data analysis to assist in the production and scale up of a live virus based vaccine Mass production of vaccines hinges upon successful scale-up. Failure to scale-up successfully results in delayed product licensure. Selecting the correct scale-up criteria, such as power input per cubic impeller diameter, was critical to the success of the increasing scale that we will present. Reactor geometry variation prevents consistent scale-up for all criteria. By choosing a power per volume approach, it becomes impossible to scale based upon Kolmogorov eddy length, as eddy length depends upon the chosen power input. Therefore, it is critical to scale up based upon the correct parameter. This work evaluates the production of a live virus by mammalian cells cultured on microcarriers. It explores various volumetric scales, as is demanded to efficiently identify a robust operational space. Metrics of successful scale up include scale comparisons in volumetric potency, specific metabolic uptake rates, specific growth rates, and specific productivity of potent virus particles. All metrics are considered in regard to time and examined through multivariate data analysis. We will report the results of partial least squares multivariate analysis to identify which variables correlate most strongly with potency, specific productivity, and the total particle to infectious particle ratio.

P2497/B755

Development and Application of a Lab Bioimage Informatics System for Fluorescence Microscopy Movies.

J. Bouffard, E. J. Cram; Northeastern University, Boston, MA.

Fluorescence microscopy is a widely used technique in cell and molecular biology. Ongoing advances in microscopes and digital imaging, sample preparation and labeling, fluorescent molecules and proteins, and genome editing are generating datasets of increasing size and complexity. The emerging field of bioimage informatics turns this big bioimaging data into biological insight. We used Fiji/ImageJ, Matlab, and GitHub/Git to build a lab bioimage informatics system that facilitates the organization, processing, and analysis of our fluorescence microscopy movies. To start, each movie is assigned a guaranteed lab-unique, human- and machine-readable identifier. This identifier then functions as a primary key for tab-

delimited text files of metadata, annotations, processing parameters, and analysis results, and also facilitates human- and machine-readable organization of raw movie files and files generated by processing and analyses. Our recently published experimental work demonstrates this system meets three main bioimage informatics goals. First, data are organized in a machine-friendly way. Almost 500 fluorescence microscopy movies, >1TB of raw data, acquired by 4 different people over 4 years, were accessed programmatically and analyzed in a consistent, semi-automated manner. Second, data are machine-readable by multiple programs. Movies were processed and annotated in Fiji/ImageJ, timeseries were analyzed and plotted in Matlab, and statistics were analyzed and plotted in Prism, R, and/or Excel, with frictionless transitions between programs. Third, there is strong data provenance. An y data point can be traced back to its raw movie, with a record of the exact processing and analysis procedures and parameters used. Our bioimage informatics system adds further value by facilitating exploration of the data, which allowed us to see that our experimental biological system responds to the level and activity of a protein of interest with a switch-like response. Our bioimage informatics system has also been used to support multiple collaborations, with cases where we have done the imaging in our lab and provided the output data to our collaborators, as well as cases where we have analyzed imaging data acquired in other labs. Recent research revealed our bioimage informatics effort to be in line with more developed and better supported solutions, including the Open Microscopy Environment (OME), Icy, BisQue, and CellProfiler. Ongoing work is exploring which of these established solutions, or combination of solutions, will best serve the ongoing and future needs of the lab. Once identified, our system will be merged with this preferred solution and optimized for ease of use.

Morphology Space of Mitochondrial Networks in Budding Yeast: Theory and Experiment.

G. R. Lewis, W. F. Marshall; University of California, San Francisco, San Francisco, CA.

Mitochondria form dynamic tubular membrane networks underneath the surface of budding yeast. Little established quantitative language exists to describe the dynamics and structure of mitochondria on a whole-cell scale, which changes over a cell's lifetime due to mitophagy, fission, and fusion. Here, I use tools from graph theory and applied topology to develop a quantitative description of whole-cell mitochondrial morphology. Using this language, I evaluate the applicability of a set of mathematical models to describe the behavior of mitochondria towards developing experimental tests of morphological regulation.

P2499/B757

A Simple Mathematical Model for Branching Morphogenesis.

B. Boman[1], Y. Ye[2], K. Decker[2], C. Raymond[2], G. Schleiniger[2]; [1]Helen F. Graham Cancer Ctr., Newark, DE, [2]University of Delaware, Newark, DE.

The lives of many multicellular organisms depend on an ability to maintain an organized branching structure of fully developed tissues. An imal tissue structure (e.g. lung, breast, kidney, pancreas, neurons, salivary glands, intestine, vasculature) often consists of branched organized systems that arise through the process of “branching morphogenesis.” However, the mechanisms that control branching morphogenesis are not fully elucidated. We hypothesize that to precisely control the organization of branches in tissues, biological rules must exist that explain branching morphogenesis. We modeled different branching patterns based on a specific number of decreasing-sized branches that arise from a

main branch and discovered that specific branching structures are generated based on p-Fibonacci sequences. An agent-based model was then created using NetLogo to show how specific branching organizational patterns can be dynamically maintained in 3D structures that simulate branching patterns found in nature. Understanding of how branching morphogenesis normally occurs in nature might also help explain how branching disorganization occurs in cancer and other diseases.

P2500/B758

Application of Topological Data an alysis Methods in Machine Learning-based TCR Specificity Prediction Models.

A. Davydov, M. Metsger, D. M. Chudakov; Central European Institute of Technology, Masaryk University, Brno, CZECH REPUBLIC.

T cells are key players of the adaptive immune system featuring an extremely diverse set of epitope-specific T cell receptors (TCRs). Computational prediction of TCR binding specificity remains one of the central problems of state-of-art adaptive immunity research. Several approaches have been recently proposed to infer TCR specificity and determine TCR specificity groups using primary sequences, structural data, and TCR physicochemical properties (1-3). The performance of the existing methods is significantly limited by the lack of available training datasets. However, machine learning methods may partially compensate for these limitations. Here we used a machine learning model based on topological data analysis approach to define TCR specificities from TCR-epitope specificity data present in the VDJdb database (4). Persistent homology (5) and persistent images (6) techniques were applied to extract features. The classification was performed using the gradient boosting algorithm provided in the XGBoost library. We prepared a synthetic dataset consisting of 3000 CDR3 sequences with a defined specificity to GILGFVFTL (Influenza a virus) peptide and 3000 CDR3 sequences sampled from naïve repertoire as a non-specific control data. The initial evaluation of our model demonstrated performance with ROC AUC score 0.76 and precision 0.75. We conclude that the proposed strategy for feature engineering can substantially boost the performance of TCR specificity prediction methods. 1. Computational Fluid Dynamics Model for Cellular Interaction Studies of Sickle Cell Disease Vaso-occlusions in a Microfluidic Device.

I. P. Blakely[1], **R. E. Horton**[2]; [1]Mississippi State University, Mississippi State, MS, [2]University of Houston, Houston, TX.

Individuals with sickle cell disease (SCD) suffer from many complications, including organ damage, stroke, and cardiovascular issues. These associated co-morbidities are linked to vaso-occlusions (VOs), chronic blockages within the vasculature. Several factors including sticky, stiffer sickled red blood cells, inflammation, upregulation of adhesion molecules, and increased cell aggregation contribute to VO formation; however the VO mechanism remains elusive. Microfluidics offer the ability to model the vasculature and probe cellular interactions in a non-invasive manner. Vasculopathies such as SCD and the vaso-occlusion phenomenon are ideal for microfluidic modeling. The addition of computational fluid dynamics (CFD) analysis can further provide results which can be used to inform experimental design decisions and potentially extended to clinical studies. Specifically, VO models can provide predictive outcomes for VO occurrences within SCD and identify occlusion prone areas within microfluidic platforms which can be extended to experimental and potentially preclinical studies. We present a CFD blood flow simulation within a branched microfluidic vascular model based on the Carreau model and Murray's law. Several models have been developed to demonstrate variations in blood flow, including, but not limited to, the Carreau, Power Law, and their modifications and derivatives. Based on previous model comparison studies, we found that the Carreau model was a suitable model for our study. We found that VOs form preferentially near bifurcations within 60 s, a timeframe which aligned with occlusion microfluidic studies. Average cellular velocities within the SCD simulation were slower than the healthy study, 1.3 versus 1.5 mm s^{-1}, respectively. Further, the SCD simulation exhibited a deceleration rate of approximately $0.35x^{-1}$ mm s^{-2} (x is time) due to cell adhesion. Velocity profiles and shear rates align with clinical and experimental reports. This study presents a CFD model capable of simulating diseased and healthy blood flow within a branched channel geometry. We assert that results from this model can be utilized to inform experimental and microfluidic system design decisions.

Development and Morphogenesis: Epithelial Development

P2502/B760

Extracellularly Extruded Syntaxin4 Acts as a Novel and Potent Regulator for Dynamic Mammary Epithelial Morphogenesis.

Y. HIROSE, Y. HIRAI; Kwansei Gakuin University, Hyogo, JAPAN.

Mammary epithelium is a unique tissue in that it undergoes distinctive morphogenesis in puberty, pregnancy and lactation periods. Thus, this tissue has been considered as a suitable model to study mechanisms underlying epithelial cell arrangement and complex epithelial morphogenesis. During puberty, the leading edges of the multilayered growing ducts (designated as terminal endbuds, TEBs) simply undergo branching morphogenesis. Upon pregnancy, however, dramatic cell arrangements occur in TEBs to construct cystic structures comprised of an enclosed single cell layer (alveoli). These epithelial morphogenic processes are known to be coordinately controlled by several extracellular signaling molecules, however, their regulation mechanisms remain largely uncovered. Previously, we have shown that a t-SNARE protein syntaxin4 (Stx4) is extruded extracellularly in subpopulation of mammary

epithelial cells and propagates morphologic signals in the nascent cells, leading to an asymmetric tissue organization that resembles branching morphogenesis. Using a polarized mouse mammary epithelial cell line EpH4, we herein show that extracellular Stx4 can also play an important role in alveolar formation. EpH4 cells that have been introduced with a tetracycline inducible Stx4 transgene connected with a signal peptide and T7-tag were rotated on non-adherent surfaces to form TEB-like multicellular cell aggregates, embedded in ECM-rich Matrigel, and cultured with induction of expression of extracellular Stx4. We found that while all the cells expressed Stx4 extracellularly, only inner cell populations in the aggregates, but not those faced to Matrigel, actively migrated outward, integrated into outermost cell layer, and ultimately, the cell aggregates exhibited inflated beautiful cystic structures comprised of an enclosed single cell layer. An alyses with electron microscopy and immunohistochemistry demonstrated that cells in these alveoli-like structures displayed clear apico-basal polarity with tight junctions at the lumen-proximal cell-cell contact sites. We also found that extracellular Stx4 directly interacted with an epithelial adhesion molecule E-cadherin to hinder epithelial cell-cell adhesions. These observations suggest that Stx4 is endowed with the ability to spatially regulate dramatic cellular arrangements for complex epithelial tissue morphogenesis, in coordination with ECM and cell adhesion molecules.

Morphogenetic Control of Epithelial Topology.

K. Ishihara[1,2], A. Mukherjee[2], E. Gromberg[3], T. Krammer[3], M. Shahbazi[4], M. Zernicka-Goetz[4], J. Brugués[1,2], F. Jülicher[2], E. Tanaka[3]; [1]Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, GERMANY, [2]Max Planck Institute for the Physics of Complex Systems, Dresden, GERMANY, [3]Research Institute of Molecular Pathology, Vienna, AUSTRIA, [4]University of Cambridge, Cambridge, UNITED KINGDOM.

The epithelium is a fundamental tissue architecture that defines the boundary of many organs. While past studies have proposed how changes in the cell's mechanical properties induce local shape changes, the statistical properties of epithelial tissues have not been addressed. What are the cell biological and physical conditions that determine whether an epithelium remains connected, or divides into multiple, topologically distinct epithelia? to address this issue, we study epithelial morphogenesis by culturing mouse embryonic stem cells as free-floating 3D aggregates and differentiating them to neuroepithelia. Within 4 days, a continuous apical membrane domain forms in the interior of the tissue as a result of collective cell polarization and epithelialization. Treatment with retinoic acid induces the apical membrane to split up into multiple spherical structures, or fluid-filled cysts. We hypothesize that apical surface area and its topology are controlled by retinoic acid-mediated down regulation of PODXL, an apical membrane protein with a negatively charged extracellular domain. Indeed, PODXL heterozygote cells show fragmented apical surfaces in the absence of retinoic acid, and PODXL overexpression show continuous epithelium overcoming the effect of retinoic acid. We develop a biophysical framework that connects the mechanics of epithelial cells to the statistical mechanics of fluid membranes. Our theory allows us to predict epithelial topology from the balance of actomyosin contractility and repulsion of PODXL molecules at the apical membrane. Thus, we elucidate the cell biological basis for retinoic acid-mediated morphogenesis, and propose that epithelial self-organization can be conceptually understood in analogy to how surfactant molecules self-assemble.

Junctional Epithelium Derived from the Icam1 Positive Papillary Layer Cells.

K. Fujikawa, M. Nakamura; Department of Oral an atomy and Developmental Biology, Showa University School of Dentistry, Tokyo, JAPAN.

Objectives: the continuity of epithelial tissue is collapsed by tooth eruption. The junctional epithelium (JE) is attached to the tooth surface by hemidesmosomes, which constitutes the front-line defense against periodontal bacterial infection. The gingival epithelium consists of the oral gingival epithelium (OGE), oral sulcular epithelium (OSE) and junctional epithelium. Previous our study indicated that JE constitutively expressed ICAM-1. Although JE might be derived from enamel organ, the exact cell source of JE has not been clarified. In this study, we examined the development of JE during the eruption of mouse mandibular molars with the special attention to the expression of ICAM-1. Methods: the mandibles of BALB/c mice from 0-21 day postnatal (21 dPN) were used in this study. Specimens were fixed with 4% paraformaldehyde, decalcified with 10 % EDTA and embedded in Tissue-Tek O.C.T Compound. Frozen sections were processed for the detection of ICAM-1. Results: ICAM-1 positive cells were detected in papillary layer of enamel organs from 12 dPN. At 16 dPN, the tip of the cusp of first mandibular molar located just below the oral epithelium. Ameloblasts differentiated into the reduced ameloblasts which were no more than detected at the tip of the cusp. At the cervical side of the crown, reduced ameloblasts attached to the enamel, which expressed no ICAM-1. The papillary layer cells expressed ICAM-1. At 19 dPN, the first mandibular molar erupted. ICAM-1-negative reduced ameloblasts still attached to the tooth surface. The cells of the papillary layer expressed ICAM-1. At 21 dPN, reduced ameloblasts were disappeared and the papillary layer cells expressing ICAM-1 directly attached to the tooth surface of both mesial and the interdental papillary layer. The epithelial cells of OSE showed no ICAM-1 expression at all. Conclusions: These results indicated that JE developed from the cells in the papillary layer.

Transcriptional Induction and Mechanochemical Propagation of a Morphogenetic Wave Duringinvagination of the Drosophila Endoderm.

C. Collinet[1], A. Bailles[1], J. Philippe[1], P. Lenne[1], E. Munro[2], T. Lecuit[1,3]; [1]IBDM UMR 7288 CNRS & Aix Marseille Université, Marseille, FRANCE, [2]Department of Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL, [3]Collège de France, Paris, FRANCE.

Morphogenesis of the *Drosophila* posterior endoderm involves complex epithelial reshaping through invagination and a dorsal anterior movement of cells. Rho1 and non-muscle Myosin II-dependent apical constriction drives invagination of the posterior endoderm, but the mechanisms underlying its polarized dynamics remain unknown. We report two phases and modalities of Rho1 and MyoII activation. First, Rho1/MyoII are induced apically in a spatially restricted primordium region via localized transcription of the GPCR ligand Fog. Second, a tissue-scale travelling wave of Rho1/MyoII activation and cell invagination progresses anteriorly across the dorsal epithelium at a constant speed of 1 cell every 3 minutes. The wave does not require sustained gene transcription, and is not governed by regulated Fog delivery. Instead, MyoII inhibition blocked acute Rho1 intracellular activation and its propagation from one cell to the next, revealing a mechanical feedback driven by MyoII. Simulations of a 1D-contractile viscoelastic material suggest that that MyoII contractility provides both local feedback amplification and spatial coupling necessary for wave progression. Finally, we identify a cycle of 3D cell deformations that

link MyoII activation and invagination in one row of cells to vitelline membrane attachment, apical spreading, MyoII activation and invagination in the next row, to drive anterior progression of the invagination wave. Remarkably, the alpha-PS3 integrin Scab mediates apical attachment of cells to the vitelline membrane and is involved in MyoII activation, revealing a role of integrins as potential molecular effectors of the mechanical relay mechanism during wave progression. Thus endoderm morphogenesis emerges from local transcriptional initiation and a mechanically driven travelling cycle of cell contraction and deformation.

P2506/B764

Mechanics of Passive Cell Rearrangement during Epithelial Convergent Extension: Understanding Experimental Observations through Theory.

S. An jum, L. Davidson; University of Pittsburgh, Pittsburgh, PA.

Convergent extension (CE) is a critical process in shaping embryos and organs, driving their growth. CE is a common trope in animal morphogenesis for narrowing tissue in one direction and lengthening it in the other. One strategy of CE involves directed cell intercalation (i.e. oriented T1 transitions). For instance, the vertebrate neural epithelium elongates via directed cell intercalation as it forms the neural tube, the precursor of the spinal cord. Failure of this process leads to birth defects such as spina bifida. CE is proposed to be the result of a coordination between biochemical patterning that establishes and maintains the direction of intercalation and mechanical responses from passive and active elements. However, it has been difficult to delineate mechanical from biochemical with traditional experimental design, so we have adopted a computational modeling approach inspired by ongoing studies of *Xenopus* neural CE. The relative contributions from active and passive processes during directed cell intercalation remains unclear. For instance, passive jamming and unjamming transitions have been implicated in epithelial morphogenesis. To understand the role of passive processes, we simulate passive epithelial responses to external CE forces. Such a model isolates the passive responses to tissue field elongation from contributions from active cellular processes. In the model, cells are represented as interacting particles in a square bounding box. Boundaries are moved such that the field of cells undergoes area-conserving CE. Time series of polygonal cell networks are analyzed to quantify deformations, cell neighbor exchanges, and cell area fluctuations. Additionally, we quantify local tissue strain by defining a 2-level *corona* as a cell, its surrounding neighbors, and its neighbors' neighbors. We then analyze the dynamics of the strain experienced by this domain. Recapitulating endogenous rates of *Xenopus* neural CE reveal neighbor exchanges and directional junctional remodeling that mimic in *vivo* observations. Extending our simple simulations by incorporating active cell elements such as actomyosin contractility and junctional remodeling will enable quantitative assessment of specific biochemical and mechanical drivers of tissue shape change.

P2507/B765

Cell-Cell Adhesion Links Cell Shape and Rearrangement Speed during *Drosophila* Axis Elongation.

X. Wang, K. E. Kasza; Columbia University, New York, NY.

During development, simple epithelia reorganize into tissues with complex form and structure. Tissue reorganization during morphogenesis can be rapid. In *Drosophila*, cell rearrangements in the embryonic epithelium double the length of the body axis in 30 minutes. Adhesion at cell-cell contacts, mediated by junctional proteins such as E-cadherin, and contractile tension, generated by actomyosin, are thought to

be key machineries controlling epithelial tissue movements. However, it remains unclear how the balance between adhesion and tension determines epithelial tissue structure and mechanics to control whether tissues remodel and flow like fluids or maintain shape like solids. To gain insight, we systematically modulated the balance between adhesion and tension in *vivo* by using multiple molecular genetics approaches to tune E-cadherin expression in the *Drosophila* embryo. We increased or decreased E-cadherin levels relative to wild type and used live confocal imaging to study the effects on cell shapes and movements before and during axis elongation. Prior to the onset of axis elongation, modulating adhesion levels influenced cell shapes and packings within the germband epithelium. In particular, we found a biphasic response, where either increased or decreased E-cadherin levels at cell-cell junctions was associated with longer cell-cell contacts and cell perimeters. We also found a biphasic dependence of cell rearrangement speed on E-cadherin levels during axis elongation. Interestingly, tissues comprising cells with the longest perimeters also tended to rearrange fastest, consistent with recent vertex model predictions that link cell shape to rearrangement energy barriers and to tissue mechanics and remodeling. To better understand the origins of the observed dependence of cell shape and rearrangement on E-cadherin levels, we also investigated F-actin and myosin II in these embryos, revealing that perturbing E-cadherin levels also influenced the actomyosin contractile machinery. These findings raise the possibility that the coupled effects of E-cadherin on the adhesive and contractile machineries might together impact tissue structure and dynamics and explain the observed behaviors. These systematic, quantitative experimental studies of epithelial tissues structure and mechanics in *vivo* are an essential step in building biophysical models of multicellular tissues and predictive models of morphogenesis.

P2508/B766

Role and Cellular Mechanism of Apico-basal Forces during Tissue Morphogenesis.

M. Suzanne[1], A. Ambrosini[1], M. Rayer[1], M. Gracia[1], S. Theis[1], B. Monier[1], C. Benassayag[1], G. Gay[2]; [1]LBCMCP, Centre de Biologie Intégrative (CBI), Université de Toulouse, CNRS, UPS, 118 route de Narbonne, TOULOUSE, FRANCE, [2]Morphogénie Logiciels, St Martin d'Armagnac, FRANCE.

Mechanical forces are critical regulators of cell shape changes and tissue remodelling during developmental morphogenetic processes. within epithelial sheets, planar forces are specifically generated at the apical or basal cell level, while orthogonal forces are developed along the apico-basal cell axis. Although planar forces have been extensively studied, the importance and the cellular machinery required to generate orthogonal forces along the cell apico-basal axis remain elusive. Recently, we revealed that apoptotic cells are generating apico-basal forces that constitute an important mechanical signal involved in epithelial folding in the developing leg of Drosophila. We further identified the cellular mechanism involved and showed that during the initial force-producing stage, cells reorganize their actomyosin cytoskeleton to create a contractile tether connecting the nucleus, which offer resistance to acto-myosin contraction. We then ask if this mechanism was specific to apoptotic cells or could be a general feature of delaminating cells. Interestingly, we revealed that cells undergoing EMT also generate an apico-basal force and that this force constitutes a crucial driving force in mesoderm invagination. Thus, the capability to drive tissue remodelling by generating apico-basal forces could be a general feature of delaminating cells.

P2509/B767

Optogenetic Control of RhoGTPase Activity Reveals Dynamics of Contractile and Adhesive Machinery during Epithelial Morphogenesis.

M. Herrera-Perez, K. E. Kasza; Columbia University, New York, NY.

Epithelial tissues undergo dramatic changes in shape and structure during development.These changes are driven in large part by contractile forces, which are generated by the cellular actomyosin cytoskeleton and transmitted across the tissue by the cell-cell adhesion machinery. The balance and coupling between contractile forces and adhesion are thought to be key determinants of the mechanical behavior of tissues. A major obstacle to dissecting the mechanisms by which the contractile and adhesive machineries organize and influence morphogenesis has been the lack of tools for flexible and precise manipulation of these machineries in *vivo*. We developed optogenetic tools to modulate actomyosin contractility in the *Drosophila* embryo by controlling the localization of upstream regulators of myosin in the Rho/Rho-kinase signaling pathway, including RhoGEF2. These tools allow for temporally precise perturbations and so are well-suited to studying the dynamics of how patterns of actomyosin activity are established and maintained. We used these tools to perturb Rho activity during germband extension, when forces generated by planar polarized myosin drive oriented cell rearrangements that narrow and elongate the head to tail body axis.We found that optogenetic recruitment of RhoGEF2 uniformly across the apical domain of the tissue is sufficient to disrupt the planar polarized pattern of myosin localization and convert it to a radially polarized pattern. RhoGEF2 recruitment to the apical cell membrane results in a two-step response. First, we observe an initial myosin recruitment to cell-cell junctions, which reduces myosin planar polarity. Second, and rapidly following the first phase, we observe myosin accumulation in the medial-apical domain of cells, which occurs concomitantly with a decrease in junctional myosin and changes in organization of the core adhesion protein E-cadherin. These perturbations to the contractile and adhesive machineries are associated with abnormal changes in apical cell shapes, defects in the orientation of cell rearrangements, and a reduction in tissue elongation. Our results reveal how patterns of RhoGTPase activity influence the spatial and temporal patterns of the contractile and adhesive machineries that drive epithelial morphogenesis and demonstrate the potential of optogenetic approaches for dissecting the dynamics of cellular machinery during morphogenesis in *vivo*.

P2510/B768

Integrin-mediated Attachment of the Blastoderm to the Vitelline Envelope Impacts Gastrulation of Insects.

S. Muenster[1,2,3], A. Mietke[3], A. Jain[1], P. Tomancak[1], S. Grill[2,1]; [1]MPI Cell Biology & Genetics, Dresden, GERMANY, [2]TU Dresden, Dresden, GERMANY, [3]MPI Physics of Complex Systems, Dresden, GERMANY.

Gastrulation is a critical step during the development of multicellular organisms in which a single-layered tissue folds into a multi-layered germband. This shape change is characterized by tissue folding and large-scale tissue flow. The myosin-dependent forces that underlie this process have been increasingly investigated; however, thus far, the possible interaction between the moving tissue and the rigid shell surrounding the embryo has been neglected. Here, we present our quantitative findings on the physical mechanisms governing gastrulation in the red flour beetle *(Tribolium castaneum)*. We investigated the forces expected within the tissue given the myosin distribution observed by multi-view light-sheet microscopy and discovered that an additional external force must be counteracting this

tissue-intrinsic contractility. We then identified that a specific part of the tissue tightly adheres to the outer rigid shell. This attachment is mediated by a specific integrin *(Inflated)* whose knock-down leads to a complete loss of the counter-force. Moreover, in the fruit fly *(Drosophila melanogaster)* knock-down of another integrin *(Scab)* leads to a severe twist of the germband, suggesting that the integrin-mediated interaction between tissue and vitelline envelope may be conserved in insects.

P2511/B769

Planar Cell Polarity and Cell-cell Adhesions Govern Force Production during Embryonic Head-to-tail Axis Extension.

R. J. Huebner, S. Weng, A. N. Malmi-Kakkada, S. Sarikaya, C. Lee, O. Papoulas, J. B. Wallingford; the University of Texas at Austin, Austin, TX.

Convergent extension (CE) is a conserved process of collective cell movement that is essential for head-to-tail axis elongation in animals. Failure of CE is associated with human diseases including neural tube closure defects. Vertebrate CE requires three deeply conserved molecular programs: planar cell polarity (PCP), actomyosin contractility, and cell-cell adhesion. However, it is currently unclear how these molecular programs interface during CE. In this study we used a systems biology approach, including in-vivo super resolution microscopy and tissue-specific mass spectrometry, to determine how PCP, actomyosin contractility, and cell-adhesion are integrated during CE. We found that PCP functioned upstream of the cell-cell adhesion molecule cadherin and PCP was specifically required for polarized localization and cis-dimerization (intracellular dimerization) of cadherin molecules during CE. Next we showed that cis-dimerization of cadherins was required for CE and that disruption of cis-dimerization resulted in axis elongation defects in animals. We then used tissue-specific affinity purification mass spectrometry to identify unique cadherin protein interactions during CE and found a strong interaction with a relatively uncharacterized catenin named Armadillo Repeat Protein Deleted in Velo-Cardio-Facial Syndrome (ARVCF). Finally, we showed that knockdown of ARVCF resulted in mis-localization of contractile actomyosin machinery, tissue scale reduction in force production, and global failure of head-to-tail axis extension. These results connect three deeply conserved molecular programs (PCP, actomyosin contractility, and cell adhesion) during a fundamental developmental process and provide mechanistic insight into the collective cell movements that shape the early embryo.

P2512/B770

Mechanisms of Tubulogenesis in the Sea Star Larva.

M. Perillo, G. Wessel; Brown University, Providence, RI.

A critical step in organogenesis is the formation of hollow tubes. This process, called tubulogenesis, involves epithelial proliferation, formation of a lumen, size control, distinct cellular polarity, and directional growth. Our aim is to understand the mechanisms of tubulogenesis by use of sea star larvae, a new, tractable model for this prevalent process. Larvae of the sea star Patiria *miniata,* develop two long hollow tubes that bud off the tip of the foregut, grow posteriorly along the length of the digestive system, and contribute to the adult structures at metamorphosis. We followed tube formation in vivo to assess this process through live imaging of actin, microtubules, plasma membranes, and nuclei. We found that tube cells undergo dynamic cell rearrangements and have extensive filopodia, potentially to follow guidance cues coming from the ectoderm. To understand the nature of these cues, we investigated whether specific signaling molecules drive the cellular rearrangements needed for tube

elongation. We found that the VEGF, Notch/Delta, and FGF signaling pathways drive distinct aspects of tube elongation and cell survival, while Wnt signaling drives tube orientation. In summary, our preliminary results establish the sea star larval tubes as a useful in *vivo* model to study cell biological aspects of tubulogenesis, and because of its phylogenetic position as a sister group to chordates, it may shed light on the evolution of vertebrate tubular structures.

P2513/B771

NOVEL Functions of Tight Junction Component Occludin in Vertebrate Epithelium.

T. Zhou, Y. Lu, C. Xu, R. Wang, **P. Lu**; ShanghaiTech University, Shanghai, CHINA.

Tight junctions (TJs) are a fundamental feature of both epithelium and endothelium and are indispensable for vertebrate organ formation and homeostasis. However, mice lacking *Occludin* (*Ocln*) develop relatively normal to term. Here, we show that *Ocln* is essential for mammary gland physiology as mutant mice fail to produce milk. Surprisingly, *Ocln* null mammary glands showed intact TJ functions and their epithelial morphogenesis, cell differentiation, and tissue polarity were all normal, suggesting that *Ocln* is not required for these processes. Using single cell transcriptomics, we identified milk-producing cells (MPCs) and found they were progressively more prone to ER stress as protein production exponentially increased during late pregnancy and lactation. Importantly, *Ocln* loss in MPCs resulted in greatly heightened ER stress; this in turn led to increased apoptosis and acute shutdown of protein expression, ultimately leading to lactation failure in the mutant mice. We show that ER stress increase was caused by a secretory failure of milk proteins in *Ocln* null cells. Consistent with a direct role in protein secretion, Occludin resided on secretory vesicles and bound to SNARE proteins. Finally, we show that Occludin is also essential for secretory functions of other epithelial organs. Together, our results demonstrate that *Ocln* play novel functions rather than its traditional roles in TJs biology in vertebrate organs.

P2514/B772

Ecdysone Regulates a Change in Epithelial Barrier Function of *Drosophila* Wing Imaginal Discs during the Third Instar.

D. DaCrema, R. Yano, F. Karanja, R. Bhandari, A. Halme; University of Virginia, Charlottesville, VA.

A key function of epithelial tissues is to compartmentalize the body and establish local microenvironments that meet the needs of organs or tissues. The epithelial barrier is regulated in response to changing needs of the organ or tissue. Understanding how the barrier is regulated during development could provide insights into how tissues respond differently to similar stimuli at different points in development. We examined the regulation and change of the epithelial barrier during a period of rapid development: the late third instar of *Drosophila* wing imaginal discs (larval precursors to adult wings). We developed a method to measure barrier permeability relative to genetically or physically disrupted barriers. We determined that by the mid-third instar, wing discs have developed a functional epithelial barrier that becomes more exclusive in the late third instar. To determine the cause of the functional change, we looked at the localization of septate junction components. One core component of septate junctions, Coracle (protein 4.1 homolog), is diffusely localized along the lateral cell membrane during the mid-third instar, but becomes tightly localized to septate junctions as barrier function changes. We determined that Coracle is only necessary for barrier function once localized at the junctions. The timing of the change in barrier function correlates with many developmental transitions,

including the limitation of regenerative ability; these processes are regulated by the steroid hormone ecdysone. To determine if ecdysone regulates changes in barrier function, we artificially increased circulating ecdysone levels by feeding the larvae ecdysone. Larvae fed ecdysone developed a more exclusive barrier earlier in development. We limited ecdysone signaling by locally expressing dominant negative alleles of the ecdysone receptor. This disruption of ecdysone signaling did not affect barrier function in mid-third instar wing discs. However, the barrier failed to transition to the more exclusive, late barrier. Late discs expressing the dominant negatives show diffuse Coracle localization. These data indicate that ecdysone regulates the localization of Coracle, which changes the function of the epithelial barrier. We hypothesized that the changing barrier could sequester signaling peptides in the disc lumen late in development. We assessed this hypothesis with the damage-response peptide *Drosophila* insulin-like peptide 8 (Dilp8). Dilp8 is secreted apically into the lumen but functions in the brain and prothoracic gland to delay development and allow time for regenerative repair. We found that disrupting the epithelial barrier synergistically amplified Dilp8 signaling, indicating that the late barrier may limit Dilp8 by preventing diffusion from the lumen.

P2515/B773

Ecdysone Signaling Shapes Tissue Regeneration through Splice Variants of the Transcription Factor *Broad*.

F. W. Karanja, B. A. Martinez, D. F. DaCrema, S. Amin, S. E. Weintraub, S. Sahu, A. J. Halme; University of Virginia, Charlottesville, VA.

As tissues develop, their regenerative capacity is often diminished. In *Drosophila melanogaster* imaginal discs (larval precursors to adult tissues) lose the ability to regenerate near the end of larval development. This loss of regenerative capacity coincides with an increase in systemic levels of the steroid hormone ecdysone, a key coordinator of *Drosophila* developmental progression. Experimentally increasing systemic ecdysone levels by feeding larvae ecdysone limited regeneration that was observed in adult tissues. Surprisingly, high ecdysone levels also increased activation of regeneration genes. This result was scalable: lower concentrations of ecdysone fed showed more activation of regeneration pathways than higher concentrations. Therefore, we hypothesized that low concentrations of ecdysone, such as those found before regeneration restriction, promotes regeneration while higher levels of ecdysone found at the prepupal stage cause changes in disc epithelia that interferes with the activation of regeneration pathways. To determine how ecdysone impacts regenerative signaling, we looked at downstream targets of ecdysone. We find that in wing discs, expression of *broad (br)* splice variants (*Z1-Z4*), which are early targets of prepupal ecdysone signaling, coincides with regeneration restriction. We determined that expression of *br* splice variants are necessary for regeneration restriction. Loss of *br* expression using *br-RNAi* or variant-specific mutants allows for activation of key regeneration genes, *wingless* (*wg*) and *dilp8*, past the regeneration restriction time-point. In addition, loss of *br* allows for increased and extended activation of regeneration pathways. Through the over-expression of the variants early in imaginal disc development, we determined that *brZ1, brZ2 and brZ4,* limit regenerative activity. Interestingly, *brZ3,* activates regeneration pathways. We are currently investigating the mechanism through which *br* variants suppress regeneration and whether they facilitate activation of regeneration pathways at lower ecdysone concentrations. Preliminary data suggests that *br* variants do not regulate JNK signaling in the wing disc but may instead facilitate the epigenetic modifications that lead to suppression of regeneration genes at the end of larval development. Our findings would provide insight into how endocrine signals regulate the regenerative competence of cells.

P2516/B774

Investigating the Principles of Homeostatic Vascular Remodeling Via 4d Imaging of Live Mice.

C. Kam[1], E. Marsh[1], K. K. Hirschi[2], V. Greco[1]; [1]Yale University, New Haven, CT, [2]University of Virginia, Charlottesville, VA.

Our organs depend on an organized vascular network that supplies them with nutrients and soluble factors via the bloodstream. The endothelial cells (ECs) that line our blood vessels dictate crucial aspects of vascular function and morphogenesis. However, there are still many open questions concerning the cellular mechanisms by which the vasculature is able to maintain homeostatic conditions. To this end, we are investigating how the vascular network 1) is able to adapt to organismal growth to reach its steady state and 2) once established, how does it keep functioning despite many insults including injury. The challenge in addressing these questions is the inability to follow the same tissues and cells over time. To overcome this roadblock, we have adapted our intravital imaging of skin epithelium to now track and manipulate endothelial cells in live mice. We have observed that the branching architecture of the dermal vascular plexus is established early during neonatal growth, with capillary loops uniformly expanding in coordination with tissue growth. Tracking of individually labeled cells reveals that the vast majority of capillary ECs undergo cell elongation, suggesting a role for this behavior for coordinated loop expansion. Interestingly, ECs were also observed to participate in migration within lumenized blood vessels during this period, a phenomenon that is reminiscent of embryonic stages. Longitudinal tracking of cells over several weeks shows that the rate of EC migration is largely diminished as the animal reaches adulthood. Genetic manipulation of Rac1 in ECs during neonatal growth to perturb luminal migration leads to defects in vessel branching and coverage. As the plexus size and cell behaviors reach stability, we next sought to understand the mechanisms by which ECs are able to cope with injury and maintain vascular integrity. By carrying out targeted laser ablations to inflict local damage at the individual cell level, we find that ECs do not respond with proliferation but instead elongate towards the site of damage. Intriguingly, we also observe that injury in the periphery of individual ECs results in a pinching off and discarding of damaged membrane in what is likely an exocytic mechanism of self repair. This is a phenomenon that has not previously been described in ECs and we are currently investigating the role that caveolae (enriched in ECs) could be playing in the self repair process by utilizing Caveolin-1 knockout mice. Overall, this study sheds light upon fundamental mechanisms by which ECs maintain and control vascular homeostasis.

P2517/B775

Zbp1 Expression Is Required to Support Epithelial Cyst Formation and Tissue Morphogenesis.

J. Davis, A. Rodriguez, E. M. Bonder; Rutgers-Newark, Newark, NJ.

It is well-appreciated that Zipcode Binding Protein-1 and its regulatory action on mRNA stability, localization, and translation are essential for normal development. For example, loss of ZBP1 expression and activity has been linked to dysfunctional chemotactic activity and metastasis. Previously, Gutierrez et al. (2014) documented the importance of localized β-actin expression, under the control of ZBP1, on the formation of adherens junction in cultures of MDCK epithelial cells. Delocalizing β-actin translation resulted in delayed assembly of the adherens junction complex and increased barrier permeability. ZBP1 has also been shown to regulate the localization and translation of E-cadherin as well as the stability of β-catenin mRNAs. Thus, ZBP1 appears to impact the formation and function of adherens junctions at

multiple physiological levels. The current study seeks to investigate the consequences of ZBP1 expression on adherens junction formation, barrier function, and epithelial cyst morphogenesis. In order to address this question, stable MDCK ZBP1 knockdown cell lines were generated using shRNA. Following ZBP1 knockdown, E-cadherin and β-catenin levels are reduced, and confocal immunofluorescence imaging identified the presence of "holes" in monolayers due to incomplete adherens junction formation. Using cell aggregation and fluorescent dextran permeability assays, MDCK ZBP1 knockdown cells exhibited slower rates of aggregation, decreased aggregate size, and increased barrier permeability. When cultured in Matrigel, MDCK cells form cysts with highly defined apical and lateral surfaces with a single lumen. Upon ZBP1 knockdown, MDCK cysts demonstrated disrupted adherens junction organization, increased number of lumens, increased barrier permeability, and altered orientation of mitotic spindles. MDCK cells expressing β-actin mRNA lacking the 3'UTR zipcode sequence recapitulated the aforementioned phenotypes observed by ZBP1 knockdown. Thus, ZBP1 appears to coordinate localization and translation of multiple adherens junction components that have direct effect on epithelial barrier function, spindle orientation, and apical-basal polarity.

Axolotl MARCKS Like Protein Is Extracellularly Released Via a Non-canonical Protein Secretion Pathway.

T. Sugiura[1,2], E. Kania[2], E. Tanaka[1,2]; [1]IMP - Research Institute of Molecular Pathology, Vienna, AUSTRIA, [2]Deutsche Forschungsgemeinschaft (DFG)-Center for Regenerative Therapies Dresden, Dresden, GERMANY.

How do regenerative animals start regeneration? a key feature of complex appendage (limb and tail) regeneration in the axolotl (*Ambystoma mexicanum*) is the accrual of a proliferative zone of progenitor cells at the injury site, a structure called the blastema. Blastema formation and proliferation is dependent on epidermal cells, which migrate in to cover the amputation plane. This newly formed epidermal layer is called the wound epidermis (WE). It was already demonstrated by Tornier in 1906 that substitution of the WE by a graft of uninjured epidermis arrested regeneration showing that the WE is an essential tissue to promote the process of appendage regeneration in salamanders (Tornier, G. 1906. *Arch. fur Entwmech*). However, it had been remained unclear what injury-related signals from the WE trigger blastema formation. To identify extracellular factors that initiate proliferation in blastema cells during regeneration, we took a functional expression cloning approach. We identified Axolotl MARCKS Like Protein (AxMLP) as an extracellular molecule that induces cell cycle in cultured myotubes. Gain- and loss-of-function assays in *vitro and* in *vivo* strongly suggested that AxMLP triggers the initial proliferative response after injury (Sugiura, T., et al., *Nature* 2016). Importantly, we found that AxMLP was expressed in the WE and AxMLP was released into extracellular space in *vitro*. This was surprising, as MARCKS family proteins had been described to be intracellular proteins (El Amri, M., et al., *J Biomed Sci.* 2018). Indeed, MARCKS family proteins (including AxMLP) do not have a canonical secretion signal sequence. In the current study, we focus on the mechanisms of AxMLP secretion. Our preliminary results suggest that: 1, AxMLP is not secreted via the canonical secretion pathway 2, Extracellular vesicles containing AxMLP can induce proliferation of cultured myotubes 3, Membrane association of AxMLP is related to its secretion Taken together with our previous study, these results imply that MLP released extracellularly from the WE via a non-canonical protein secretion pathway stimulates progenitor cell proliferation and eventually contributes to forming the blastema. We are now performing a drug screen to identify the molecules that regulate AxMLP secretion.

Deciphering How Spatial Patterning of Radial Cell Fates Drives Hair Follicle Morphogenesis.

L. Leybova, R. Sharan, D. Devenport; Princeton University, Princeton, NJ.

During embryonic development, signaling pathways are activated in spatially-defined patterns that specify new cell fates and drive tissue morphogenesis. The mammalian epidermis, which is decorated with thousands of hair follicles arranged in a periodic pattern, is an ideal model system to investigate how spatial patterning drives cell shape and motility changes that underlie epithelial morphogenesis. Periodically-patterned Wnt and Shh signaling specify early hair placodes, which are comprised of two, radially-arranged cell types that undergo extensive cell rearrangements to form polarized epithelial buds. Although both cell types are required for placode morphogenesis, their individual contributions to this stereotyped cell motion are unknown. Here we show that Wnt signaling directs changes in cell-cell adhesion in developing hair placodes and investigate how reciprocal gradients of classical cadherin expression contribute to placode morphogenesis. Ongoing work is testing the necessity of these cell adhesion differences for rearrangements using long-term live imaging of placodes from embryos lacking either E-Cadherin or P-Cadherin.

Targeting Filopodia during Pattern Formation.

A. Sherrod[1], J. Zhumi[2], **G. Hunter**[1]; [1]Clarkson University, Potsdam, NY, [2]Hunter College, New York, NY.

The ability of Notch signaling to drive the formation of a broad range of biological patterns relies, in many systems, on the activity of cellular protrusions that allow contact between cells at a distance. One example of this is the patterning of sensory bristles on the thorax of the fruit fly Drosophila melanogaster. In this tissue, cellular protrusions are thin, dynamic, actin-based, filopodia-like structures which extend from the basal surface of the patterning epithelia. A challenge in the study of the role of these protrusions is the lack of a specific genetic tool that allows for perturbation of protrusions without simultaneous perturbation of other critical actin-based cell structures and processes. An unconventional myosin, Myosin XV, has previously been shown to localize to, and play a role in the dynamics of, filopodia in Drosophila as well as in other cellular protrusions in mammals, including stereocilia. We hypothesized that specific manipulation of cell protrusions via Myosin XV would lead to changes in the pattern of Notch signaling and bristle patterning in vivo. Using a combination of genetics, cell biology, and confocal imaging, we observed that expression of Myosin XV RNAi leads to increased density of sensory bristles. Consistent with this finding, we observe changes in filopodia dynamics. Finally, we observe that Notch signaling is affected by specific targeting of filopodia, through the use of a transcriptional reporter of Notch signaling. Together these results support a role for filopodia in lateral inhibition during bristle patterning.

Dia1 Coordinates Differentiation and Cell Sorting in a Stratified Epithelium.

R. Harmon, J. Devany, M. Gardel; University of Chicago, Chicago, IL.

Prior studies implicate the actin nucleator, Dia1, in shaping cellular adhesions. However, few approach Dia1 and adhesion in terms of cell sorting. Dia1 localizes to the basal layer of stratified mammalian

epidermis, a tissue which relies on cell sorting to maintain its multilayered architecture. Specifically, induction of differentiation in basal keratinocytes coincides with apical movement into suprabasal compartments. In 3D skin cultures, we found that genetic depletion of Dia1 resulted in a poorly packed basal layer. Dia1-deficiency did not prevent stratification but did perturb expression of suprabasal differentiation markers. Since crowding is known to induce differentiation and initiate basal layer egress, we hypothesized that Dia1 prevents keratinocytes from escaping the basal layer before reaching densities amenable to inducing differentiation. Consistent with this hypothesis, we found that forced crowding of Dia1-deficient cells rescued transcriptional abnormalities. Dia1 both supported cortical tension and, paradoxically, accelerated vertical expansion of nascent, intercellular contacts. In aggregation assays, this feature drove Dia1 positive and negative cells into distinct stratified layers in a ROCK-dependent manner. Our results suggested that as basal cells proliferate, Dia1 expression favors reintegration with other Dia1 positive basal cells, in effect, opposing dissemination into the Dia1 negative, suprabasal compartment. Though linked to ulceration and carcinoma, this study illuminates the scarcely explored role of formins in normal physiological processes leading to tissue stratification.

Utilizing Single-cell Sequencing Technology to Improve Synthetic Skin Equivalents.

A. R. Stabell, S. Wang, S. X. Atwood; University of California, Irvine, Irvine, CA.

Organotypic culture systems are artificial environments designed to model complex 3D biological systems more accurately than 2D cell cultures. They provide a means to study cellular behavior with more physiological relevance than cell lines while offering higher throughput than in vivo models. While these organotypic cultures are powerful tools, it is important to know which aspects of them are biologically relevant. In our lab, we have performed single cell RNA-sequencing on fully stratified human epidermal tissue that was generated using multiple distinct organotypic culture system protocols. Sequencing experiments coupled with molecular and histological staining elucidated the similarities and differences between in vivo human epidermis and our skin equivalents grown in vitro and provided insight into the cell-cell signaling between different cell types. Both homologous and heterologous clusters of cells exist between normal human epidermis and our skin culture systems. Alterations to the organotypic skin culture were made to abate these distinctions and further sequencing experiments were performed to evaluate these changes. This study moves us closer to generating skin organoids that accurately mimics in vivo human skin which can be used in genetic experiments, drug screens, and ultimately transplantation.

P2523/B781

Developmental Transitions in Epithelial Cell Behaviour Drive Skin Morphogenesis.

S. J. Ellis, A. F. Mertz, V. F. Fiore, T. Eilertsen, N. C. Gomez, E. Fuchs; the Rockefeller University, New York, NY.

A key feature of animal embryogenesis is the formation of a protective, fluid-retaining permeability barrier. In mammals, the skin epidermis, a tissue comprised of stratified layers of specialized epithelial cells, fulfils this function. In the mouse embryo, epidermal development begins at E9.5 from a single layer of progenitor cells. To initiate the transition to a stratified epithelium, cell divisions within the monolayer are increasingly skewed towards axes of division that are oriented perpendicular to the underlying basement membrane, such that one daughter cell populates an emerging “suprabasal” layer

on top of the preexisting “basal” layer. Consistent with others in the field, we find that until E14.5, the probability of a basal cell to divide perpendicularly positively correlates with increased cell crowding; regions of greater epithelial crowding stratify more quickly than less crowded regions. This phase of cell density-driven stratification precedes differentiation and does not depend on oriented localization of classical asymmetric cell division (ACD) machinery components such as LGN. However, by E15.5, a correlation between cell density and axis of division is no longer observed and stratification is governed by ACD-machinery dependent control. Intriguingly, we previously discovered that E15.5 also represents a developmental transition in modes of loser cell elimination during cell competition in the skin. Before E15.5, loser cells are removed by apoptosis and subsequent engulfment by their epidermal neighbours. However, from E15.5 onwards, losers no longer undergo apoptosis, but instead exit the basal layer via ACD and differentiation. We hypothesize that these two transitions, in stratification mechanisms and in loser cell elimination mechanisms, are linked. Using functional genetics, immunofluorescence and time-lapse imaging, we systematically test a series of candidate genes that may govern this transition. Our candidates fall into two categories: (1) genes that influence the basal cell microenvironment such as adhesion to the underlying extracellular matrix, and the ECM itself; (2) genes associated with the early stages of differentiation in the overlying suprabasal layer that directly contacts the basal layer. Our study will provide fundamental insights into our understanding of how stratified barrier tissues are built in the embryo. Moreover, in epithelial barrier tissues such as the skin that continue to turnover throughout the life of the organism, we speculate that such early developmental transitions are ultimately important for and part of the eventual transition to homeostasis that must occur to both maintain tissue integrity and prevent overgrowth once development is complete.

P2524/B782

Investigating Mechanisms Regulating Cell Adhesion during Tissue Remodeling.

N. Clarke, A. Martin; Massachusetts Institute of Technology, Cambridge, MA.

Proper regulation of cell-cell adhesion is crucial for embryonic development and tissue homeostasis: dysregulation of adhesion during development leads to failures in morphogenesis that produce congenital disorders, and abnormal activation of signals that regulate adhesion in tumors can result in epithelial-mesenchymal transition (EMT) and cancer metastasis. In epithelial tissues, cells adhere to each other through Adherens Junctions (AJs) containing the cell adhesion molecule E-Cadherin. The transcription factor Snail is a conserved regulator of cell adhesion and cell motility that was first identified as a necessary factor for promoting cell motility and EMT during gastrulation in the fruit fly, *Drosophila melanogaster*. Snail has since been shown to repress E-cadherin transcription in many model organisms, and the ectopic expression of Snail in cell culture is thought to promote precocious by reducing adhesion through transcriptional silencing of E-cadherin. Interestingly, recent observations have shown that Snail regulates the stability and localization of AJs independent of transcriptional regulation of E-Cadherin levels. However, the specific mechanism by which Snail controls AJ organization remains unknown, highlighting an important gap in our understanding of the signals that regulate adhesion and govern the cellular decision to undergo EMT. We have begun to investigate this process in the *Drosophila* embryo using a combination of biochemical, cell biological, and genetic approaches to define this mechanism. Here, we present preliminary evidence from the naturally occurring EMT of the *Drosophila* mesoderm during gastrulation, as well as from an ectopically induced EMT in an embryonic epithelium.

P2525/B783

Role of the Arrangement of Basal Bodies in Establishment of the Coordinated Ciliary Beating in Multi-ciliated Cells.

S. Nakayama[1], S. Konishi[1], T. Yano[1], E. Herawati[2], H. Kashihara[1], A. Tamura[1], S. Tsukita[1]; [1]Dept. Of Bio Sci., Grad. Sch. Of Medicine., Osaka University, Suita-shi, JAPAN, [2]Faculty of Mathematics and Natural Sciences, Universitas Sebelas Maret, Surakarta, INDONESIA.

Multiciliated cells (MCCs) promote fluid flow through coordinated ciliary beating. Tracheal MCCs contain large numbers of basal bodies (BBs), which are short cylindrical structures at the bases of cilia that are docked to the apical membrane. The orientation of BBs, identified by their asymmetrically associated basal feet (BF), is precisely coordinated to support efficient mucociliary transport. In our previous work, we developed a long-term and high-resolution live cell imaging system by using super-resolution microscopy to observe green fluorescent protein (GFP)-centrin2 labeled BBs in mouse tracheal epithelial cells (MTECs). This system revealed stereotypical patterns of BBs and we constructed a theoretical model which indicated that the apical cytoskeleton provides a self-organizing mechanism to align BBs linearly in tracheal MCCs. However, the biological relevance of the alignment and orientation of BBs is still unknown. Here, we examined the mechanism to coordinate the alignment and orientation of BBs and found some pattern of coordination of BBs' orientation in relation to BBs' alignment through apical cytoskeleton network in a PCP-dependent manner. These understanding in coordinated ciliary beating provides a deep insight into how mucociliaty transport is established and how its defects might cause disease.

P2526/B784

Dorsal Closure in Numbers: Quantification of Epithelial Cell Oscillations Using Deep Learning.

D. Haertter[1,2], D. Rhodes[3], J. Crawford[3], D. P. Kiehart[3], C. F. Schmidt[1]; [1]Department of Physics and Soft Matter Center, Duke University, Durham, NC, [2]Third Institute of Physics-Biophysics, University of Göttingen, Göttingen, GERMANY, [3]Department of Biology, Duke University, Durham, NC.

Dorsal closure in *Drosophila melanogaster* embryos is a key model system for cell sheet morphogenesis and wound healing. Multiple sub-systems are involved in the mechanical closing of the dorsal opening. Understanding system dynamics, regulation and causal relations requires a quantitative understanding of the mesoscopic mechanical and dynamic properties of this "active soft material". Individual cells in the amnioserosa, a one-cell-thick sheet of epithelial cells filling the dorsal opening, show sustained oscillations of apical cell area. These oscillations exhibit large variations from cell to cell and during the course of closure. Past studies of epithelial dynamics were restricted to semi-manual segmentation of cell shapes and thus suffered from relatively low statistics. We present a novel analysis pipeline, based on a convolutional neural network (deep learning), that allows an automated and robust segmentation of large numbers of video recordings. We further employ statistical approaches to analyze spatial-temporal dynamics and quantify embryo-to-embryo variability. We observe emerging long-range dynamical patterns providing clues about possible communication mechanisms between cells.

P2527/B785

Microtubules Coordinate Collective Cell Migration in the Developing Mammary Epithelium.

A. K. Fraser, A. J. Ewald; Johns Hopkins University School of Medicine, Baltimore, MD.

Branching morphogenesis closely coordinates cell proliferation and collective cell migration to expand tubular epithelial structures. In the mammary gland, early branching relies on cell proliferation to establish a stratified Terminal End Bud (TEB). Once this unit forms, coordinated migration of TEB cells acutely drives elongation and branching. To investigate the dynamic contributions of microtubules to mammary epithelium, we use three-dimensional cultures of mammary organoids--epithelial cell clusters embedded within extracellular matrix. This culture system recapitulates the events of mammary development in a controlled and observable environment. We demonstrate that microtubule targeting drugs paclitaxel, nocodazole, and colchicine acutely arrest elongating branches and that this effect is independent of their effects on mitosis. Tracking individual cells in active TEBs through time-lapse confocal microscopy reveals that stabilizing microtubules with paclitaxel reduces cell speed while destabilizing microtubules with nocodazole reduces cell directionality. A dynamic microtubule cytoskeleton is therefore required for collectively migrating epithelial cells to maintain their speed and direction in 3D substrates. Time-lapse confocal microscopy of microtubule and organelle dynamics in TEB cells indicate that microtubules support the reorganization of epithelial cells for collective migration. These results offer novel insights into the role that the interphase microtubule cytoskeleton plays in collective migration and mammary epithelial morphogenesis.

Stem Cells-Pluripotent Stem Cells

Secretion of Cardioprotective Factors from Cardiac Colonies Derived from Germline Pluripotent Stem Cells to Combat Myocardial Fibrosis [Samiksha Mahapatra, Breanna Brownson, Conor Dillon,Dr. G. Ian Gallicano]

S. Mahapatra; Georgetown University, Washington, DC.

Stem cell research for treating or curing ischemic heart disease has, to date, culminated in identifying which scenario is more important; 1) stem cell differentiation into cardiomyocytes that integrate electrically with the heart, 2) stem cells that secrete paracrine factors that promote healing, or 3) combination of both. Following myocardial injury, cardiomyocytes are replaced by extracellular matrix proteins secreted by activated human cardiac fibroblasts that rapidly proliferate eventually forming a mature scar in the infarct area. This process is initially reparative but its long-term effect contributes to fibrosis and myocardial dysfunction. In our work, we consistently found that unipotent germline stem cells, when removed from their niche and cultured in the correct medium endogenously express pluripotency genes, which induce them to become human germline pluripotent stem cells (hgPSCs). These cells are then capable of producing cell types from all three germ layers. Using hgPSCs along with a modified version of a relatively novel cell-expansion culture methodology to induce quick, indefinite expansion of normally slow growing hgPSCs, it was possible to test the potential of cardiac colonies derived from hgPSCs for treating myocardial fibrosis following injury. Upon differentiation into cardiac lineages, our data consistently showed that they not only express cardiac genes, but also express cardio-protective paracrine factors. Our data also suggests that cardio-protective secreting cardiac colonies fuse and integrate with the surrounding tissue via gap junctions in *vivo.* Taking these data a step further, we found that these cardioprotective factors affect human cardiac fibroblasts (HCFs) and human

cardiomyocytes (HCMs) by suppressing *activation* of HCFs. More importantly, we found that these factors induce significant migration/proliferation of HCMs into the infarct zone. Our data suggest that secreted cardio-protective paracrine factors from hgPS-derived cardiac colonies could help tip the balance from fibrosis towards myocardial repair. Note, while the work presented here was based on testes-derived hgPSCs, data from other laboratories have shown that ovaries contain very similar types of stem cells that can give rise to hgPSCs. As a result, hgPSCs should be considered a viable option for eventual use in patients, male or female, with ischemic heart disease.

Modelling Naa15 Haploinsufficiency, a Cause of Congenital Heart Disease, Induced Pluripotent Stem Cells.

T. Ward; Harvard Med School, Boston, MA.

To better understand the contribution of the NatA complex, responsible for amino terminal (Nt) protein acetylation, to congenital heart disease we characterized NAA15 sequence variants in 4511 congenital heart disease (CHD) probands and genetically engineered isogenic induced pluripotent stem (iPS) cells. 4 loss-of-function, LOF, and one damaging missense (R276W) de novo NAA15 variants and 15 rare inherited missense mutations were found in this cohort. Haploinsufficent (heterozygous LOF), null (compound heterozygous LOF) and NAA15 missense carrying iPS cells were constructed using CRISPR/Cas9 technology to create cell-based models of NAA15-deficiency where the effects of these mutations on Nt acetylation could be evaluated. Haploinsufficent NAA15 iPS cells could differentiate into cardiomyocytes, but NAA15-null iPS cells could not, presumably due to alterations in both the amount and composition in NatA complex (documented by western blot analyses). Although nearly 80% of proteins detected by mass spectrometry have partial or complete Nt-acetylation, Nt acetylation of only 32 and 9 proteins differed in null and haploinsufficient NAA15 cells, respectively. Levels of more than 560 proteins were altered in mutant cells compared to wildtype cells. While most Nt acetylated proteins are fully acetylated, ~30 proteins are partially acetylated; NAA15-haploinsufficiency abrogated Nt-acetylation of 5 of these proteins but did not affect the acetylation of the other 25 proteins. Similar changes were observed in NAA15 R276W iPS cells. These studies define human proteins requiring a complete NAA15 complement for normal activity; deficiencies in one or more of these NAA15 target proteins are likely required for normal cardiac development.

Mitophagy-induced Release of the Mitochondrial Phosphatase PGAM5 Activates a Nuclear Wnt Signaling Feedback Loop in Differentiating Human Induced Pluripotent Stem Cells.

S. Krantz, Y. Kim, P. Toth, G. Marsboom, J. Rehman; University of Illinois at Chicago, Chicago, IL.

Background: Stem cells undergo metabolic reprogramming as they transition from a predominately glycolytic state during pluripotency towards enhanced mitochondrial respiration as they differentiate. The GTPase Mitofusin 2 (Mfn2) is a key mediator of mitophagy, the autophagic degradation of dysfunctional mitochondria. We hypothesized that mitophagy coupled with compensatory biogenesis of new mitochondria could serve as a key mediator of metabolic reprogramming during stem cell differentiation and that mitophagy may also further stabilize the differentiation process. The mitochondrial phosphatase PGAM5 is cleaved upon mitophagy and modulates Wnt signaling in the nucleus, thus providing a mitochondrial-nucleus crosstalk mechanism. We assessed whether cleaved

PGAM5 modulated Wnt/β-catenin signaling to direct stem cell differentiation. ***Methods and Results:*** Human induced pluripotent stem cells were differentiated towards a mesodermal-endothelial cell lineage. In the early stages of mesodermal differentiation, mitophagy doubled as assessed by the colocalization of mitochondria and activated lysosomes from 6.2% to 14.5% (p=0.004). Following this initial burst of mitophagy, mitochondrial mass subsequently increased in differentiated cells as measured by immunofluorescence for the mitochondrial membrane protein TOM20 from (from a mean of 162 to 307 mitochondrial pixels per visual field, p=0.003). Genetic inhibition of mitophagy by shRNA depletion of Mfn2 reduced the efficiency of differentiation by 50% as assessed by qPCR and flow cytometry of the mature endothelial markers VE-cadherin and CD31 (PECAM), indicating the essential role of mitophagy in differentiation. The mitochondrial phosphatase PGAM5, which is cleaved during mitophagy and modulates the Wnt pathway, increased three-fold after the induction of mitophagy on day 4 of differentiation ($p<0.05$). However, shRNA depletion of Mfn2 prevented the increase in PGAM5. Concomitantly, there was an increase in Wnt signaling on day 4 as seen in a doubling of the nuclear localization of β-catenin. Immunoprecipitation demonstrated a direct interaction between β-catenin and cleaved PGAM5 on day 4 of differentiation. ***Conclusion:*** Mitophagy is required for the metabolic reprogramming of differentiating human pluripotent stem cells. Importantly, mitophagy releases the Wnt signaling modulator PGAM5 which regulates the differentiation process and the biogenesis of new mitochondria. This novel feedback mechanism of mitochondrial-nuclear crosstalk in differentiating pluripotent stem cells provides new insights into the intersection of metabolic and developmental signaling.

P2531/B789

Establishment of Culture Method for Intestinal Stem Cells Derived from Human Ips Cells and Applications of Enterocytes Derived from Human Ips Cells for Drug Development.

S. Kondo[1], S. Mizuno[2], T. Iwao[2], T. Matsunaga[2]; [1]Otsuka Pharmaceutical Co., Ltd., Tokushima, JAPAN, [2]Nagoya City University, Nagoya, JAPAN.

The small intestine plays an important role in the pharmacokinetics of orally administered drugs due to the presence of drug transporters and metabolizing enzymes. Enterocytes differentiated from human iPS cells are useful cells for investigating intestinal pharmacokinetics. However, there is a problem with the stable supply. Hence, as a solution to this issue, we attempted to establish a new two-dimensional culture method to maintain intestinal stem cells (ISCs) derived from human iPS cells. Furthermore, we evaluated whether they have a potential to differentiate into enterocytes exhibiting appropriate pharmacokinetic functions. In established culture method, we succeeded in maintaining stemness of ISCs by activating the signaling pathway necessary for maintaining stemness, such as Wnt and Notch signaling. Furthermore, our results verified that the differentiated enterocytes from the maintained ISCs demonstrated appropriate pharmacokinetics functions. We also confirmed the presence of microvilli, which is characteristic structures of the small intestine. In addition, we investigated the use of enterocytes derived from human iPS cells for toxicity evaluation. The main component of intestinal mucus is mucin 2 (MUC2) secreted from goblet cells. MUC2 expression level in enterocytes derived from human iPS cells is comparable to that in the human small intestine. We evaluated drug-induced mucosal damage and protective effects using changes in MUC2 expression as an indicator. We examined changes in MUC2 mRNA expression in enterocytes by non-steroidal anti-inflammatory drugs (NSAIDs) and mucosal protective drugs (MPAs) as model drugs. As a result, NSAIDs decreased MUC2 expression level in enterocytes, whereas MPAs increased MUC2 expression level. In the present study, expression levels

of cytokines such as IL-1β, NF-κB, and TNF-α were changed by NSAIDs and MPAs, therefore, the cytokines were considered to be involved in MUC2 expression changes in enterocytes. In conclusion, the intestinal stem cells maintained by developed culture method was shown to be capable of differentiation into the intestinal cells having pharmacokinetic functions. In addition, by using MUC2 as an indicator, it is possible to evaluate the mucosal damage and protective effect of drugs, which may contribute to pharmacological efficacy and safety of novel drug development research.

P2532/B790

Isolation of Clonal Genome Edited Dual-fluorescent Reporter Human Stem Cell Populations Without Single Cell Cloning.

J. R. Stinson, M. Halter, A. L. Plant; National Institute of Standards and Technology, Gaithersburg, MD.

The ability to translate human stem cell research results into therapeutic products is burdened by several factors including uncertainty about the influence of stem cell culture reagents, protocols and procedures. Results from stem cell laboratory investigations tend to be difficult to evaluate and compare to results from other labs, and clear correlations between culture conditions and cell state and fate are difficult to discern. In an effort to better track the correlations between culture conditions and stem cell response, we have initiated a program to improve our basic understanding of induced pluripotent stem cell (iPSC) growth and to build predictive models by defining the critical measurable parameters that regulate the maintenance of iPSC pluripotency and differentiation. This effort is dependent on the creation of well-characterized dual-fluorescent reporter stem cell lines that accurately report the transcriptional expression patterns of three transcription factors (TF) known to be regulate pluripotency and transitional cell states during differentiation in human stem cells, OCT4, SOX2, and NANOG. A challenge to this effort is the poor survival of stem cells passaged at low seeding density, which makes the generation of clonal cultures from single cells highly problematic. Our work flow was designed to address this problem. WTC-11 cells were transfected in the presence of TF-specific gRNA-cas9 ribonuclear protein (RNP) complex and “donor” plasmids with homology arms to drive gene specific recombination. The “donor” plasmids are designed to replace the stop codon with a translational read-through signal (P2A) and a nuclear localization signal-sequence (NLS) upstream of a fluorescent protein (GFP or m-Cherry) encoding sequence. Thus, the expression of the fluorescent reporter is regulated by the endogenous control elements and the normal expression of the TF is unaffected. After testing fourteen transfection conditions, we chose a protocol that provide us with ~.01% efficiency of insertion of fluorescent protein. This relatively low efficiency is convenient for our next steps. We distribute post-transfection cells into 96 well plates together with untransfected helper cells to bring the final concentration of cells to ~12,000 cells/ cm^2. Starting three days post-transfection, entire wells are imaged with bright field and fluorescence optics using a very low level of excitation light. Genome editing events are clearly identifiable as clusters of small numbers of fluorescent cells and wells containing single events are noted for further expansion. Using this approach, we have generated clonal dual-fluorescent reporter stem cells without the necessity of single cell cloning.

P2533/B791

Role of Small Molecules in Generation of Cord Blood-Derived Pluripotent Stem Cells.

I. JASRA, P. Wismayer; University of Malta, Msida, MALTA.

In 2006 Takahashi and Yamanaka developed a ground-breaking technology in the field of nuclear reprogramming which doesn't rely on fusion or enucleation of ES cells. They found that differentiated somatic cells can be reprogrammed to a pluripotent state by a set of defined transcription factors (also called Yamanaka Factors). Forced expression of Oct-4, KLF, Sox-2 and c-myc (OKSM) would reprogram somatic cells into pluripotent like stem cells. The resulting cells are named as induced pluripotent stem cells (iPSCs). The term pluripotency means the cells capable of differentiate into all types of cells lineages. Technical and ethical issues hindered the medical use of somatic cell nuclear transfer and embryonic stem cells. Therefore, induced pluripotent stem cells emerged as a powerful technique with great potential for clinical applications. iPSCs were generated by forced expression of Transcription Factor (TFs)Oct4, KLF4, SOX2, and Myc-c from skin fibroblasts. Recently, iPSC has been generated more rapidly and efficiently and the only hurdle which comes across is the rate of conversion of these cells is very slow. In this study, we have initroduced an easy way to reprogram cord blood stem cells using combination of small-molecules in a feeder-free system. Small Molecules carries a unique property which directly or indirectly helps in maintaining pluripotency of stem cells. The development of the integration-free method in a feeder-free system offers a great potential in clinics, drug testing and other applications.

Membrane Tension Regulates Fgf Driven Fate Choice in Embryonic Stem Cells.

H. De Belly[1], P. H. Jones[2], K. J. Chalut[3], E. K. Paluch[4,1]; [1]MRC Laboratory for Molecular Cell Biology, University College London, Gower Street, London, WC1E 6BT, UK., London, UNITED KINGDOM, [2]Department of Physics & Astronomy, University College London, Gower Street, London WC1E 6BT, London, UNITED KINGDOM, [3]Wellcome Trust/Medical Research Council Cambridge Stem Cell Research Institute, Tennis Court Road, University of Cambridge, Cambridge, CB2 1QR, UK., Cambridge, UNITED KINGDOM, [4]Department of Physiology, Development and Neuroscience, Downing Street, University of Cambridge, Cambridge, CB2 3DY, UK., Cambridge, UNITED KINGDOM.

Changes in cell shape and mechanics frequently accompany cell fate transitions. Yet how mechanics affects the regulatory pathways controlling cell fate is poorly understood. To probe the interplay between shape, mechanics and fate, we used embryonic stem (ES) cells, which spread as they undergo early differentiation. We found that this spreading is regulated by a decrease in plasma membrane tension, and preventing this decrease obstructs early differentiation of ES cells. Moreover, we found that if cell membrane tension is not decreased, endocytosis of FGF signaling components, which direct the exit from the ES cell state, is significantly inhibited. Strikingly, the early differentiation defects we observed can be rescued by increasing Rab5a-facilitated endocytosis. Thus, we show that a mechanically-triggered increase in endocytosis regulates fate transitions. Our findings are of fundamental importance for understanding how cell mechanics regulates biochemical signaling, and therefore cell fate.

Recreating a Novel 3D Cellular Microenvironment of Human Joint Tissue to Understand the Mechanism of Cellular Senescence in Aged Stem Cells.
J. Y. Choi, J. P. Fisher; University of Maryland, College Park, MD.

Physiological aging in human is linked to cellular aging which is associated with oxidative stress, genetic instability, telomere shortening, mitochondrial dysfunction, and DNA mutation in some genes that result in premature aging. Age-related changes due to cellular aging in joint lead to degenerative bone disease such as osteoarthritis (OA). Although past studies noted that accumulation of senescent cells in cartilage causes early onset of OA in response to injury or aging, less is known about the interaction of senescent cells with neighboring cells within the local and distant tissues that forms articular cartilage and synovial joint. Here, the study investigates how high level of cellular senescence negatively influence the differentiation commitment of local stem cells for terminal differentiation into chondrogenic/ osteogenic lineages, and develop ineffective communication between different cell types within 3D reconstructed joint tissue. To understand the cellular interactions between senescent cells and neighboring non-senescent cells in human joint tissue, we designed the system to co-culture gradient of 4 different cell types that are encapsulated in hydrogel scaffold, and cultured in the bioreactor. This study uses cell lines derived from induced pluripotent stem cells (iPSCs) to generate gradient of cell layers with consistent genetic background. Cylindrical form of collagen scaffold is cross-linked to compose 3 major layers embedding senescent and non-senescent iPSC-osteoblasts/ osteocytes, iPSC-chondrocytes, and synoviocytes. This cell-embedded scaffold is cultured in tri-chamber bioreactor with osteogenic, chondrogenic, and synovial cell culture media, respectively. The design allows the nutrient flow for corresponding layer section, and gradual fusion of different cell layers through collagen construct. This novel method of co-culturing three cell lines allows to recapitulate cellular microenvironment of human joint, and to further study the role of senescent cells in altering joint tissue microenvironment, which later progresses to OA.

Cell Fate Determination 2

Overexpression of ROR2 in WNT1 Producing Cells Augments Signaling.
W. A. Orellana, L. M. Galli, F. R. Santana, L. Moroney, R. Cisneros, L. W. Burrus; San Francisco State University, San Francisco, CA.

Morphogens, such as Wnts, are signaling molecules that play a vital role in the early stages of development. Their graded distribution pattern promotes the specification and differentiation of multiple cell types. While the effects on cell specification and differentiation are evident, the Wnt gradient has yet to be directly visualized. Adding to the ambiguity of how the Wnt gradient is formed is that all vertebrate Wnts are post-translationally modified with a palmitoleate group, thus rendering them hydrophobic. As such, it is unlikely that the Wnt gradient is established simply through the diffusion of hydrophobic Wnts in the aqueous extracellular space. We have found that (1) cell-to-cell contact is necessary for WNT1 signaling, (2) that the co-expression of WNT1 with its intracellular transporter, Wntless (WLS), induces the formation of cellular projections, and (3) that WNT1 is localized within these projections. Furthermore, we have seen that the projections containing WNT1 are actin and not tubulin-based projections suggesting that these projections are filopodia. To test if filopodia are needed for Wnt signal transport we leveraged the ability of Myosin 10 to induce new filopodia and

found that Wnt signaling increased when we co-expressed Myosin 10, WNT1, and WLS in a co-culture assay. Similar to Myosin 10, other reports have shown that ROR2, a tyrosine kinase Wnt receptor, also induces filopodia growth when co-expressed with WNT8A, and was localized to WNT8A positive filopodia, thus suggesting that ROR2 may have a role in both Wnt producing and Wnt responding cells. Taken together, I hypothesize that overexpression of ROR2 in WNT1 producing cells will promote WNT1 signaling by enhancing the production of filopodia. To test this hypothesis, I first investigated the endogenous expression levels of ROR1 and ROR2 in HEK293T cells using RTPCR. Results show that HEK293T cells express endogenous ROR1 and ROR2. I then utilized a co-culture assay in which WNT1-producing HEK293T cells, transfected with WLS, were mixed with Wnt-responding HEK293T cells, which were transfected with a SuperTopFlash Wnt reporter. In order to test the role of ROR2 in Wnt-reception and Wnt-production, cells were transfected +/- ROR2. Though ROR2 is not typically linked to β-catenin dependent signaling, our results show that the overexpression of ROR2 in Wnt responding cells increase signaling. Furthermore, we show that ROR2 augments WNT1 signaling when present in WNT1 producing cells. These results are novel in that ROR2 not only plays a role in WNT1 reception, but also in WNT1 production. If our hypothesis is valid, we would expect that the ROR2 expressing HEK293T cells would be making more filopodia. We are currently testing this prediction.

MicroRNA Regulation of Mesodermal Cell Fate in Early Development.

K. Konrad, S. Suarez, J. Song; University of Delaware, Newark, DE.

MicroRNAs are short non-coding RNAs that fine-tune gene expression by pairing to the 3' untranslated region (3'UTR) of protein coding mRNAs to repress translation. These non-coding RNAs are vital for regulating early developmental processes. MicroRNA-124 (miR-124) is an evolutionarily conserved small RNA that has been examined in the context of neural specification; however, this research defines the novel role of miR-124 in the specification and development of two different mesodermally-derived immune cells: pigment and blastocoelar cells. Early in development, these two groups of immune cells share the same progenitor cell type and later must make a binary fate decision to differentiation. In the sea urchin, Nodal signaling activates genes expressed in blastocoelar cells and inhibits key transcription factors in pigment cell specification at about 10h into development. Two hours later, the Delta/Notch signaling pathway activates genes expressed in both blastoceolar and pigment cells. To examine the function of miR-124 in the early embryo, we microinjected the miR-124 inhibitor into newly fertilized sea urchin eggs. Results indicate that miR-124 inhibition caused ectopic misexpression of *Ese, GataC and Scl* which are transcription factors that controls the specification of blastocoelar cells. miR-124 knockdown (KD) led to increased number of blastcoelar cells at the expense of pigment cells. Based on our results, I hypothesize that miR-124 regulates both blastocoelar and pigment cell development by suppression of Nodal and Notch signaling pathways. We bioinformatically identified potential miR-124 binding sites within the 3'UTR of *Notch*, *Nodal* and their downstream targets *Gcm* and *Ese* in the pigment and blastoceolar cells, respectively. To test the direct regulation of miR-124 of *Notch*, we cloned the *Notch* 3'UTR downstream of *Renilla* luciferase reporter construct and identified one functional miR-124 regulatory site. The impact of miR-124's suppression of *Notch* was tested with miR-124 target protector (miR-124 *Notch* TP), which competitively blocked the miR-124 regulatory site within the *Notch* 3'UTR. Surprisingly, *Notch* TP resulted in increased expression of *GataC and Scl* of the blastocoelar cells, as well as increased expression of *Gcm and Pks* of the pigment cells. Interestingly, this increase of *Gcm* expression domain correlated with a doubling of differentiated pigment cells in the

larvae. Results from this study will identify the regulatory mechanism of miR-124 in mesodermal cell fate determination.

Unraveling the Gene Regulatory Network of Early Lineage Commitment and Context-Dependent TGF-beta Response.

J. Valcourt[1], **R. E. Huang**[1], S. Kundu[2], R. E. Kingston[3], S. Ramanathan[1]; [1]Harvard University, Cambridge, MA, [2]Intellia Therapeutics, Cambridge, MA, [3]Massachusetts General Hospital, Boston, MA.

During mammalian development, progenitor cells differentiate and commit to ever-more-specific lineages. The cell's response to signaling molecules changes with commitment: selecting a given lineage entails reinterpreting signals that would have previously promoted an alternative lineage. This process of committing to a lineage by changing response to signaling molecules is of critical importance for proper development, but the dynamics and mechanism that govern the process are unclear. We investigate the binary response of human embryonic stem cells to BMP and Activin a during differentiation toward the bipotent ectoderm lineage by discovering a two-gene reaction coordinate that allows us to monitor the dynamics of differentiation and lineage commitment in real time. We show that knowledge of the expression levels of OCT4:RFP and SOX2:YFP in a double-tagged reporter line is sufficient to predict the cell's commitment to bipotent ectoderm and therefore its loss of mesendoderm-competent response to TGF-beta signals; in contrast, classical neural/ectodermal marker genes activate too late to be useful for this purpose. We predict candidate genes of the commitment gene regulatory network (GRN) using detailed RNA-seq and ATAC-seq analysis of cells that are pre- and post-commitment to bipotent ectoderm. We are able to extend or shorten the window of mesendoderm competency by overexpression of the putative GRN components, thereby validating their role in the network. This study elucidates the GRN governing commitment and provides high-time-resolution details of the commitment process.

Erk Signaling Dynamics Is Coordinated with Mitosis to Direct Epiblast and Primitive Endoderm Specification in Mammalian Blastocysts.

M. Pokrass, 21205; Johns Hopkins University School of Medicine, Baltimore, MD.

During preimplantation development, mammalian embryos rely on constant crosstalk between signaling networks and gene expression to robustly specify the trophectoderm, epiblast (EPI), and primitive endoderm (PRE) lineages in the absence of maternal patterning cues. The latter two lineages emerge from a core of cells known as the inner cell mass (ICM) in a process dependent on ERK signaling downstream of fibroblast growth factor receptors (FGFRs). Higher levels of FGFR signaling promote PRE specification while inhibition of FGFRs or ERK promote EPI commitment. How these signaling differences arise during in vivo development remains unclear because it was previously impossible to study ERK activity in live embryos. To address this, we generated a mouse model that utilizes kinase translocation reporter (KTR) technology to monitor ERK activity in real time in live embryos cultured ex vivo. Single cell analysis of ERK KTR embryos revealed that all ICM cells exhibit prolonged periods of high ERK activity; however, a subset of ICM cells exhibit transient periods of ERK inactivity immediately following mitosis. Sister cell pairs adopt this low ERK activity status independent of their position within the ICM. Importantly, cells that exhibit low ERK activity ultimately express higher levels of NANOG, an EPI specific

marker, compared to cells that adopt high ERK activity. These data provide evidence for coordination of ERK activity with cell cycle progression in the ICM to direct EPI and PRE differentiation in developing blastocysts.

Visualizing the Proliferation/differentiation Decision Using a CDK Activity Sensor during Metazoan Development.

A. Q. Kohrman[1], R. C. Adikes[1], J. J. Smith[1], A. S. Aydin[1], S. J. Collins[1], O. Ahmed[1], N. J. Palmisano[1], C. Tian[2], M. A. Martinez[1], T. Medwig-Kinney[1], S. Tank[1], S. Liu[3], W. Zhang[1], R. A. Morabito[1], N. Kim[1], E. Feiner[4], N. Weeks[1], G. H. Thomsen[1], T. Miller[1], L. A. Davison[5], S. L. Spencer[2], B. L. Martin[1], D. Q. Matus[1]; [1]Stony Brook University, Stony Brook Univesity, NY, [2]University of Colorado, Boulder, Boulder, CO, [3]University of California, Santa Cruz, Santa Cruz, CA, [4]Princeton Univesity, Princeton, NJ, [5]University of Pittsburgh, Pittsburgh, PA.

During organismal development, differential regulation of the cell cycle is critical to many cell biological processes, including cell fate specification and differentiation. While the mechanisms of the cell cycle are well studied, how the control of cell cycle is linked to differentiated cell behavior remains poorly understood. To truly understand this interplay, we must be able to directly and precisely measure cell cycle state. In order to characterize cell cycle state in living animals, we adapted a CDK2 biosensor for in *vivo* use. We generated transgenic strains in the nematode, *C. elegans*, and zebrafish, *D. rerio*, and performed transient RNA injections in the frog, *X. laevis*. The biosensor reports Cyclin-Dependent Kinase (**CDK**) activity as the cytoplasmic/nuclear localization ratio of a GFP-tagged human CDK2 substrate, DNA Helicase B (**DHB**). Phosphorylation of the sensor by CDKs causes its translocation from the nucleus to the cytoplasm. We have modified this sensor to allow for automated assessment of cell cycle state using a U-Net based automated image segmentation approach. Unlike other live cell cycle imaging tools (e.g., FUCCI), DHB can be used to distinguish actively cycling cells in the G1 phase of the cell cycle versus quiescent or terminally differentiated cells in G0. We have used this biosensor to quantify lineage specific differences between cycling cells, and to examine the link between quiescence and differentiation. We examine the interplay between proliferation, differentiation, and morphogenesis across multiple metazoan species and provide new biological insights into the control and timing of the metazoan cell cycle during specification and differentiation.

P2541/B799

An Increase in the Duration of an Extended G1 Period Enables Stochastic Competition between Terminal Cell Differentiation and Cell-cycle Re-entry.

M. L. Zhao, A. Rabiee, K. M. Kovary, B. Taylor, Z. Bahrami-Nejad, **M. N. Teruel**; Stanford University, Stanford, CA.

Terminal cell differentiation is essential for developing and maintaining tissues in all multi-cellular organisms and typically requires that proliferating progenitor cells exit the cell cycle. However, the relationship and timing between the underlying opposing processes, proliferation and terminal differentiation, is not yet understood. Using adipogenesis as a model system for terminal cell differentiation, we delineate the timing between cell-cycle exit and terminal differentiation by live-cell imaging of cell-cycle reporters and expression of PPARG, a master regulator of differentiation. We show that, during terminal cell differentiation, the levels of PPARG and of the CDK inhibitor p21 are coupled,

and both gradually increase after mitosis. Expression of p21 regulates the duration of a variable extended G1 phase that allows some cells sufficient time to reach a PPARG threshold for differentiation instead of entering the next cell cycle when PPARG is again suppressed. By way of regulating the duration of an extended G1 phase during terminal differentiation, progenitor cells can stochastically control the number of final cell divisions and thus, the total number of differentiated cells.

Mating Yeast Cells Use an Intrinsic Polarity Site to Assemble a Pheromone-gradient Tracking Machine.

X. Wang, W. Tian, B. T. Banh, B. Statler, J. Liang, D. E. Stone; University of Illinois at Chicago, Chicago, IL.

The mating of budding yeast depends on chemotropism, a fundamental cellular process. The two yeast mating types secrete a peptide pheromone that binds to GPCRs on cells of the opposite type. Cells find and contact a partner by determining the direction of the pheromone source and polarizing their growth toward it. Actin-directed secretion to the chemotropic growth site (CS) generates a mating projection. When pheromone-stimulated cells are unable to sense a gradient, they form mating projections where they would have budded in the next cell cycle, at a position called the default polarity site (DS). Numerous models have been proposed to explain yeast gradient sensing, but none address how cells reliably switch from the intrinsically determined DS to the gradient-aligned CS, despite a weak spatial signal. Here we demonstrate that, in mating cells, the initially uniform receptor and G protein first polarize to the DS, then redistribute along the plasma membrane until they reach the CS. Our data indicate that signaling, polarity, and trafficking proteins localize to the DS during assembly of what we call the gradient tracking machine (GTM). Differential activation of the receptor triggers feedback mechanisms that bias exocytosis upgradient and endocytosis downgradient, thus enabling redistribution of the GTM toward the pheromone source. The GTM stabilizes when the receptor peak centers at the CS and the endocytic machinery surrounds it. A computational model simulates GTM tracking and stabilization, and correctly predicts that its assembly at a single site contributes to mating fidelity.

Elucidating the Role of Tpc2 in *Dictyostelium* Cell Proliferation and Development.

M. RATHORE, S. SARAN; JAWAHARLAL NEHRU UNIVERSITY, NEW DELHI, INDIA.

Dictyostelium discoideum is a preferable multicellular model system for the study of various cellular and molecular mechanism. Starvation induced multicellular development is achieved by cells aggregation and culmination to form a fruiting body having two terminally differentiated cell types: prestalk and prespore cells. During differentiation prestalk cells undergoes autophagy leading to autophagic cell death (ACD). Calcium plays an important role in the process of cell differentiation and high ca^{2+} load shows biasness towards prestalk pathway that involve autophagic cell death in *Dictyostelium discoideum*, Therefore we selected Two-pore calcium channel 2 (TPC2) for our studies to analyze its role in cell proliferation, development and autophagy in *Dictyostelium*. Two pore channels (TPCs) are the members of voltage-gated ion channel superfamily consisting of two subunits of six transmembrane domains that are ubiquitously present in organelles of animals and plants. Two strains of TPC2 [overexpressor ($TPC2^{OE}$) and knockout ($TPC2^{KO}$)] were created. Role of TPC2 in growth, development and cell death was analyzed. Involvement of TPC2 in autophagy fluxes was measured by co-expression of TPC2 mutant strains with RFP-GFP-ATG8 (autophagy marker) and with GFP-Tkt1 (cytosolic marker). Here we report the *spatio-temporal* mRNA expression patterns of TPC2 in *Dictyostelium*. We observed that

the mRNA transcript of TPC2 was present throughout the growth and developmental stages of Dictyostelium with highest expression during later stages of development i.e. slug and culminant. We also observed that the absence of TPC2, increases the cell proliferation rates and delays development of the *Dictyostelium*. Our results showed that TPC2 is a calcium channel which is involved in growth, development and has a significant role in autophagy.

P2544/B802

Cilia and Centrioles Are Extruded during Multiciliated Cell Transdifferentiation in Xenopus Embryonic Skin.

R. Ventrella, B. J. Mitchell; Northwestern University, Chicago, IL.

While there have been significant advances in how a cell commits to a certain cell fate, the mechanisms that govern cell fate malleability after this occurs remains relatively unknown. Transdifferentiation is a process whereby a differentiated cell can directly transform into another differentiated cell type without regressing through a proliferative, stem cell-like state. It has been proposed that multiciliated cells (MCCs) are capable of undergoing transdifferentiation. The skin of Xenopus embryos contains numerous MCCs that work to create a directed fluid flow over the epithelial surface. To generate this flow these cells become extremely specialized, containing approximately 150 evenly spaced motile cilia each anchored to a basal body and connected via an extensive cytoskeletal network. Additionally, these cells have massive numbers of mitochondria that provide the energetic requirements to fuel cilia motility. The extreme specializations of these cells provide a unique opportunity to understand the steps required to undergo transdifferentiation. We have found that as embryos continue to mature the cilia-induced flow decreases until it ultimately disappears. Interestingly, during this window of development, by utilizing biochemical approaches and long-term live cell imaging with a light sheet microscope, we have observed cilia cleavage and extrusion of centrioles from the surface of MCCs as they begin the process of transdifferentiation, each representing a distinct step. We found that cilia are first cleaved off of the surface of MCCs. Then, basal bodies are collected and removed from cells in a dynamic and rapid manner where cells pinch off and extrude a large basal body-filled vesicle. We hypothesize that the elimination of these structures is a prerequisite to continue transdifferentiation. Moreover, the treatment of Xenopus embryos with a gamma-secretase inhibitor can delay this transdifferentiation process suggesting that Notch signaling likely plays a role in cell malleability. By combining our live imaging approaches with MCC lineage tracing studies we will be able to better understand additional signaling pathways that govern transdifferentiation. Ultimately, this will be useful to identify the steps required for a cell to undergo transdifferentiation and alter its cellular identity.

Genetic Fate Mapping Reveals Heptatoblast Potential and Lineage Relationships between Endoderm-derived Organs in the Mouse.

S. Peguero, G. El Sabae, T. Guertin, J. Mager, K. Tremblay; University of Massachusetts Amherst, Amherst, MA.

The Definitive Endoderm (DE) is the embryonic germ layer that will produce the bulk of the gastro-intestinal tract as well as the associated organs including liver, lungs and pancreas. The focus of our laboratory is to understand how the DE initiates liver formation. Hepatoblast are the first liver cell type produced by the embryo and this population will produce the two mature liver cell types: hepatocytes,

the cells that produce bile, and cholangiocytes, the cells that form the bile ducts. We recently used a genetic inducible fate mapping (GIFM) system to demonstrate that single hepatoblasts were multi-potent, producing hepatocytes and cholangiocytes. An intriguing observation was that a percentage of the hepatoblasts also appeared to produce endothelial cells, the cells that form the vasculature and are typically believed to derive from the mesoderm, a separate germ layer. To learn more about how hepatoblasts furnish the liver, we used a similar GIFM as used previously and labeled cells with a Cre-inducible reporter (Rosa26LacZ) paired with a DE-expressing Cre-ER transgene (FoxA2CreER). We identified that a low dose of tamoxifen that result in infrequently labeled descendants that can be detected using X-Gal. We used immunohistochemistry with the endothelial marker, ERG1, to identify the presence of labeled endothelial cells in all 5 livers that contained LacZ positive cells at E12.5. We propose to use the GIFM strategy to determine when hepatoblasts have this potency by examining embryos at earlier time-points starting with E10.5. Together these results will provide further evidence for the provocative hypothesis that DE cells can produce cell-types previously believed to be formed by the mesoderm and may help to explain the remarkable regenerative capacity that is unique to the liver.

P2546/B804

Transcriptomic an alysis of the Compensatory Response to Notch Signaling Perturbation during Embryonic Development.

G. Solini[1], M. Pownall[2], A. Halleran[3], R. Cutler[4], M. Saha[1]; [1]College of William and Mary, Williamsburg, VA, [2]Yale University, New Haven, CT, [3]California Institute of Technology, Pasadena, CA, [4]University of Texas at San an tonio, San an tonio, TX.

During early development, embryos display a remarkable degree of plasticity and resilience. They can redirect cellular movement, proliferation, and even fates of determination in order to compensate for physical, chemical, and genetic perturbations. At some point in the developmental process, however, this plasticity diminishes, and as they grow into mature organisms, embryos can no longer recover from significant damage without scarring or defects. Understanding the molecular basis of embryonic plasticity has applications in cancer therapy and regenerative medicine. Therefore, we sought to investigate how developing *Xenopus* embryos respond to and compensate for perturbations to the Notch signaling pathway; the Notch signaling pathway is a conserved juxtacrine signaling network that is responsible for directing early neurogenesis during vertebrate development, and whose dysregulation has been linked to various types of neurodegenerative diseases and cancers. Initial experiments have suggested that *Xenopus* embryos are able to elicit a remarkable response to both over- and underexpression of this critical pathway; injection of Notch mRNA constructs that either over- or underexpress the pathway results in initial perturbation to the system as assayed by in *situ hybridization* of the pan-neural marker gene *tubb2b*, but marker gene expression as well as normal stimuli responses are restored in embryos by early tailbud stages of development. In order to understand the molecular basis of this plasticity, we have begun to characterize this compensatory response by performing dosage experiments and RNA-sequencing for Notch over- and underexpression at early neurula, tailbud, and tadpole stages. RNA-Seq analysis suggests that this response includes regulation of both the Notch and Wnt signaling pathways as well as changes in cell proliferation, apoptosis, and calcium activity. Further, it also suggests that while embryos appear anatomically healthy by tailbud stages, at the gene expression level, the compensatory response lasts well into tadpole stages. Additionally, preliminary data suggests that the degree of recovery is dosage-dependent. Finally, having established that *Xenopus laevis* embryos compensate in response to perturbations in the Notch signaling pathway, we have asked

whether this response is conserved across vertebrate species. We have begun characterizing the compensatory response to Notch signaling perturbation in two closely related species, the tetraploid *Xenopus borealis* and diploid *Xenopus tropicalis*. The findings from these experiments will yield insight into both the question of how conserved the response to Notch signaling perturbation is in closely related species, as well as whether ploidy is involved in this response.

P2547/B805

Mechanical Control of Mucociliary Epithelia Regeneration on the Surface of Embryonic Aggregates.

H. Y. Kim[1,2], T. R. Jackson[2], C. Stuckenholz[2], L. A. Davidson[2]; [1]Institute for Basic Science (IBS), Daejeon, KOREA, REPUBLIC OF, [2]University of Pittsburgh, Pittsburgh, PA.

Mucociliary epithelia line organs throughout the body including lung, gut, and kidney and play a key role in maintaining the protective mucosal barrier against foreign particles. This first line of shield often disrupted through injury, surgery, and diseases and require a regeneration to restore its structure and function. Here we introduce a mucociliary epithelia organoid that rapidly recapitulate the regeneration process of epithelialization and cell specification on the surface of the embryonic aggregate. Following disruption of embryonic tissue architecture and assembly of a compact aggregate using embryonic mesenchymal cells, regeneration first proceed with restoration of an epithelium, transitioning from mesenchymal cells at the surface of the aggregate. Surface cells selectively establish apico-basal polarity within 5 hours and differentiate into mucus-secreting goblet cells that complete with muticiliated cells within 24 hours. Regeneration coincides with nuclear translocation of the putative mechanotransducer YAP1 and a sharp increase in aggregate stiffness. Acute and chronic alterations of tissue stiffness reveal that tissue mechanics drives the regeneration of a mucociliary epithelia on the surface of mesenchymal aggregates.

Mutations in Vacuolar-type H+-atpase (v-atpase) Cause Necrosis-like Cell Death of Mechanosensory Hair Cells.

P. Santra, A. N. Whellan, J. D. Amack; SUNY Upstate Medical University, Syracuse, NY.

The vacuolar type H^+-ATPase (V-ATPase) is a membrane-bound, multi-subunit complex that pumps protons from cytoplasm into organelle lumens or into extracellular space. V-ATPase activity is important for regulating pH of cellular compartments, and hence has been implicated in multiple cellular processes. Previous genetic analyses indicate V-ATPase has vital functions during embryonic development. However, mechanisms by which V-ATPase impacts cellular behaviors during development remain poorly understood. Here, we show mutations in two core V-ATPase subunits—*atp6v1f* and *atp6v1h* that are required for V-ATPase function—disrupt neuromasts in the lateral line of the zebrafish embryo. Neuromasts are mechanosensitive organs that are used by aquatic vertebrates to detect vibrations. Neuromasts consist of a cluster of non-sensory support cells surrounding centrally located sensory hair cells that are functionally identical to mammalian inner ear hair cells. Interestingly, V-ATPase mutations have been identified in patients with sensorineural deafness, but underlying mechanisms are unclear. In *atp6v1f*$^{-/-}$ and *atp6v1h*$^{-/-}$ mutant zebrafish embryos, we observed smaller and misshapen neuromasts. These neuromasts had a reduced number of sensory hair cells, but support cell numbers were normal. V-ATPase mutant neuromasts also showed the presence of pyknotic nuclei that increased over time. Using molecular markers, we found that loss of V-ATPase specifically reduces the

survival of hair cells, but not support cells. Previous work in cell cultures and zebrafish embryos indicates loss of V-ATPase function can induce Caspase 3-dependent apoptotic cell death in specific cell types. Surprisingly, we found that V-ATPase loss of function induced Caspase 3-independent death in hair cells undergoing functional maturation. In addition, Caspase 8 levels were similar in mutant and wild-type hair cells, which is consistent with a non-apoptotic mechanism. Confocal imaging of living embryos indicated mutant hair cells undergo a necrosis-like mode of cell death: mutant hair cells were found to swell and then rupture, rather than form apoptotic blebs characteristic of apoptotic cell death. These findings reveal a new function for V-ATPase in hair cell survival, where loss of V-ATPase induces a Caspase-independent and necrosis-like cell death pathway. This may have implications in furthering our understanding of the causes of sensorineural deafness.

P2549/B807

Evolution of an imal Cell Fate Determination.

D. S. Booth; University of California, Berkeley, CA.

The origin of animal multicellularity coincided with the evolution of mechanisms for determining the identities and fates of different cell types. Remarkably, the closest living relatives of animals, the choanoflagellates, uniquely share with animals regulatory genes that influence cell fate in animal development. Here, we use ATAC-seq and RNA-seq to profile gene regulatory changes between four different life history stages in the model choanoflagellate *S. rosetta*. In these data, we identify RNA-binding proteins with a universal role for germ cell determination in animals that may regulate gametogenesis and the transition from a benthic to pelagic lifestyle. These results will help illuminate the evolution of cell fate determination pathways, especially a potential core regulatory program that gave rise to the animal germ line.

P2550/B808

Cell Fusion Induces a Structural-to-transcriptional Differentiation Switch through Membrane Remodeling, Transient Energy Deprivation and Yap1 Cytoplasmic Retention.

D. Feliciano[1,2], I. Espinosa-Medina[2], C. Ott[2], A. Weigel[2], T. Lee[2], J. Lippincott-Schwartz[2]; [1]Thoracic & GI Malignacies Branch, National Cancer Institute, NIH, Bethesda, MD, [2]Howard Hughes Medical Institute, Janelia Research Campus, Ashburn, VA.

Developmentally-regulated cell fusion generates highly differentiated skeletal muscle, bone and placental cells, but whether the act of fusion contributes to differentiation, independent from tissue-specific cues, is unclear. To address this, we employed a viral-protein mediated cell fusion model involving undifferentiated cells in tissue culture. RNA-sequence analysis revealed that cell-cycle arrest after fusion was accompanied by a dramatic shift from proliferation-associated to differentiation-causing transcripts. This shift coincided with nuclear depletion of the proliferation-promoting factor YAP1 triggered by enhanced endocytosis of glucose transporters, and transient decrease of cytoplasmic glucose and ATP levels. This low energy state stimulated AMPK activation promoting YAP1 inhibition. Impairing either endocytosis or AMPK prevented nuclear depletion of YAP1 and cell-cycle arrest after cell fusion. Together, these data show that structural changes and their effect on cell-bioenergetics can induce a cell differentiated-like state in response to cell fusion. This occurs in the absence of tissue-specific signaling molecules.

Germ Cells, Gametogenesis, and Fertilization

Ras Inhibition of Contractile Ring Function in *Drosophila* Primordial Germ Cells.

M. Saiduddin, J. Pae, R. Lehmann; New York University, New York, NY.

While Ras has been studied extensively for its role in cancer and tumorigenesis, there is still much unknown about how its activity is toggled and modulated during normal development and morphogenesis. We can use the formation of primordial germ cells (PGCs) as a model system for understanding transcription-independent regulation of cellular morphogenesis through Ras. PGCs are the first cells to form in the syncytial Drosophila embryo, separated from the rest of the embryo by a spindle-independent cleavage that constricts pole buds. This process requires a ubiquitin ligase adaptor Germ-cell-less (GCL), which has been shown to degrade Torso (Tor), a receptor tyrosine kinase. Tor activates Ras signaling, and without suppression of this activation, PGCs will not form. Later in embryogenesis, Ras is known to initiate the Raf/MEK/MAPK signaling cascade, leading to the transcriptional upregulation of somatic terminal genes. However, at the time of PGC formation, the embryo still has not activated zygotic transcription, and relies entirely on the maternal contribution of RNAs and proteins. Therefore, Ras acts in a transcription-independent way to antagonize the formation of PGCs. Our data suggest that Ras is activating RalA, an effector of somatic cellularization, thus inhibiting pole bud constriction from occurring.

P2552/B810

A Demographic Model to Estimate the Cell Division Rates of Stem Cells and Transit-amplifying Cells.

P. Gadre, S. Chatterjee, B. Varshney, D. Mazumdar, C. Joshi, S. Gupta, N. Nitsure, K. Ray; Tata Institute of Fundamental Research, Mumbai, INDIA.

Regulation of adult stem cell division and differentiation is critical for maintenance of tissue. In many tissues, the stem cell progenitors proliferate for several rounds, termed as transit amplification (TA) divisions, prior to terminal differentiation. Stem cells are described as slow-cycling cells which retain their mitotic potential for a long duration, whereas their transit-amplifying daughters proliferate relatively rapidly and have limited mitotic potential. We used *Drosophila* spermatogenesis as a model system to study the regulation of stem cell and TA cell mitosis. We describe a demographic model which uses the theory of probability to predict the lifetimes of the germline stem cells and TA stages at steady-state in the adult testis using fixed-tissue data. Numerical analysis of the data derived from cyst distribution, mitotic indices and the germ-cell death counts along with the time-lapse imaging of the germline stem cell (GSC) division in wild-type background suggested that halfway into the germline TA, the cell division periods are reduced by about 2-folds. We verified the model by knockdown of known cell cycle regulators such as CycE and CDK1 and observed an expected slowdown of the GSC and TA divisions. Upon overexpression of String, we noted a speed-up of the early germline divisions, as expected. Using the same model, we then investigated the role of somatic EGFR signaling in the regulation of GSC and TA cell division rates. Previous reports suggested that high levels of somatic EGFR signaling could induce premature germ cell differentiation. We found that localized gain of somatic EGFR signaling by Spitz (EGF ligand) overexpression or knockdown of a feedback molecule Argos led to a slowdown of the GSC and TA divisions, suggesting a dose-dependence between the somatic EGFR signaling and the rates of germline divisions. Together, these results established the efficacy of our

demographic model in estimating the role of different intrinsic and extrinsic components in the regulation of GSC and TA divisions.

Adipocyte Nutrient Sensing Controls the Ovarian Germline Stem Cell Lineage in *Drosophila Melanogaster*.

S. Sahu, T. Bradshaw, **A. R. Armstrong**; University of South Carolina, Columbia, SC.

External factors, particularly nutritional status, can positively or negatively impact reproduction by affecting gamete production. The stem cell-supported ovary in *Drosophila melanogaster* sustains robust reproductive capacity of adult females. Female flies fed a protein-poor diet lay significantly fewer eggs than those fed a protein-rich diet. This response to diet is mediated by the activity of nutrient-sensing pathways within the ovary, which control germline stem cells (GSCs) and their progeny. It is well-established that target of rapamycin (TOR)-mediated and insulin/insulin-like growth factor signaling within the ovary control GSC maintenance and proliferation, germline survival, vitellogenesis and ovulation. Our previous studies revealed that inter-organ communication serves as an added level of control in modulating the ovarian response to changes in diet. More specifically, distinct nutrient sensing pathways function within adipocytes, the major cellular component of *Drosophila* fat tissue, to remotely control cellular activity in the ovary. We find that insulin signaling within adipocytes influences GSC maintenance as well as germ cell survival using distinct downstream signaling effectors. We have also shown that amino acid sensing by adipocytes controls GSC maintenance and ovulation of mature oocytes via activity of the amino acid response pathway and TOR, respectively. Currently, we are using genetic and cell biological tools to determine how remote nutrient sensing modulates oocyte development by 1) deciphering the complex molecular mechanisms of insulin signaling within adipocytes and 2) assessing the contribution of the two downstream effects of adipocyte amino acid response pathway activity. Ultimately, our goal is to identify adipocyte factors downstream of insulin signaling and amino acid response pathway activation that modulate GSCs and other cell types in the *Drosophila* ovary. This work will illuminate how cell-cell communication between organs regulates the germline to match an organism's nutritional status to an investment in egg production.

P2554/B812

Levels of the Adaptor Protein, Dreadlocks, Must Be Precisely Regulated during Development of the *Drosophila* Egg Chamber.

K. M. Stark, O. Crowe, L. Lewellyn; Butler University, Indianapolis, IN.

Intercellular communication is critical for the function of any multicellular organism; many medical conditions can be attributed to errors in cellular connections such as heart disease, neurological disorders, and infertility. Cellular communication is especially important during gamete formation, as it often relies on intercellular bridges to connect developing germ cells to each other or to supporting cells. An excellent system to study intercellular bridges is the germline of the developing *Drosophila* egg. Mature eggs are derived from multicellular structures called egg chambers; each egg chamber contains a germ cell cluster (one oocyte and fifteen nurse cells), which is surrounded by a layer of somatic cells. The germ cells are connected to each other through intercellular bridges, called ring canals, which form following incomplete cytokinesis and expand 20-fold in diameter during oogenesis. The stability and regulated expansion of the ring canals are essential for fertility. We have identified a novel role for the

conserved adaptor protein, Dreadlocks (Dock), in regulating ring canal size and germ cell stability. Dock localizes to the germline ring canals, and depletion of Dock leads to a modest, yet significant, increase in ring canal diameter. Over-expression of Dock in the germline leads to dramatic defects in ring canal structure, nurse cell fusion, and apoptosis. We have utilized a series of UAS-HA-Dock constructs with point mutations in each of the four domains (SH3-1, SH3-2, SH3-3, SH2, and SH3-1,2,3) in order to determine which domains are required for Dock localization and for the over-expression phenotype. Future experiments will identify the specific Dock-interacting proteins that regulate ring canal structure and membrane integrity.

P2555/B813

Examining Size Scaling Relationships in the Developing *Drosophila* Egg Chamber.

U. R. Shaikh, J. Wilson, L. Lewellyn; Butler University, Indianapolis, IN.

Proper regulation of the size of cellular structures is essential for the normal function of cells, and a scaling relationship is often seen between cell size and the size of intracellular structures and organelles. For instance, larger cells often have larger structures or more organelles than smaller cells. Although these scaling relationships have been observed, few studies have been done to compare the scaling of cellular structures within and between species, especially in growing tissues. We are using the developing fruit fly egg chamber as a model system to study size scaling relationships throughout development. The developing egg chamber is composed of a central cluster of germ cells (fifteen nurse cells and one oocyte) that are connected to each other through intercellular bridges called ring canals; this germ cell cluster is surrounded by a layer of somatic cells. During oogenesis, the egg chamber undergoes a 20-fold increase in volume, and many of the structures must also undergo significant growth to support the formation of a viable egg. We have chosen to initially focus on the size scaling of two structures: the germline intercellular bridges, or ring canals, which connect the nurse cells to each other and to the oocyte, and the nurse cell nuclei. We have found that both nuclear size and ring canal size scale with egg chamber size across multiple *Drosophila* species. Similar analysis of a collection of *D. melanogaster* lines that have been artificially selected to produce either big eggs or small eggs suggests that this size scaling relationship is also maintained when looking within a single species. Future studies will follow up on these data and explore the mechanisms that could establish and maintain these size scaling relationships during tissue growth.

P2556/B814

Kar4 Is Required at Multiple Stages during Meiosis and Engages in a Function Specific Interaction with a Novel Meiotic Regulator, Kfc1.

Z. Park[1], A. Sporer[2], M. Remillard[2], M. Rose[1]; [1]Georgetown University, Washington D.C., DC, [2]Princeton University, Princeton, NJ.

Budding yeast can embark on several distinct differentiation pathways including mating and meiosis. Although these pathways are vastly different in induction and outcome, both require the highly conserved eukaryotic protein Kar4. Kar4's mating function involves interacting with the transcription factor Ste12 to activate the expression of genes required for nuclear fusion. Our understanding of Kar4's meiotic function is much less complete. The mammalian ortholog of Kar4, Mettl14, is a key member of the WTAP complex that catalyzes RNA methylation, but Kar4 is not required for RNA methylation in yeast. How then does it regulate meiosis? a "separation of function" mutation screen identified *KAR4*

alleles specific to either the mating or meiotic function. Surprisingly, the meiotic mutants fell into two classes revealing that Kar4 has two distinct meiotic functions. The defect associated with the first function (Mei) is suppressed by over-expression of the master meiotic transcription factor Ime1. Suppression of the second function (Spo) requires the over-expression of an additional gene, *RIM4*, encoding a translational regulator. These findings led us to hypothesize that the Mei function acts at the level of transcriptional regulation, whereas the Spo function acts at the level of translational regulation. How is Kar4 able to have three distinct functions? We hypothesized that Kar4 might have different function-specific binding partners (e.g. Ste12 during mating), which we sought to identify using immunoprecipitation coupled with mass spectrometry. We chose to focus on an uncharacterized interacting protein, Ygl036, which we have since named Kar4 Collaborator 1 (KFC1). Here, we confirm that Kar4 interacts with Kfc1 and show that the interaction is specific to Kar4's Spo function. *KFC1* is essential for meiosis and we have begun to characterize the *kfc1*Δ/Δ meiotic defect at both the cellular and molecular level.

P2557/B815

Understanding Translation Regulation during the Developmental Process of Meiosis.

E. Powers, G. Brar; UC Berkeley, Berkeley, CA.

Meiosis is the developmental program where precursor diploid cells divide into non identical haploid gametes. Meiosis is conserved from yeast to humans, and budding yeast can be induced to synchronously undergo meiosis in the lab. Our lab utilizes budding yeast to study the diverse cellular reprogramming events that allow this process to occur through both gene regulation and organelle biology. My studies have focused on trying to understand how strong and diverse changes to the yeast translatome are modulated during meiosis, and what the function of these changes may be.

P2558/B816

FBF-1 and FBF-2 Coordinatedly Regulate Germline Stem and Progenitor Cell Proliferation and Differentiation in *Caenorhabditis Elegans*.

X. Wang, M. Ellenbecker, B. Hickey, N. J. Day, E. Voronina; University of Montana, Missoula, MT.

Control of the balance of stem cell proliferation and differentiation is one of the central questions of stem cell biology relevant for our understanding of ageing, cancer and various degenerative disorders. Here, we report that FBF-1 and FBF-2, two Pumilio and FBF (PUF) family RNA-binding proteins in *C. elegans*, coordinately regulate the rate of both proliferation and differentiation of germline stem and progenitor cells (SPCs). The two FBF homologs share most of their target mRNAs (Kershner et al., 2010, Prasad et al., 2016 and Porter et al., 2018) and function redundantly in maintaining germline SPCs (Crittenden et al., 2002). Surprisingly, we found that FBFs have distinct effects on proliferation and differentiation of germline SPCs. The analysis of cell cycle dynamics of germline SPCs in different genetic backgrounds revealed that loss of *fbf-1* gene (*fbf-1(lf))* causes faster cell cycle rate of SPCs than the wild type, suggesting that FBF-1 protein causes slower SPC proliferation. By contrast, *fbf-2(lf)* causes slower progression through the G2 phase of the SPC cell cycle compared to the wild type, suggesting that FBF-2 facilitates progression through G2. Furthermore, estimating the rate of meiotic entry or differentiation in each *fbf* mutant compared to the wild type suggests that FBF-1 protein causes slower differentiation rate while FBF-2 promotes faster differentiation. Together, these data suggest that FBFs coordinatedly regulate cell proliferation and differentiation rates of germline SPCs. Quantitative PCR analysis of steady

state mRNA levels of FBF targets regulating proliferation and differentiation revealed that compared to the wild type, *fbf-1(lf)* leads to increased abundance of tested target mRNAs while *fbf-2(lf)* causes decreased abundance of the same mRNAs, suggesting that FBF-1 destabilizes target mRNAs while FBF-2 promotes accumulation of target mRNAs. We propose that the balance of FBF-1 and FBF-2 activities determines the steady-state abundance of target mRNAs and ultimately sets the rates of both cell cycle and meiotic entry in SPCs. Finally, we found that FBF-1 activity in SPCs requires CCR4-NOT deadenylase machinery and FBF-1 promotes deadenylation of its target mRNA. By contrast, FBF-2 activity in stem cells shows less dependence on CCR4-NOT, which reflects its amino acid sequence divergence from FBF-1. In conclusion, our study suggests a new mechanism for control of stem cell proliferation in concert with differentiation by PUF proteins through differential cooperation with CCR4-NOT deadenylase machinery, which may be conserved across species.

P2559/B817

Lipid Droplet-associated Proteins Are Required to Build the Eggshell Permeability Barrier In*C. Elegans*.

G. De La Torre Pinedo, A. Reyes-Guzman, B. Wysolmerski, S. Olson; Pomona College, Claremont, CA.

The *C. elegans* embryo is surrounded by a rigid and impermeable eggshell that provides protection during early development. The eggshell contains four distinct layers that are built through the rapid secretion and deposition of extracellular glycoproteins and lipids. The innermost layer of the eggshell, called the permeability barrier, is formed during meiosis II via assembly of an uncharacterized class of lipids (likely to contain polyunsaturated fatty acids). Not only does the identity of permeability barrier lipids remain a mystery, it is also unknown what organelle synthesizes the lipids or how they are delivered to the extracellular environment. We previously conducted an RNAi screen to identify proteins involved in eggshell formation, and found that a number of lipid droplet-associated proteins were required to maintain the impermeability of the eggshell. Depletion of Seipin, Lipin, and Diacylglycerol acyltransferase (DGAT)-related protein led to disruption of the permeability barrier, with little effect on the assembly of other eggshell layers. Depleted embryos also contained enlarged spherical structures reminiscent of lipid droplets. These three proteins are known to regulate lipid droplet formation and function in diverse animal species, from worms to humans. Likewise, the uncharacterized protein PERM-1, which contains predicted hydroxysteroid epimerase and reductase domains, exhibited a similar permeable eggshell phenotype. GFP- and mCherry-tagged versions of the proteins co-localized with the lipid droplet marker perilipin-1 (GFP::PLIN-1) or the endoplasmic reticulum marker SP12::mCherry. We therefore hypothesize that lipid droplets are the site of synthesis and/or storage of lipids that are used to assemble the eggshell permeability barrier. Current studies are underway to examine lipid droplet dynamics when the permeability barrier forms at meiosis II, and to identify the relevant lipid species through lipidomics analysis.

P2560/B818

The Role of ZK813 Proteins in Sperm-egg Recognition and Eggshell Formation in C. Elegans.

C. Vazquez, S. Olson; Pomona College, Claremont, CA.

In metazoans, oocytes are covered by a layer of extracellular matrix that aids in fertilization and egg coat assembly. In the nematode *C. elegans*, the outermost layer of the egg coat is called the vitelline layer. Our lab previously characterized the first set of vitelline layer components - CBD-1, PERM-2, and PERM-4 - which form a protein complex on the nascent vitelline layer. *To* identify additional proteins involved in

vitelline layer assembly, we performed a co-immunoprecipitation of PERM-2 followed by mass spectrophotometry and identified the novel interactors ZK813.1 and ZK813.3, which are components of a four-gene cluster of paralogs that may have arisen due to a chromosomal duplication event. The ZK813 gene cluster was knocked out using CRISPR, and the worms were found to have a fertilization defect. We recently knocked out each individual ZK813 gene in the cluster to determine which one(s) are responsible for the phenotype. Additionally, we generated GFP and mCherry tagged versions of ZK813.1 and ZK813.3, respectively, using CRISPR. Both proteins were found in the spermatheca, and ZK813.3 also localized to the eggshell after fertilization. We are currently performing experiments to explore the structural relationships among PERM-2, PERM-4, CBD-1, and the ZK813 proteins. We are also conducting ZK813 co-immunoprecipitations to identify additional interactors.

P2561/B819

The Species-limited Membrane Protein; *Minus* Adhesion Receptor 1 (Mar1), Controls Gamete Membrane Interactions Immediately Preceding Fusion during Fertilization in *Chlamydomonas*.

J. F. Pinello[1], Y. Liu[2], J. Zhang[1], W. J. Snell[1]; [1]University of Maryland, College Park, MD, [2]University of Texas Southwestern Medical Center, Dallas, TX.

The essential first steps in the creation of a new, genetically distinct, individual diploid cell during fertilization are gamete recognition, membrane adhesion, and the fusion of the gamete lipid bilayers. In many eukaryotes, the ancient, conserved fusogen HAP2 is necessary for the gamete membrane fusion step during fertilization. The tight association of the two gamete membranes is a prerequisite for bilayer merger by HAP2, yet a protein pair controlling this adhesive event has yet to described. Here, we report the identification of a species-limited membrane protein, *Minus* Adhesion Receptor 1 (MAR1), on the *minus* gametes of the model green alga *Chlamydomonas reinhardtii,* that interacts during fertilization with the previously identified, species-limited *plus* gamete membrane adhesion protein, FUS1. MAR1 is expressed predominantly by *minus* gametes, and localized to the *minus* mating structure, which is the site of fusion with the cognate, FUS1-expressing mating structure of *plus* gametes. FUS1 from *plus* gametes and MAR1 from *minus* gametes associate with each other in *vivo* and recombinant forms of the proteins bind to each other in *vitro*, demonstrating a direct interaction. Disruption of the MAR1 gene in *minus* gametes completely blocks mating structure adhesion and gamete fusion, a phenotype corresponding to that of *fus1 plus* mutants. *Plus* gametes bearing the disrupted MAR1 gene are fully capable of mating structure adhesion and gamete fusion. Transformation of the MAR1 deletion *minus* gametes with a FLAG-tagged MAR1 gene rescues the ability of these mutants to fuse with *plus* gametes. Immunoprecipitation studies also indicate that endogenously-expressed MAR1 and HAP2, which are both localized on the *minus* mating structure, are biochemically associated with one another. Moreover, both degrade rapidly during a block to polygamy after gamete fusion. These initial studies of the MAR1-FUS1 interaction in *Chlamydomonas* fertilization suggest the model that during the gamete membrane fusion reaction, species-limited membrane proteins bring the plasma membranes of gametes into close proximity, thereby allowing the conserved eukaryotic class II fusion protein HAP2 to perform its function of bilayer merger. Thus, while the introduction of the ancient fusogen HAP2 was likely the key factor responsible for the origin of two-parent sexual reproduction in eukaryotes, the gamete membrane adhesion proteins could theoretically have served as the initial incompatibility factors responsible for the origin of species.

P2562/B820

Proteome-wide Phosphorylation Dynamics during Oocyte Arrest, Meiosis, and the Transition to Embryogenesis.

S. Swartz[1], H. Nguyen[2], M. Adamo[2], I. M. Cheeseman[1], A. N. Kettenbach[2]; [1]Whitehead Institute for Biomedical Research, Cambridge, MA, [2]Geisel School of Medicine at Dartmouth, Lebanon, NH.

Cell cycle transitions throughout fertility and development depend on the robust control of the cell division apparatus across changing physiological contexts. Oocytes exist in an extended primary cell cycle arrest, persisting for up to decades in humans. After hormonal stimulus, oocytes execute two highly distinct and specialized divisions during the process of meiosis, undergo fertilization, and then transition to embryonic mitoses. Our goal is to understand how the cell division machinery is modulated during this dramatic developmental transition from prophase I arrest through early embryogenesis. Using the sea star *Patiria miniata*, which displays a high synchrony of meiotic events, we performed quantitative proteomics on oocytes at intervals from the prophase I arrest through the first embryonic cleavage. Despite the substantial rearrangements to the cell division machinery during this window, we find that the proteome is remarkably stable, with very little changes in protein levels. In contrast, we find the protein phosphorylation landscape is highly dynamic with multiple distinct waves and patterns of phosphorylation. We find that the prophase I arrest is defined by a uniquely low phosphorylation state achieved through high phosphatase activity. Indeed, we demonstrate that PP1/PP2A phosphatase activity is essential to maintain the prophase I arrest. Upon meiotic resumption, we identify waves of phosphorylation both unique and common to the meiotic divisions and first embryonic cleavage. In particular, our work identifies the behaviors of key regulatory kinases and phosphatases throughout the oocyte-to-embryo transition, as well as phosphorylation dynamics of their putative substrates. Our results provide a rich dataset of phosphorylation events that drive the rapid rearrangements to the cell division apparatus during the oocyte-to-embryo transition.

Effect of Natural Extracts on Viability of Sea Urchin Eggs.

H. Molina[1,2], L. Kwok[1], L. Jayant[1]; [1]Borough of Manhattan Community College, New York, NY, [2]The City College of New York, New York, NY.

Sea urchins, like humans, are deutrostomes and they share many common genes with higher order mammals. This makes them an ideal organism for embryonic development studies. However, harvested sea urchin eggs become heavily infested with a certain species of protist and disintegrate within 24 hours. The study investigated the effect of plant extracts of *Nigella sativa* and *Moringa oleifera* on the viability of sea urchin eggs. Freshly spawned eggs from the sea urchin *Lytechinus variegatus* were incubated with water extracts of both plants in a 1:1 ratio. Intact eggs were observed and counted on a hemocytometer for six days. Results indicate that while *Nigella sativa* extracts did not prevent the disintegration of eggs, phytochemicals of *Moringa oleifera* were able to preserve many egg cells for six days in intact conditions, far longer than the control. Future studies will focus on identifying and isolating the phytochemicals responsible for the protective effects of Moringa oleifera.

P2564/B822

The Effects of Triclosan on the Development of *Lytechinus* Variegatus Embryos.

N. Cornejal[1], L. Ferrante[2], A. Al-Zaabi[3], H. Molina[4], K. Romeus[1], L. Jayant[1]; [1]Borough of Manhattan Community College, NYC, NY, [2]Hunter College, NYC, NY, [3]New York University, NYC, NY, [4]City College of New York, NYC, NY.

This project aims at investigating the effects of triclosan on the development of the sea urchin *Lytechinus variegatus* embryos. Gametes of *L. variegatus* were extracted from spawned adult urchins using potassium chloride (KCl) and in *vitro* fertilization was carefully performed. Fertilized gametes were treated with triclosan at nominal concentrations (0.5, 1, 5, 10 and 20 µM) allowing for embryogenesis to take place. Viability and development of embryos were analyzed using a light microscope. Embryos were counted using a hand drawn grid. Results indicate that embryos exposed to low triclosan concentration (0.5-1 µM) displayed normal development until the pluteus stage, while embryos exposed to high triclosan concentrations (>5 µM) displayed low viability and arrested development at early stages of embryogenesis. Results of this project suggest that higher concentrations of triclosan might have potential deleterious effects on embryonic development of *L. variegatus.* Future results will focus on studying the effect of triclosan on the rate of fertilization and the possible reason for the harmful effects of Triclosan.

Protein an alysis of Infertile Male Testis by Two-dimensional Electrophoresis-relationship between Johnsen's Score and Protein Spots-.

H. Yoshizawa[1], R. Hara[2], S. Kitazawa[3,4], S. Ohira[2], S. Sugiyama[2], A. Nagai[2], S. Tone[1]; [1]Graduate School of Science and Engineering, Tokyo Denki University, Saitama, JAPAN, [2]Department of Urology, Kawasaki Medical School, Okayama, JAPAN, [3]School of Science and Engineering, Tokyo Denki University, Saitama, JAPAN, [4]Showakoyu Co., Ltd., Tokyo, JAPAN.

Currently, approximately 15 % of couples who want children are sterile and about half of them are attributed to male infertility. The causes of male infertility might include protein or chromosomal abnormalities due to genetic mutations, stress, lifestyle related disease such as obesity or smoking, aging and spermatogenic dysfunction such as azoospermia. In this study, we focused on proteins and aimed to find the relationship between the disease stage (Johnsen ’s score: JS) and protein spots by two-dimensional electrophoresis. JS has been used for sperm diagnosis, which evaluate male infertility, and expresses 1-10 scores at which stage the differentiation has been abrogated in spermatogenic process. The higher the score, the closer to normal differentiation. The testicular specimen of each JS was used as a sample for protein analysis. After protein extraction, protein spots were detected by two-dimensional electrophoresis (isoelectric focusing:pI 3-11, 19 hours, SDS-PAGE:4-20%, 180 V, 35 minutes) and silver staining. Samples with JS 7-10 were used as control. Twenty protein spots specific for sterile patients could be found after comparing samples derived from normal and sterile patients. In addition, many spots were lost in sample derived from lower score JS patients. Two protein spots defective in 1-4 JS scores were supposed to be involved in the arrest of differentiation after the spermatocytes, and suggesting that a protein spot only expressed in the control might be necessary for the completion of spermatogenesis. After analysis of more samples per each JS stages, it would be possible to correlate individual spots to each JS stages and spermatogenic process. Furthermore, identification of each spots by MS would shed light on maker proteins for each JS stages.

P2566/B824

Luteinizing Hormone Receptor and Natriuretic Peptide Receptor 2 Guanylyl Cyclase Communication in Mouse Ovarian Follicles.

V. Baena, C. M. Owen, S. Yee, L. A. Jaffe; University of Connecticut, Farmington, CT.

Meiotic arrest and resumption in mammalian oocytes is regulated by two opposing signaling proteins derived from the somatic cells of the follicle: the guanylyl cyclase natriuretic peptide receptor-2 (NPR2), which keeps the oocyte arrested in meiosis by maintaining elevated levels of cGMP, and the luteinizing hormone receptor (LHR), which inactivates NPR2, decreasing the levels of cGMP and in turn restarting meiosis in preparation for fertilization. These two membrane proteins have distinct cellular locations within the follicle, raising the question of how they interact to coordinate their opposing activities. We investigated this by localizing both proteins by immunofluorescence confocal microscopy and serial section immunogold electron microscopy in mouse preovulatory follicles. The LHR is absent from cumulus cells and is localized almost entirely to the outer mural granulosa cells. We found that only about 20-40% of outer mural granulosa cells express the LHR protein. In contrast, NPR2 is expressed in all the follicle cells with a higher concentration in cumulus cells. When protein expression levels are normalized to the size of the follicle, we find that most of the total NPR2 protein is found in the mural granulosa cells, but only 10-20% of the total NPR2 is in cells that also express LHR. These findings indicate that in order to account for the cGMP decrease that occurs in response to LH, the cells that express the LHR must also send a signal that inactivates NPR2 in the neighboring cells which do not express the LHR.

P2567/B825

Proteostasis Renewal in the *C. Elegans* Germline: Identifying Changes in Oocyte Cell Biology Triggered by Signals from Sperm.

M. Samaddar, J. Goudeau, M. Ingaramo, C. Kenyon; Calico Life Sciences LLC, South San Francisco, CA.

Somatic cells age and die, yet the germ lineage is rejuvenated with each generation, ensuring germline immortality. In *C. elegans*, protein aggregates accumulate in unfertilized oocytes of females, which lack sperm. These aggregates are removed, by a process resembling microautophagy, in response to sperm-derived signals when the animals are mated. Our previous findings indicate that oocytes in the hermaphrodite germline respond to sperm-derived signals by rapid acidification of lysosomes and a subsequent shift in mitochondrial physiology, that are required for aggregate clearance (1). We have performed a genome-wide RNAi screen to identify additional components of this quality control switch, and to explore changes in oocyte cell biology triggered by sperm signals. By knocking down individual genes and monitoring an aggregation-prone protein within maturing oocytes, we have identified about 100 genes necessary for preventing oocyte-protein aggregation when sperm are present. Multiple different organelles and cellular processes are regulated by these genes. Our findings indicate that the endoplasmic reticulum (ER) and its trafficking function are required to acidify lysosomes. We hypothesize that these factors are important for the assembly of the lysosomal V-ATPase proton pump and are conducting experiments to visualize the dynamics of ER and V-ATPase subunits following mating. We are also investigating how other candidates identified in the screen contribute to oocyte proteostasis. Taken together, we hope that this study helps to better understand the natural rejuvenation strategies of the germ lineage. The insights could potentially guide approaches for

activating quality control pathways in somatic tissues during aging. (1) Bohnert KA and Kenyon C. 2017. A lysosomal switch triggers proteostasis renewal in the immortal *C. elegans* germ lineage. *Nature* **551**:629-33

The Inner Nuclear Proteome Is Dynamic.

S. N. Shelton, S. E. Smith, S. L. Jaspersen; Stowers Institute for Medical Research, Kansas City, MO.

Changes in the inner nuclear membrane (INM) proteome have been proposed to occur during development, differentiation, and numerous disease processes. However, how the INM proteome changes and how these changes are coupled with nuclear function remains poorly understood. In addition, the timing of when these changes happen at the INM remain unknown although it is reasonable to speculate that it coincides with its function at the INM. We previously developed a system using bimolecular fluorescence to study the INM proteome in mitotic cells. Here, we adapted the split-GFP system to study the INM during gametogenesis. In yeast cells, following two meiotic cellular divisions, newly formed haploid genomes are each encapsulated by a spore wall within the mother cell. This highly regulated developmental process, sporulation, leads to the production of four gametes from the mother diploid cell. We observed specific changes in the INM composition during spore formation, including loss and gain of INM components compared to the mitotic INM proteome. We are currently using several strategies to determine when some of these changes occur. Having insight regarding the timing of the protein changes at the INM may give insight into the nuclear function of the change or help to explain why the change is important. Interestingly, we have found that all positive proteins are detected in two of the four spores. Our INM split-GFP cell strains were heterozygous for the tagged gene. The simplest explanation for this distribution pattern is that these INM proteins are made *de novo* in the spores that inherit the tagged gene. Unlike the INM during mitosis, where it is partitioned between the mother and daughter; the unique pattern of INM inheritance that we observe involves spore-specific *de novo* INM assembly. The changes that we observe during gametogenesis at the INM may all be spore-specific rather than being dependent on meiosis I or II.

Increased Vascular Endothelial Growth Factor by Placenta-derived Mesenchymal Stem Cells Promotes Folliculogenesis in Ovariectomized Rat Model.

J. Cho[1], J. Seok[1], M. Kweon[2], S. Kim[1], J. Lim[3], G. Kim[1]; [1]CHA University, Seongnam, KOREA, REPUBLIC OF, [2]University of Glasgow, Glasgow, UNITED KINGDOM, [3]Korea University, Seoul, KOREA, REPUBLIC OF.

Primary ovarian insufficiency (POI), also known as premature ovarian failure (POF), is one of the most prevalent pathologies for women at reproductive age. The symptoms include reduced number of follicles and diminished secretion of the reproductive hormones before reaching the age of 40. An d the conventional treatment for the dysfunction focuses on hormonal therapy, most commonly hormone replacement therapy (HRT). However, due to its limitation of side effect risks such as heart disease and osteoporosis, an alternative treatment method is desirable, and, thus, studies on stem cell therapy have rapidly advanced. Recent studies reported that transplantation of human mesenchymal stem cells (MSCs) from various sources has promoted ovarian regeneration. However, not many studies were conducted in regards to the effect of placenta-derived mesenchymal stem cells (PD-MSCs), and its mechanism of the ovarian recovery remains to be elucidated. PD-MSCs are derived from the chorionic

plate of the human placenta and are known to promote angiogenesis and have therapeutic effect of liver regeneration. Here, we investigated the restorative effect of PD-MSCs on folliculogenesis using ovariectomized (OVX) rat model. $5x10^5$ of PD-MSCs were intravenously injected into OVX rat models and after 5 weeks the animals were sacrificed for analysis of their serum, genes and proteins. The engraftment and localization of PD-MSCs to the ovaries were confirmed by the expression of *hAlu* upto 5 weeks after the transplantation. ELISA analysis of the serum revealed that the group treated with MSCs for 3 weeks showed decreased level of estradiol (E2) compared to the non-treatment group ($P<0.05$). In addition, histological analysis showed the treatment group had increased number of follicles than the non-treatment group ($P<0.05$), along with the increased number of antral follicles ($P<0.05$), contributing 2-fold increase. Furthermore, the elongated and expanded arteries in ovary were restored with reduced thickness of the wall and decreased luminal area as observed in the wild-type group ($P<0.05$). To investigate the mechanism, cytokine assay was performed and discovered elevated secretion of vascular endothelial growth factor (VEGF) by PD-MSCs, and the increased VEGF secretion was confirmed in the serum of the OVX models. Also, high expression of vascular endothelial growth factor receptor 2 (VEGFR2) was detected through western blot and immunofluorescence at the arteries in ovary. In summary, these findings suggest that the engrafted PD-MSCs secreted VEGF and, thereby, enhanced follicular development in OVX model, providing a theoretical foundation for their application.

P2570/B828

Colocalization and Functional an alysis of *Arabidopsis Thaliana* Tts Protein.

M. Marcelin Reyes; University of Massachusetts Amherst, Amherst, MA.

Colocalization and Functional an alysis of *Arabidopsis Thaliana* TTS Protein Arabinogalactan proteins (AGPs) are a superfamily of glycoproteins in plants. They have been implicated with important roles in plant growth, development and reproduction. Several AGPs are expressed in pistils, the female organs of plants, and perform important functions in the fertilization process. Examples of these are the Transmitting Tissue-specific (TTS) proteins from tobacco plants, which stimulate and promote pollen tube growth in plants, and attract them to their target ovules where fertilization takes place. TTS-1, 2 are located in the extracellular matrix that form the transmitting tissue inside the pistils, where pollen tubes grow and transport sperm for fertilization. Recently, we have identified three homologs of the tobacco TTS in *Arabidopsis thaliana* (At), which is considerably more amendable for genetic analysis than tobacco. We refer to these TTS genes as AtTTS-1, 2, 3. The focus of the project is to determine the function of the AtTTS gene family (i.e. TTS-1,-2,-3) in *Arabidopsis Thaliana*. Initial characterization of T-DNA induced knockout mutants of AtTTS-1, 2 did not reveal reproductive defects. Additionally, RNAi construct for these two genes induced reduced fertility. Our hypothesis is that the RNAi may have targeted other TTS-related genes and we have identified a potential candidate, AtTTS-3 by virtue of its high homology with AtTTS-1, -2 and with the original tobacco TTS-1, 2. We have obtained two T-DNA insertion mutant lines in AtTTS-3. Currently, we are characterizing these mutant lines. We will examine the mutant lines reproductive phenotypes to compare with the At-TTS-1, -2 RNAi and generate double or triple mutants with tts-3. In addition, we shall carry out varying assays, these will be conducted to reveal information about fertility properties, such as monitoring seed setting, in *vivo* and semi-*in vivo* pollen germination and tube growth assays.

P2571/B829

Proteins Released from the Egg Cell Surface at Fertilization in Sea Star.

E. M. Wiseman, L. S. Bates, D. J. Carroll; Florida Institute of Technology, Melbourne, FL.

One of the biggest challenges facing the egg during fertilization is the ability to fuse with a single sperm while blocking all others. There are two clearly documented methods that the egg uses to protect against polyspermy; the fast block, in which the egg cell surface depolarizes to prevent further sperm binding, and the slow block, due to cortical granule exocytosis during egg activation, which raises the fertilization envelope creating a stable and permanent barrier around the egg. Juno and Izumo1, the first fertilization-critical sperm-egg binding partners, were recently discovered. Juno, the egg membrane protein, was discovered to be shed off of the surface after fertilization, perhaps as another mechanism to prevent polyspermy. Shedding of membrane proteins has been documented in other cell types and a variety of processes as well, including the initiation of signaling processes. To this effect, I have observed peptide shedding during egg activation in the sea star *Patiria miniata*. This system offers a unique opportunity to elucidate the molecules that may be required for sperm-egg fusion and activation of the signaling cascade that leads to calcium release at fertilization. Using *P. miniata* as the model organism, egg cell membrane proteins were labeled with biotin, fertilized, and the surrounding seawater was collected. An y biotinylated peptides that are released from the surface were concentrated using biotin-streptavidin affinity interaction. The eluted proteins are subjected to western-blotting probing for biotin. Biotinylated proteins were shown to be released into the seawater around unfertilized eggs, along with a distinct increase in biotinylated proteins in the seawater after fertilization. These proteins range from approximately 50 to 250 kDa, with several unique bands presenting after fertilization. The seawater eluate from unfertilized and fertilized eggs was subjected to tandem mass spectrometry to identify the released proteins. However, identification is a challenge in this particular model organism because there is no proteomic database available. To overcome this limitation, we developed a mature egg transcriptome (NCBI BioProject: 398668), which was used to identify the peptides detected via tandem mass spectrometry by aligning them to an in silico proteome derived from the open reading frames within the transcriptome. A total of 175 transcripts were identified in the seawater samples; 60 were unique to the unfertilized egg, 78 to the fertilized egg, and 38 transcripts were found in both samples. Using these identified transcripts, proteins that are potentially critical for fertilization can be identified, which can lead to a better understanding of what may be happening at the surface of the egg during this vital step to creating life.

P2572/B830

Genomic and Proteomic Identification of the Signaling Complex Controlling Egg Activation in the Sea Star, *Patiria Miniata*.

L. S. Bates, E. M. Wiseman, 32901, D. J. Carroll, 32901; Florida Institute of Technology, Melbourne, FL.

Fertilization is the process of sperm and egg fusing to produce a zygote. Despite being studied for more than 30 years, the signaling pathway controlling egg activation has yet to be fully described in any species. One of the most well-established egg activation pathways is that of sea urchins and sea stars, in which sperm-egg interaction leads to activation of two Src family kinases (SFKs) and phospholipase Cγ (PLCγ). PLCγ cleaves membrane-bound PIP_2 into diacylglycerol (DAG) and inositol 1,4,5-triphosphate (IP_3), and IP_3 binds to its receptor on the endoplasmic reticulum causing an internal calcium release. This internal calcium release stimulates the permanent block to polyspermy and reinitiates the cell cycle. The

PLC protein and the internal calcium release are components of the egg activation pathway shared across species; however, the isoform of PLC varies, for example PLCγ is responsible in sea stars, while PLCζ is responsible in mammals. PLC proteins are pivotal in prompting this internal calcium release in many signaling pathways and are components of larger signaling complexes transducing this signal from an activated membrane receptor. PLCγ can be activated by receptor or non-receptor tyrosine kinases through phosphorylation of Y783 located between the N-terminal SH2 domain and the SH3 domain. In an effort to identify more of the signaling complex responsible for stimulating and transducing this signal, proteins binding to the tandem PLCγSH2 domains during egg activation in the sea star model system have been identified. Furthermore, since tyrosine phosphorylation is pivotal for activation of the SFKs and PLCγ that are involved in egg activation in sea stars, the global tyrosine phosphorylation changes during egg activation and all of the SH2-domain containing transcripts within the mature, unfertilized egg will be examined. From the combination of these studies, we are narrowing down the potential proteins that may be functioning in the signaling pathway to calcium release during egg activation in the sea star, *Patiria miniata*. These fundamental studies will contribute to identifying new targets for contraception development, as well as, new infertility diagnostics and treatments.

P2573/B831

Transcriptional Activity and Morphological Changes of Somatic Cell Nuclei Transferred into Germinal Vesicle Stage Oocytes.

I. Okumura[1,2], K. Minobe[3,2], T. Mitani[1,3], **S. Kurosaka**[2]; [1]Faculty of Biology-Oriented Science and Technology, Kindai University, Kinokawa, JAPAN, [2]Institute of Advanced Technology, Kindai University, Kainan, JAPAN, [3]Graduate School of Biology-Oriented Science and Technology, Kindai University, Kinokawa, JAPAN.

Mammalian oocytes become transcriptionally silent during the germinal vesicle (GV) stage, and arrest at the metaphase of second meiosis (MII) until fertilization. The nuclear activities and dynamics during this process are unique to female germ cells and never seen in somatic cells. To understand the mechanisms to make the differences between germ cells and somatic cells, we have attempted to induce meiotic events in somatic nuclei. In this study, mouse or guinea pig fibroblast nuclei were transferred into enucleated mouse or porcine GV stage oocytes, and the reconstructed oocytes were matured in vitro. The nuclear activities especially transcriptional activity and spindle formation were analyzed by the incorporation of ethynyl uridine (EU) and immunostaining for tubulin, respectively. For the EU incorporation analysis, the reconstructed oocytes were cultured in vitro with cAMP to prevent GV breakdown and entry into metaphase, so that we were able to observe nuclei until 15 hours after the initiation of in vitro maturation (hours post maturation, hpm). The incorporation of EU into the nuclei of reconstructed oocytes was evaluated in every 3 hour-periods from 0-3 hpm to 12-15 hpm. The reconstructed oocytes received G0 phase cells had the transcriptional activity until 9-12 hpm, and gradually lost it at 12-15 hpm, while those received M phase cells didn't show the transcriptional activity at any time point observed, suggesting that the cytoplasm of GV stage oocyte suppresses the transcriptional activity of the somatic cell nucleus in cell cycle-dependent manner. The ratio of transcriptionally active oocytes to inactive ones in the control GV stage oocytes didn't change from 0-3 hpm to 12-15 hpm, possibly because the transcriptional status of each oocyte didn't change in the presence of cAMP. This suggests that the cytoplasm of GV stage oocyte doesn't affect the transcriptional status of germ cell nucleus in the presence of cAMP. For immunocytochemistry for tubulin, reconstructed oocytes were cultured without cAMP, and the localization of chromosomes and tubulin

was analyzed. Reconstructed oocytes using mouse GV oocytes had chromosomes spread to entire cytoplasm. Though tubulin was detected around chromosomes, none of reconstructed oocytes had the spindles. Reconstructed oocytes using porcine oocytes also failed to form the spindle, but interestingly, chromosomes didn't spread and existed as an aggregate near the cortical region of the oocyte. These results suggest some species-dependent mechanisms to form the meiotic spindle. Taken together, the somatic nucleus behaves differently from the germ cell nucleus in the cytoplasm of the GV stage oocyte in the manner dependent on species of the oocyte.

Nuclear Reprogramming of Interspecies Somatic Cell Nuclear Transfer in A*Danionin* Genus Model.

R. Trevena; University of Wisconsin, Madison, WI.

Mechanisms underlining animal oocytes capabilities to be powerful nuclear reprogrammers can be harnessed by Somatic Cell Nuclear Transfer (SCNT) for studies of key molecular events involved in embryonic development to generate pluripotent stem cells and tissues for transplantation. Limitations of SCNT regarding lack of access to enough high-quality oocytes and ethical considerations, alternative methods to study these key molecular events have been established. A derivative method called interspecies somatic cell nuclear transfer (iSCNT) has been developed in which a somatic cell nucleus is transferred into an enucleated donor oocyte obtained from a relative species. The outcomes of this process are nucleo-cytoplasmic hybrids (cybrids) having the nucleus of one species and the cytoplasm of another. Molecular boundaries in this method involve promoting functional interactions between the donor nucleus and the host egg (i.e. nuclear reprogramming). Phylogenetic parameters dictate these boundaries. Understanding these parameters are imperative to drive forth the use of iSCNT in translation applications. The model developmental system, zebrafish (*Danio rerio*), along with an array of additional members of the *Danionin* genus, including *D. kyathit , D. Albolineatus*, *D. margaritatus* are to be used as a "model genus" for testing nucleo-cytoplasmic incompatibilities of iSCNT cybrids at the key developmental timepoint, the mid-blastula transition (MBT). *We hypothesize that changes in key cellular players driving MBT, acquired during the divergence of two species, will result in defects in gene network activation and cybrid incompatibility*. Cybrids are generated via UV irradiation of zebrafish eggs subject to in *vitro* fertilization using sperm of related species. The embryos are assessed via live imaging to record developmental staging and to track cell cycling. The cybrid embryos that have been generated are: *D. kyathit, D. Albolineatus, and D. margaritatus*. Normal developmental staging of zebrafish is recapitulated by all cybrid embryos in early developmental timepoints prior to MBT. Following MBT (4 hours post-fertilization (hpf)), the *D.* kyathit cybrids continued to exhibit no changes in cell cycling. *D. Albolineatus and D. margaritatus* cybrid embryos exhibited elongated cell cycles and delay in developmental staging. Developmental defect was observed in 100% of *D. margaritatus* cybrids by 12 hpf. The other cybrid groups survived up to 72 hpf. Our data suggest that nucleo-cytoplasmic incompatibility of cybrids is directed by phylogenetic relatedness. The more proximally related *D. kyathit* cybrids demonstrated indistinctive development to zebrafish, while the distally related species, *D. Albolineatus* and *D. margaritatus*, exhibited developmental defect.

Involvement of a Membrane Curving Protein in HIV-1 Gag Assembly.

K. Inamdar[1], F. Tsai[2], A. de Poret[1], P. Merida[1], J. Mak[3], C. Favard[1], P. Bassereau[2], D. Muriaux[1]; [1]Institut de Recherche en Infectiologie de Montpellier, Montpellier, FRANCE, [2]Institut Curie, PSL Research University, Paris, FRANCE, [3]School of Medicine, Deakin University, Melbourne, AUSTRALIA.

The I-BAR proteins are a family of proteins known to sense and induce negative curvature at the cell plasma membrane. They also act as scaffold proteins for several actin signalling pathways at the cell membrane. Our lab have revealed that by siRNA knockdown that I-BAR1, an I-BAR domain protein, involved in HIV-1 Gag assembly via a small GTPase dependent signalling. Hence we examined the role of I-BAR1 in HIV-1 Gag assembly. During HIV-1 assembly and budding, the structural Gag proteins are targeted to the plasma membrane where they oligomerize on the viral genome and the cell membrane, leading to the virus budding from the cell membrane. Here, we confirmed the effect of siRNA mediated gene inhibition of I-BAR proteins on Gag VLP production in 293T cells and wild-type HIV-1 production in host CD4 T cells. Secondly, we analysed the possible interactions between Gag and I-BAR proteins by immunoprecipitation. Then we examined the incorporation of the I-BAR1 protein in infectious wild-type HIV-1 as well as Gag VLPs produced in 293T cells. We tested the specificity of this incorporation across other I-BAR family proteins. Our results show that inhibition of I-BAR1 by siRNA leads to a significant reduction in VLP production. An interaction between Gag and I-BAR1 was established in cells by IP. We then performed studies of purified HIV-1 Gag and I-BAR1 domain in a cell free system to analyse their molecular interplay. Our results indicate an enhancement of Gag binding to lipid membranes in the presence of I-BAR1 domain indicating that preferential binding of Gag to membranes with I-BAR1 clusters, and more so when the membrane is curved. In addition, imaging and gradients of purified VLPs showed that I-BAR1 is specifically incorporated into Gag VLPs as compared to other I-BAR family proteins, and is likewise incorporated in infectious purified HIV-1 particles. We further compared the localization of 2 I-BAR proteins at hundreds of virus budding sites by dual colour super resolution PALM/dSTORM microscopy. Imaging analyses indicated the presence of IBAR-1 in close proximity to Gag assembly sites as compared to I-BAR2. Taken together, our results point towards a novel role for I-BAR1 in HIV-1 Gag particle assembly where it may aid Gag binding to the cell membrane providing the initial cluster and curvature necessary for bud formation.

P2576/B835

Single-cell Glycolytic Activity Regulates Membrane Tension and Hiv-1 Fusion.

C. A. Coomer[1,2], I. Carlon-Andres[2], M. Iliopoulou[2], M. L. Dustin[3], E. B. Compeer[3], A. A. Compton[1], S. Padilla-Parra[2]; [1]National Cancer Institute, Frederick, MD, [2]Wellcome Centre Human Genetics, University of Oxford, Oxford, UNITED KINGDOM, [3]Kennedy Institute of Rheumatology, Oxford, UNITED KINGDOM.

There has been resurgence in determining the role of host metabolism in viral infection yet deciphering how the metabolic state of single cells affects viral entry and fusion remains unknown. Here, we have developed a novel assay multiplexing genetically encoded biosensors with single virus tracking (SVT) to evaluate the influence of global metabolic processes on the success rate of virus entry in single cells. We found that cells with a lower ATP:ADP ratio prior to virus addition were less permissive to virus fusion and infection. These results indicated a relationship between host metabolic state and the likelihood for

virus-cell fusion to occur. SVT revealed that HIV-1 viruses were arrested at hemifusion in glycolytically-inactive cells. Interestingly, cells acutely treated with glycolysis inhibitor 2-deoxyglucose (2-DG) become resistant to virus infection and also display less surface membrane cholesterol. Addition of cholesterol in these in glycolytically-inactive cells rescued the virus entry block at hemifusion and enabled completion of HIV-1 fusion. Further investigation with FRET-based membrane tension and membrane-order reporters revealed a link between host cell glycolytic activity and host membrane order and tension. Indeed, cells treated with 2-DG possessed lower plasma membrane lipid order and higher tension values, respectively. Our novel imaging approach that combines lifetime imaging (FLIM) and SVT revealed not only changes in plasma membrane tension at the point of viral fusion, but also that HIV is less likely to enter cells at areas of higher membrane tension. We therefore have identified a connection between host cell glycolytic activity and membrane tension that influences HIV-1 fusion in real-time at the single-virus fusion level in live cells.

P2577/B836

Visualization of HIV-1 Virus-like Particles at Nuclear Pore Complexes by Cryo-Electron Tomography in *Cellulo*.

E. Margiotta[1], V. Zila[2], I. de Castro[2], C. E. Zimmerli[1], B. Turonova[1], M. Allegretti[1], D. Bejarano[2], T. Holdt[2], H. G. Kräusslich[2], M. Lusic[2], M. Beck[1]; [1]EMBL, Heidelberg, GERMANY, [2]Department of Infectious Diseases, Virology -Universitätsklinikum Heidelberg, Heidelberg, GERMANY.

Human Immunodeficiency virus type 1 (HIV-1) is a lentivirus that infects non-dividing cells of the immune system and causes acquired immune deficiency syndrome (AIDS). Replication of the virus is dependent on nuclear entry of the HIV-1 pre-integration complex (PIC) consisting of the reverse-transcribed genome, viral capsid proteins (CA) and integrase (IN), and the subsequent integration of the viral DNA into the host genome. In non-dividing-cells nuclear import occurs through the nuclear pore complex (NPC), a large macromolecular assembly that forms a channel across the nuclear envelope, and requires interactions between viral and host factors. It is generally accepted that HIV-1 CA play a key role in HIV-1 nuclear entry by interacting with NPC components, notably Nup358 and Nup153, and nuclear and transport factor such as CPSF6 and TNPO3. Single mutations in the HIV-1 CA, such as N74D and A77V, abrogate these interactions and interfere with multiple steps of HIV-1 infection. In the mature HIV-1 ~1500 CA assemble into ~200 hexamers and 12 pentamers to form a cone-shaped capsid core. It is not known yet, however, whether the CA of the PIC, reaching the nuclear periphery and interacting with the NPC, keep the same degree of assembly as in the mature capsid core, or whether it is partially or completely lost in a process known as “uncoating”. In order to study the mechanism of nuclear entry and timing of HIV-1 CA uncoating from a biological and structural point of view, we applied cryo-focused ion beam (FIB) milling of T-helper cells transduced with HIV-1 virus-like particles (VLPs) carrying a A77V mutation in the CA followed by cryo-electron tomography (Cryo-ET) to visualize HIV-1 particles interacting with the NPC in *cellulo*. 3D Cryo-correlative light electron microscopy (Cryo-CLEM) was used to validate the nature of the identified particles. Furthermore, we performed subtomogram averaging to define the ultrastructure of HIV capsid-derived structure at the NPC. Our preliminary data show capsid-like structures at the cytoplasmic and the nuclear side of NPCs that resemble the capsid core in shape and size. These findings open new avenues to studying the NPC structural modification during PIC translocation.

P2578/B837

Using Polarization to Image Structural Changes in HIV-1 Maturation.

K. Bredbenner, J. Pulupa, S. Simon; Rockefeller University, New York, NY.

The HIV-1 virus life cycle requires a maturation step where a newly made virus is cleaved by the genetically encoded HIV-1 protease. This maturation step is necessary for infectivity, but the exact kinetics of maturation during assembly of new viruses is unclear. We are using polarized light microscopy to determine the kinetics of the HIV-1 protease in live cells that are assembling new HIV-1 viruses. Polarized light microscopy makes use of the following facts: 1) fluorophores have an excitation dipole, and the fluorophore is excited by light parallel, but not perpendicular to the dipole; 2) fluorophores emit light polarized parallel to their emission dipole; 3) generally the emission dipole is roughly co-aligned with the excitation dipole. We are using anisotropy which is a form of polarization imaging that detects changes in the arrangement of the protein complex that a fluorophore is attached to and how dynamic the fluorophore is. Here we show fluorescence polarization can be used to assay structural differences due to active protease-driven maturation of HIV-1 virus-like particles both in collected supernatant and during active assemblies.

Zika virus (ZIKV) invades and persists in the central nervous system (CNS), causing severe neurological diseases. However, the virus journey, from the bloodstream to tissues through a mature endothelium, remains unclear. Here, we show that ZIKV-infected monocytes represent suitable carriers for viral dissemination to the CNS using human primary monocytes, cerebral organoids derived from embryonic stem cells, organotypic mouse cerebellar slices, a xenotypic human-zebrafish model, and human fetus

brain samples. We find that ZIKV-exposed monocytes exhibit higher expression of adhesion molecules, and higher abilities to attach onto the vessel wall and transmigrate across endothelia. This phenotype is associated to enhanced monocyte-mediated ZIKV dissemination to neural cells. Together, our data show that ZIKV manipulates the monocyte adhesive properties and enhances monocyte transmigration and viral dissemination to neural cells. Monocytes transmigration may represent an important mechanism requires for viral tissue invasion and persistence that could be specifically targeted for therapeutic intervention.

P2580/B839

Ifitm3 Inhibits Retroviral Infectivity by Rerouting Viral Envelope Glycoproteins to Lysosomes.

Y. Ahi, D. Yimer, S. Shi, K. Rahman, A. Rein, **A. Compton**; National Cancer Institute, Frederick, MD.

Interferon-induced transmembrane (IFITM) proteins are encoded by many vertebrate species and exhibit antiviral activities against a wide range of viruses. IFITM proteins, particularly IFITM3, perform multiple antiviral functions during HIV-1 infection. First, IFITM3 prevents virus-cell fusion when expressed in naïve target cells. Second, when present in virus-producing cells, it reduces the fusion potential of virus particles. This latter activity was first characterized during HIV-1 infection, and the mechanism responsible may involve IFITM protein incorporation into virions, reduction of Envelope (Env) incorporation, or both. To address the breadth of antiviral activity exhibited by IFITM3 as well as the underlying mechanism(s) involved, we took advantage of a murine leukemia virus (MLV)-based pseudotyping system. By carefully controlling quantities of IFITM3 and viral glycoproteins in virus-producing cells, we found that ectopic IFITM3 potently inhibits MLV virion infectivity, and most potently when Env levels are limiting. Loss of virion infectivity was associated with defective proteolytic processing of Env, lysosomal degradation of the Env precursor, and a paucity of Env incorporated into virions. Ecotropic and Xenotropic variants of MLV Env, as well as HIV-1 Env and VSV-G, are sensitive to IFITM3 while Ebola glycoprotein is resistant, suggesting that IFITM3 selectively targets certain viral glycoproteins. Furthermore, endogenous IFITM3 in human and murine cells negatively regulates MLV Env production. These data indicate that IFITM3 decreases virion infectivity in a viral glycoprotein-dependent manner, and it does so in part by limiting viral glycoprotein production. However, by titrating Env levels during virus production, we found that the negative impact of IFITM3 on virion infectivity is greater than the impact of decreasing Env incorporation, suggesting that IFITM3 also affects Env qualitatively. Lastly, we demonstrate that virion infectivity in the presence of IFITM3 is rescued by the expression of GlycoGag, a murine retrovirus accessory protein previously described to antagonize the antiviral activity of other intrinsic immune factors SERINC3 and SERINC5. Overall, we show that IFITM3 impairs virion infectivity by regulating Env abundance and function but that enhanced Env expression and GlycoGag confer resistance to IFITM3.

P2581/B840

Influenza Versus Host: Interferon an tagonism by Viral Nucleoprotein and Novel Copper-related Host Factors in Antiviral Defenses.

R. P. Dagdag, C. A. Kollander, J. L. Burkhead, E. Bortz; University of Alaska an chorage, an chorage, AK.

Influenza a virus is a respiratory orthomyxovirus that causes 3-5 million cases of severe illness and 250,000-500,000 deaths annually in humans. The NS1 protein antagonizes RIG-I and IRF3-induced IFN-βresponses during an influenza infection. Some influenza strains also contain nucleoproteins (NP)

variants that impart resistance to the antiviral protein Mx. To better understand roles of NP in antagonizing interferon responses, NP plasmids from H1N1, H5N1, or H7N9 influenza subtypes were transfected into A549 human lung adenocarcinoma and HEK293T IFN-βreporter cells. The viral RNA mimic poly-I:C was used to induce a type-I IFN response. Quantitative RT-PCR showed that NP expression led to a 16-fold decrease in IFN-β expression compared to control, and significant reductions in interferon-stimulated genes MxA (185-fold), ISG56 (450-fold), and IL-8 (32-fold). On the host side, copper handling machinery has been recently recognized as regulating influenza infection. RNA interference experiments showed that copper transporter ATP7A, a protein that imports [Cu1+] into trans-Golgi derived compartments, is required for influenza viral RNA and protein syntheses. The trafficking-regulatory Commander complex includes the 10-member COMMD protein family, first identified in regulation of copper export. Preliminary experiments reveal that a type I IFN response induced by poly-I:C in A549 cells also results in dose-dependent upregulation of COMMD5 (13-fold) and COMMD7 (12-fold), but not COMMD1. While simultaneous knockdown of COMMD5 and COMMD7 did not enhance influenza A/WSN/33 (H1N1) infection of A549 cells, knockdown of the copper-binding protein ATOX1 licensed viral replication in a limiting dilution assay. Taken together, these results suggest a previously unrecognized interplay between viral NP, antiviral proteins and copper-binding proteins to regulate influenza a virus infection in mammals, providing novel targets for antiviral therapy.

P2582/B841

The Functional Relationship between Antiviral Restriction Factor IFITM3 and Cellular Cholesterol Homeostasis.

K. Rahman[1], S. Majdoul[1], C. A. Coomer[2], S. Ding[1], T. An dresson[3], S. Padilla-Parra[2], A. A. Compton[1]; [1]HIV Dynamics and Replication Program, National Cancer Institute, Frederick, MD, [2]Cellular Imaging, Wellcome Trust Centre for Human Genetics, Oxford, UNITED KINGDOM, [3]The Protein Characterization Laboratory, National Cancer Institute, Frederick, MD.

The interferon-induced transmembrane proteins (IFITM) proteins broadly inhibit infection by multiple viruses, including Influenza a virus, Zika virus, and HIV-1. Previous reports illustrated that IFITM3 perturbs cholesterol trafficking in cells but how it contributes to its antiviral functions is unclear. We confirmed that cholesterol levels are elevated in cells ectopically expressing IFITM3, particularly in the endocytic compartment. Furthermore, we show that increases in cellular cholesterol are associated with increases in membrane order and rigidity using fluorescence lifetime imaging microscopy. Surprisingly, a single point mutation in the intracellular loop of IFITM3 prevents the observed increases in cholesterol and membrane order while concomitantly reducing antiviral activity against Influenza a virus and HIV-1. We found that nystatin and amphotericin B, two antifungal compounds which displace membrane cholesterol, counteracted both the antiviral function of IFITM3 and its capacity to increase membrane order, further linking the antiviral phenotype with membrane lipid composition. To further understand how IFITM3 expression leads to increased intracellular cholesterol concentrations, we used immunoprecipitation and mass spectrometry to identify binding partners that differentially bind wild-type and mutant IFITM3. Initial analyses revealed that wild-type IFITM3 interacts with the rate-limiting enzyme of cholesterol biosynthesis known as SQLE, whereas mutant IFITM3 interacts to a lesser extent. Furthermore, bioinformatic analysis identified a potential cholesterol binding motif which overlaps with the single point mutation present in mutant IFITM3 and we are performing in *vitro* experiments measuring its direct cholesterol binding capacity. We will present experiments using RNAi and specific inhibitors to determine whether SQLE expression is required for IFITM3-mediated antiviral activity. Our

studies will determine the mechanism by which IFITM3 inhibits virus entry and will identify an important metabolic axis that may be targeted for host-directed antiviral therapy.

P2583/B842

The Multiple Roles of Canine Parvovirus Non-structural Protein 2.

K. Salokas[1], **S. Mattola**[2], E. A. Niskanen[3], E. Mäntylä[4], S. Salminen[2], J. Svirskaite[1], T. O. Ihalainen[4], K. Airenne[5], M. Kaikkonen-Määttä[3], M. Varjosalo[1], M. Vihinen-Ranta[2]; [1]University of Helsinki, Helsinki, FINLAND, [2]University of Jyväskylä, Jyväskylä, FINLAND, [3]University of Eastern Finland, Kuopio, FINLAND, [4]University of Tampere, Tampere, FINLAND, [5]Kuopio Center for Gene and Cell Therapy, Kuopio, FINLAND.

Canine parvovirus (CPV) is a small DNA virus with only four virally encoded proteins. Viral proteins 1 and 2 form the capsid core, while non-structural protein 1 performs a number of nuclear functions required for viral replication. The exact role of the fourth CPV protein, non-structural protein 2 (NS2), has remained undefined. Here, we used BioID combined with confocal microscopy and other protein-protein interaction analyses to identify binding partners for NS2. Our results revealed multiple NS2 - host protein associations, which could have a significant impact on the interplay between virus and cell machinery and thereby influence CPV replication. NS2 was found to be associated with the key factors that control chromatin remodeling, presumably either to promote viral replication or to inhibit cellular functions that counteract infection. An alyses of the factors involved in DNA damage response and transcription showed that NS2 is associated with regulators of cell cycle arrest and apoptosis. Finally, NS2 appears to be involved in splicing, binding and NPC docking of mRNA, thereby contributing as an important mediator and effector in mRNA processing and nuclear export. Our analyses reveal novel data of the transient interactions and implicated mechanisms by which parvoviral NS2 could operate in infection.

CRISPR/Cas9-Mediated Knockout of the Coxsackievirus and Adenovirus Receptor in Polarized Epithelial Cells.

A. Alkahlout, J. M. Readler, K. J. Excoffon; Wright State University, Dayton, OH.

Adenovirus (AdV) infection generally causes cold-like symptoms, but in some cases can be severe and can be fatal. The Coxsackievirus and adenovirus receptor (CAR) is encoded by the *CXADR*gene and the transcript is alternatively spliced yielding two transmembrane protein isoforms of CAR, CAR^{Ex7} and CAR^{Ex8}. The only difference between the two isoforms is at the extreme C-terminus where the last 26 amino acids of $CAR^{Ex7}$is replaced by 13 unique amino acids encoded by the eighth exon of *CXADR*. This sequence difference results in distinctly different localization for each isoform in polarized epithelial cells. Whereas CAR^{Ex7} is found on the basolateral surface, CAR^{Ex8} is localized at the apical surface where it can mediate the infection of AdV from the airway lumen. We hypothesized that isoform-specific knockout of CAR^{Ex8}would prohibit apical AdV infection while the knockout of both isoforms would prevent apical and basolateral AdV infection. To test this, we used CRISPR/Cas9 to target CAR^{Ex8}or all CAR isoforms and then investigated AdV5-LacZ entry and transduction. We previously had established a Madin-Darby canine kidney cell line that has a stably-integrated lentiviral-based dox-inducible human CAR^{Ex8}insert (MDCK-CAR^{Ex8}). We used this cell line to create two CRISPR/Cas9 edited MDCK-CAR^{Ex8} cell lines, one with CAR^{Ex8}knockdown (JR1) and one total CAR knockout (AA1). Knockdown/knockout of

CAR^{Ex8} andtotal CAR significantly decreased apical AdV transduction in comparison to parental cells demonstrating the importance of the apical isoform for AdV infection. This effect was reversed and infection was restored with dox-mediated induction of the lentiviral CAR^{Ex8}insert. Future work will evaluate basolateral infection and investigate whether AdV can exploit additional mechanisms to enter into polarized epithelia.

P2585/B844

Contributions of the Four Essential Entry Glycoproteins to HSV-1 Tropism and the Selection of Entry Routes.

A. T. Hilterbrand, R. Daly, E. E. Heldwein; Tufts University School of Medicine, Boston, MA.

Herpes simplex virus type 1 (HSV-1), an enveloped virus that is a member of the herpesvirus family, can enter cells by either fusion at the plasma membrane or endocytosis, depending on the cell type being infected. However, it remains unclear how this choice is made. In order to enter a cell, HSV-1 requires four of its 15 total envelope proteins: gB, gH, gL, and gD. While these are the only four proteins required for entry and membrane fusion, their contributions to the ability of HSV-1 to infect different cell types and the selection of different entry routes remains unclear. To address the specific contributions of gB, gH, gL, and gD to HSV-1 cellular tropism and different entry pathways, we generated vesicular stomatitis virus (VSV) lacking its native glycoprotein G, and pseudotyped it with gB, gH, gL, and gD, which we termed VSVΔG-BHLD virions. Six HSV-1 susceptible cell lines were then screened for their ability to support VSVΔG-BHLD virion entry. Out of those six cell lines, only two supported VSVΔG-BHLD entry: C10 and CHO-nectin-1 cells. In those two cell lines, HSV-1 and VSVΔG-BHLD entry mechanisms were determined using a combination of redundant chemical and genetic inhibitors of cellular uptake pathways. Our results show that VSVΔG-BHLD virions lack the broad cellular tropism that HSV-1 possesses. Additionally, VSVΔG-BHLD virions utilize different entry pathways compared to HSV-1 in C10 and CHO-nectin-1 cells. While HSV-1 utilized an entry pathway in both cell lines that was dependent on clathrin, dynamin, cholesterol, and Arf6, and independent of endosomal pH and Rab5 or Rab7 function, VSVΔG-BHLD virions entered C10 and CHO-nectin-1 cells by a clathrin- and Arf6-independent mechanism that was dependent on dynamin and cholesterol. Endosomal pH and Rab5 and Rab7 GTPases were important for VSVΔG-BHLD virion entry in a cell-line dependent manner. Thus, while the four essential HSV-1 entry glycoproteins enable entry in certain contexts, they are insufficient for entry into any HSV-1-susceptible cell and do not specify native entry routes. We conclude that the HSV-1 envelope proteins outside the essential four (so-called “non-essential”) contribute towards the tropism and the selection of entry routes. Our work draws attention to the need for systematic investigation of the HSV-1 entry mechanisms and the roles of the envelope proteins long considered non-essential in the selection of target cells, routes of entry, and pathogenesis.

HIV-1 Envelope Glycoprotein Trafficking and Viral Transmission.

M. V. Fernandez, 21702[1], L. N. Naing[1], D. A. Scheiblin[2], J. A. Simmons[1], E. O. Freed[1]; [1]Virus-Cell Interaction Section, HIV Dynamics and Replication Program, Center for Cancer Research, National Cancer Institute, FREDERICK, MD, [2]Optical Microscopy and an alysis Laboratory, Cancer Research Technology Program, Frederick National Laboratory for Cancer Research, FREDERICK, MD.

HIV-1 encodes an envelope glycoprotein complex (Env) containing a long cytoplasmic tail (CT) harboring trafficking motifs implicated in Env incorporation into virions. Although the requirement for the Env CT in viral transmission is known, the precise mechanism by which Env is incorporated into nascent virions and localizes to the virological synapse remains poorly defined. To further elucidate the mechanism of Env trafficking we examined two HIV-1 strains: the lab-adapted clade B strain, NL4-3, and a transmitted/founder clade C virus, K3016. The HIV-1 Env CT contains a highly conserved tyrosine endocytosis motif, Y^{712}SPL, and C-terminal dileucine motif, LL^{855}. Virion Env incorporation analysis revealed that Y^{712}SPL is necessary for efficient Env incorporation while LL^{855} is dispensable. Spreading infection kinetics were analyzed in various T-cell lines and primary human PBMCs; the results indicated that both endocytic motifs contribute to efficient viral spread in culture. An alysis of Env localization to the T-cell uropod, the portion of the plasma membrane that forms a virological synapse with uninfected cells, was found to be dependent on the Env CT and the Y^{712}SPL motif. Cell-to-cell and cell-free transmission assays using T cells infected with HIV-1 bearing Y_{712}A or LL_{855}AA Env CT mutations are ongoing to establish a role for these motifs in both modes of viral transmission. These studies will significantly enhance our understanding of Env trafficking and viral transmission, providing insights into viral Env-host interactions in physiologically relevant cells.

DLK/JNK-dependent Reactivation of Herpes Simplex Virus from Latency in Response to Neuronal Hyperexcitability.

S. R. Cuddy[1], A. R. Schinlever[1], S. A. Dochnal[1], J. B. Suzich[1], T. K. Downs[1], M. Farah[1], P. Kundu[1], C. Boutell[2], B. N. Desai[1], A. R. Cliffe[1]; [1]University of Virginia, Charlottesville, VA, [2]MRC-University of Glasgow Centre for Virus Research (CVR), Garscube Campus, Glasgow, UNITED KINGDOM.

Herpes simplex virus (HSV) establishes a latent infection in peripheral neurons. The viral DNA episome persists in the nucleus and assembles into heterochromatin resulting in silencing of HSV lytic genes. In response to certain stimuli, viral lytic gene expression initiates, which can result in production of viral particles and reactivation from latency. The exact physiological triggers contributing to reactivation are not well understood. Previously, we found that dual leucine zipper kinase (DLK)-mediated activation of c-Jun N-terminal kinase (JNK) was essential for reactivation in response to inhibition of PI3K signaling, which mimics loss of nerve growth factor (NGF) support. Moreover, JNK activation in sympathetic neurons was associated with a histone phospho/methyl switch on HSV lytic gene promoters, therefore linking NGF signaling to epigenetic changes on the viral genome that would permit gene expression. Given that the same histone phospho/methyl switch occurs in cortical neurons following hyperexcitability (triggered by forskolin or KCl depolarization) we examined whether HSV reactivation was linked to hyperexcitability and the contribution of JNK activity and histone phosphorylation. Using a model of HSV reactivation in mouse sympathetic neurons, we found that forskolin induces HSV lytic gene expression and reactivation in a DLK/JNK-dependent manner. The initial burst of lytic gene expression occurred independently of histone demethylase activity and was accompanied with a transient histone phospho/methyl switch. Reactivation in this context was not linked to loss of AKT phosphorylation. In addition, forskolin and inhibition of PI3K signaling synergized to enhance reactivation, indicating that loss of NGF support and forskolin trigger reactivation via distinct pathways that converge on DLK/JNK. Forskolin-mediated reactivation of HSV was blocked following treatment with ion channel inhibitors. In addition, hyperexcitability resulting from removal of a tetrodotoxin block triggered HSV reactivation in a DLK/JNK-dependent manner. We next investigated whether physiological

triggers induce HSV reactivation via hyperexcitability. Notably, IL-1β induced DNA damage associated with hyperexcitability in adult neurons. IL-1β also triggers DLK/JNK-dependent reactivation of HSV that was dependent on ion channel activity. Therefore, we posit a model that neuronal hyperexcitability in response to physiological stimuli such as inflammation trigger HSV reactivation. These data also place activation of DLK/JNK and a histone phospho/methyl switch as a key event in hyperexcitability-mediated reactivation.

P2588/B847

The Cell-specific Role of Viral Kinase in the Formation of Tunneling Nanotubes and in Cell-to-cell Spread of an Alpha-herpesvirus.

M. Panasiuk, M. Rychlowski, **K. Bienkowska-Szewczyk**; University of Gdansk, Faculty of Biotechnology, Dept. Molecular Virology, Gdansk, POLAND.

The Us3 gene coding for a serine-threonine protein kinase is highly conserved among alphaherpesviruses. The Us3 kinase is a multifunctional protein which plays role in many processes including virus egress from the nucleus, blocking apoptosis and modulation of immune response. Us3 interaction with host cell actin cytoskeleton can lead to dramatic changes in the cell morphology. For our model herpesvirus, bovine herpesvirus 1 (BoHV-1) we reported that overexpression of Us3 in epithelial cells or fibroblasts caused actin stress fibers breakdown and very fast formation of numerous cell projections. This phenomenon was also observed for other alpha-herpesviruses, e.g. pseudorabies virus (PRV). We showed that such projections were produced during natural infection with BoHV-1 and many of these cell connections had features characteristic for tunneling nanotubes (TNT): they contained actin and microtubules, they were long (over 100 nm), thin and fragile. Using fluorescent viral mutants, we demonstrated that viral proteins were transported through TNTs. Moreover, TNTs were used for viral dissemination by cell-to-cell spread—quick, direct intercellular transmission of viral particles. TNTs were detected in uninfected cells permissive for BoHV-1 but virus infection stimulated more than two-fold increase both in number and length of TNTs. That increase was more conspicuous in infected fibroblasts than in epithelial cells. We also observed TNTs formation in human transformed cells which were permissive for BoHV-1. Cells infected with viral mutants lacking Us3 gene or expressing inactive form of this protein generated significantly less connections than cells infected with wild type virus. These data indicate that Us3 kinase plays role in TNTs formation during BoHV-1 infection and contributes to viral spread by cell-to-cell route. In contrast to these data, we discovered that the expression of Us3 in live neurons led to reducing the number of dendrites and, gradually, to cell death. The inactive form of Us3 kinase did not cause such effect. These observation show that viral kinase may interact with host proteins in different ways in various types of cells permissive for herpesviruses. In view of ubiquitous presence of herpesviruses in human and animal populations and the potential use of herpesviral vectors for therapeutic purposes, the precise understanding of molecular mechanisms of herpesviruses interaction with their hosts is of great importance.

Cpsf6 Accumulation in Speckles After Hiv-1 Infection.

K. Lee, H. Yu, S. H. Hughes, V. N. KewalRamani; National Cancer Institute, NIH, Frederick, MD.

CPSF6 Accumulation in Speckles after HIV-1 Infection KyeongEun Lee[1], Hyun Jae Yu[1], Stephen H. Hughes[2], and Vineet N. KewalRamani[1] [1]Basic Research Laboratory, National Cancer Institute, Frederick,

MD, [2]HIV Dynamics and Replication Program, National Cancer Institute, Frederick, MD HIV-1 infection at the cellular level involves a successive series of host factor interactions to drive the viral replication program. HIV-1 capsid (CA) plays a central role in these early replication steps facilitating cytoplasmic-nuclear trafficking of the virus and access to chromatin during integration. CPSF6 is as an HIV-1 CA interacting factor that enables HIV-1 integration in gene-rich regions of chromatin. The majority of CPSF6 resides in nucleoplasm with a fraction that also localizes within nuclear speckles. Soon after HIV-1 infection, CPSF6 and HIV-1 begin to accumulate in speckles, such that the majority of CPSF6 is observed within the phase-separated compartments in as little as 6 hours after virus exposure. The enrichment in speckles requires CA interacting with an FG-motif in CPSF6. We find that this localization is essential for HIV-1 targeting of gene-rich regions of chromatin and observe a proximity of speckles to these regions. Notably, while HIV-1 requires CPSF6 to access speckles, when the HIV-1/CPSF6 binding is disrupted with a drug that targets the CA interface essential for interaction, CPSF6 is rapidly flushed from the speckles into the nucleoplasm. Thus, while HIV-1 requires CPSF6 to access speckles, CPSF6 appears to require HIV-1 to persist in speckles. We are currently examining CPSF6 domains to determine whether these phenotypes are genetically and functionally separable. CPSF6 trafficking to speckles in response to HIV-1 infection may provide a model to better understand both the localization and persistence of factors in phase-separated compartments.

RSV-induced TGFb Plays a Protective Role in Epithelial Barrier Function.

L. Buchholtz, S. N. Talukdar, **M. Mehedi**; University of North Dakota, Grand Forks, ND.

Respiratory Syncytial Virus (RSV) is a global health and economic burden due to lack of a vaccine or cost-effective antiviral therapy and RSV-associated hospitalization. Studying RSV-host interactions in the human airway epithelium model will likely enhance our understanding of RSV pathogenesis and assist in identifying novel strategies for limiting the severity of RSV-induced pathophysiology. We developed pseudo-stratified and fully differentiated mucociliary epithelium of human bronchial epithelial (NHBE) cells in air-liquid interface 3D culture system. RSV infection in human airway epithelium neither reduced epithelial barrier function nor impaired ciliary function. We found RSV infection increased tumor growth factor-beta (TGFb) induction in NHBE monolayers and pseudostratified airway epithelium. TGFb is known to induce epithelial-mesenchymal transition (EMT). To our surprise, RSV infection in respiratory epithelium neither reduced tight junction markers (E-cadherin and Zonula occludens-1) nor increased mesenchymal cell markers (Vimentin and Alpha-Smooth Muscle Actin). We found that TGFb alone can increase not only ciliary beat frequency but also transepithelial electrical resistance in the airway model. Thus, RSV-induced TGFb may play a protective role in epithelial barrier function in this human airway epithelium.

Structure-function an alyses of the Small, Non-structural Proteins A30.5 and L2 Provide New Insights into Our Understanding of ER Dynamics and the Formation of the Vaccinia Virus Membrane.

M. Greseth, J. Carten, P. Traktman; Medical University of South Carolina, Charleston, SC.

The choreography of viral infections often sheds light on the cell biology of the host. Vaccinia virus, a complex dsDNA virus, is unusual in replicating exclusively within the cytoplasm of infected cells. Viral replication depends upon dynamic interactions with endoplasmic reticulum (ER) membranes. Viral membrane biogenesis involves diversion of ER membranes, independent of classical vesicular trafficking pathways, leading to the appearance of single-bilayer crescents. These then enlarge to form the delimiting membrane of nascent virions. A30.5 and L2 are small (42 and 87 aa, respectively), non-structural, essential viral proteins that localize to the ER. To better understand how these proteins function, we generated CV1 cell lines that express 3xFLAG-A30.5 or HA-L2 in a DOX-inducible manner, as well as deletion viruses. Loss of either A30.5 or L2 leads to a reduction in viral yield of 2-3 logs and an early arrest in viral membrane biogenesis. We have conducted structure-function studies to identify critical regions within these proteins. A series of truncation, clustered charge-to-alanine, and chimeric alleles were generated and tested in our transient complementation assay. Interestingly, these two proteins are remarkably resistant to perturbation; however, an A30.5 mutant that is predicted to break an N-terminal α-helix and an L2 mutant (RRD^{38,42,46}-AAA), failed to restore viral yield. We have shown that A30.5 and L2 interact with each other in the absence of other viral proteins. Interestingly, the stability of A30.5 is dependent upon the presence of L2, indicating that the vΔL2 mutant actually reflects a loss of both L2 and A30.5. Biological competency of our mutant L2 and A30.5 alleles correlates with their ability to interact. Interestingly, the L2-RRD protein has a significantly retarded mobility compared to L2-WT, which we suspect reflects an aberrant post-translational modification that perturbs L2's biological competency. We are using our cell lines and mutant alleles to monitor ER dynamics through both electron microscopy and immunofluorescence analyses. We have generated cell lines expressing APEX2-A30.5 and -L2 to identify interacting partners of L2 and A30.5 in the absence or presence of infection. In sum, these studies are furthering our understanding of poxviral membrane biogenesis and providing new insight into the dynamic regulation of ER.

P2592/B851

Suppressor of Cytokine Signaling 3 Is Involved in Regulation of Interleukin 6 Expression during the Viral Infection.

J. Chen, R. Yan, S. Liu; Fujian Agriculture and Forestry University, Fuzhou, CHINA.

Upon the recognition of viral pathogen associated molecular patterns by pattern recognition receptors, such as toll-like receptors or retinoic acid-inducible gene I-like receptors, various inflammatory cytokines including interleukin 6 (IL-6) are produced in host in response to the infection. However, IL-6-involved excessive inflammatory response to viral infection such as Influenza a virus (IAV) infection profoundly contributes to the virus pathogenesis. The precise mechanisms underlying such a response are poorly understood. Here we found from both in *vivo* and in *vitro* studies that acute infection with IAV not only induced surge of IL-6 release, but also greatly increased expression of suppressor of cytokine signaling 3 (SOCS3), the potent suppressor of IL-6/signal transducer and activator of transcription 3 (STAT3) signaling. Interestingly, there existed a cytokine-independent mechanism of the robust induction of SOCS3 by IAV at early stage of the infection. Furthermore, we employed SOCS3-knockdown transgenic

mice (TG), and surprisingly observed from virus challenge experiments using these mice that disruption of SOCS3 expression provided significant protection against IAV infection, as evidenced by attenuated acute lung injury, a higher survival rate of infected animals and lower viral load in infected tissues as compared with those of wild-type littermates under same condition. The activity of NFκB and the expression of its target gene IL-6 were markedly suppressed in SOCS3-knockdown A549 cells and the TG mice after infection with IAV. Moreover, we defined that enhanced STAT3 activity caused by SOCS3 silencing was important for the regulation of NFκB and IL-6. These findings establish a critical role for SOCS3 in the pathogenesis of IAV through regulating IL-6-STAT3 signaling, and suggest that influenza virus may have evolved a strategy to circumvent IL-6/STAT3-mediated immune response by upregulation of SOCS3.

P2593/B852

Pathogenicity Factors Related to Augmented Virulence of Esbl *Klebsiella Pneumoniae*.

C. E. Palavecino, 8550850; Universidad Central de Chile, Santiago, CHILE.

Abstract the emergence of multi-drug resistance (MDR) for pathogenic bacteria is one of the most serious global threats to human health in the 21st century. In fact, the world health organization (WHO) and the US CDC described the situation as a global crisis and an impending catastrophe of a return to the pre-antibiotic era. The MDR is especially concentrated in bacteria that cause infections associated with health care (HAIs). The global rate of HAIs in the United States is approximately 5% resulting in 88,000 deaths. *K. pneumoniae* is one of the major producers of HAIs and one of the most important bacteria that increasingly acquired antimicrobial drug resistance. Its high resistance does not fully explain its great success as one of the agents HAIs producers, which suggests that other factors facilitate its high frequency. Factors that increase their survival are virulence factors, such as fimbria, siderophores or capsule. In order to find a relationship between virulence factors and the MDR, in this work we analyses 122 randomly selected clinical isolates of *K. pneumoniae*. By PCR, we identify the frequency of the presence of the genes that encode the virulence factors K2, *mag*A, *mrp*A, *ent*B, *ybt*S and *all*S. We also establish their susceptibility profile for the antibiotics; Amk, Cfx, Cfz, Imp, Mer any Pip-taz, by quantification of the minimal inhibitory concentration (MIC). Our results showed a significantly increased frequency of virulence genes in ESBL producing bacteria compared to non-ESBL producing bacteria (Fisher´s; $p<0.026$). We found three of the genes K2, *ybt*S and *all*S that improve the β-lactamase production in the *K. pneumoniae* population. A risk evaluation calculating odds ratio (OR), determinate that the presence of the K2 gene increase 5.9 times (CI: 1.6 – 21), and the gene *ybt*S 3 times (CI 1.2 – 8) the risk to generate ESBL producing bacteria. None of the genes analyses in its study modifies the risk to generate carbapenem resistant bacteria. We observed that all strains of *K. pneumoniae* in or population of the $K2^+$, *ybt*S^+ and *all*S^+ genotype, were ESBL producers. These strains also deploy higher virulence as they shown an increased resistance to human serum, and for human macrophages and polymorphonuclear cells. In sum, the genes $K2^+$, *ybt*S^+ and *all*S^+ provide higher virulence and affect the susceptibility of *K. pneumoniae* improving its resistance to β-lactamic antibiotics.

P2594/B853

Role of Host Exocytosis in Internalin A-mediated Entry of *Listeria Monocytogenes*.

G. C. Gyanwali, K. Ireton; Microbiology and Immunology, University of Otago, Dunedin, NEW ZEALAND.

Listeria monocytogenes (*Lm*) is a gram-positive food-borne pathogen that causes meningitis and abortion. The ability of *Listeria* to induce its internalization (entry) into human cells is critical for virulence. One major pathway of entry is mediated by interaction of the bacterial surface protein InlA with its host receptor, E-cadherin. Binding of InlA to E-cadherin results in localized polymerization of the host actin cytoskeleton, which contributes to remodeling of the host plasma membrane during entry. A key unanswered question is whether host physiological processes apart from actin polymerization are exploited by *Listeria* in order to promote entry through E-cadherin. Therefore, the objective of this study is to assess the role of other host processes in InlA-mediated entry of *Listeria*. We report that InlA-mediated entry of *Lm* involves bacterial stimulation of the host process of exocytosis. Using the exocytic probe VAMP3-GFP and latex beads coated with InlA as a model for entry of *Lm*, we found entry of beads is accompanied by localized stimulation of exocytosis. Many exocytic pathways are known to involve the exocyst complex, which tethers exocytic vesicles to the plasma membrane prior to membrane fusion. Importantly, we found that RNAi-mediated depletion of components of the exocyst complex (Sec6, Exo70, and Exo84) reduced entry of InlA-coated beads. These results demonstrate a role for the exocyst in InlA-mediated internalization. We also assessed the role of the exocyst regulators RalA, Rab8, and Rab11 using RNAi or dominant negative mutants. Our results show that uptake of InlA-coated beads was reduced upon inhibition of each of these regulators, indicating roles for RalA, Rab8, and Rab11 in entry. Furthermore, we found that n-ethylmaleimide-sensitive factor (NSF), a protein critical for membrane fusion during exocytosis, is required for InlA-mediated entry. These studies were performed using a cell-permeable NSF peptide that inhibits the function of endogenous NSF. Finally, by performing biotinylation of surface proteins, we showed that inhibition of NSF or the exocyst proteins Sec6, Exo70, Exo84 failed to significantly reduce surface levels of E-cadherin. These findings suggest that exocytosis promotes InlA-mediated entry by acting downstream of InlA/E-cadherin interaction. Collectively, our results indicate that *Lm* subverts exocytosis through the host exocyst in order to facilitate entry into human cells.

P2595/B854

The Small Gtp-binding Protein Arf6 Is Recruited to Actin-rich *Listeria Monocytogenes P*Rotrusions during Cell-to-cell Spreading.

B. D. Walker, A. S. Dhanda, **J. A. Guttman**; Simon Fraser University, Burnaby, BC, CANADA.

Listeria monocytogenes commander the actin filaments of their host cells to propel themselves throughout the host cytoplasm using actin-rich comet/rocket tails that form behind the advancing bacteria. ADP-ribosylation factor 6 (Arf6), a small Guanine triphosphate (GTP)- binding protein plays a variety of roles during endocytic events and actin-remodeling and has long been known to be involved in the initial invasion of *L. monocytogenes* into non-phagocytic epithelial cells. A key part of the virulence of *L. monocytogenes* is their ability to move from one cell to another. This cell-to-cell spreading involves actin tails pushing the bacteria into the host cell plasma membrane. These membrane protrusions form corresponding invaginations in the neighbouring cells allowing for the uptake of the bacteria into the neighbouring cells. Using immunofluorescence microscopy and Arf6-GFP we demonstrate that Arf6 is present on both the *L. monocytogenes* protrusions and their corresponding invaginations.

P2596/B855

The Host GTPase Arf1 and Its Effectors Ap1 and Pick1 Stimulate Actin Polymerization and Exocytosis to Promote Entry of *Listeria*.

K. Ireton, S. Saila, G. Gywanwali, M. Hussain, A. Gianfelice; University of Otago, Dunedin, NEW ZEALAND.

Listeria monocytogenes is a food-borne bacterium that causes gastroenteritis, meningitis, or abortion. Critical for disease is the ability of *Listeria* to induce its internalization ('entry') into human epithelial cells. One of the major pathways of *Listeria* entry is mediated by binding of the bacterial surface protein InlB to its host receptor the Met receptor tyrosine kinase. InlB/Met interaction stimulates uptake of *Listeria* by inducing two host processes: localized polymerization of the actin cytoskeleton and focal exocytosis. How actin cytoskeletal changes and exocytosis are controlled during entry is not well understood. One group of mammalian proteins that has the potential to control actin filament assembly and exocytosis is Arf family GTPases the objective of this study was to investigate the role of these GTPases in infection of human cells with *Listeria*. Our results indicate an important role for the GTPase Arf1 and its effectors AP1 and PICK1 in actin polymerization and exocytosis during InlB-dependent uptake. Depletion of Arf1 by RNAi or inhibition of Arf1 activity using a dominant negative allele impaired InlB-dependent internalization, indicating an important role for Arf1 in this process. InlB stimulated an increase in the GTP-bound form of Arf1, demonstrating that this bacterial protein activates Arf1. RNAi and immunolocalization studies indicated that Arf1 controls exocytosis and actin polymerization during entry by recruiting the effectors AP1 and PICK1 to the plasma membrane. In turn, AP1 and PICK1 promoted plasma membrane translocation of both Filamin a (FlnA) and Exo70, two host proteins previously found to mediate exocytosis during InlB-dependent internalization. PICK1 mediated recruitment of Exo70, but not FlnA. Collectively these results indicate that Arf1, AP1, and PICK1 stimulate exocytosis by redistributing FlnA and Exo70 to the plasma membrane. We propose that Arf1, AP1, and PICK1 serve as key coordinators of actin polymerization and exocytosis during infection of host cells by *Listeria.*

P2597/B856

Determining the Role of E-cadherin in Promoting *Listeria Monocytogenes* Cell-to-cell Spread in Epithelial Monolayers.

P. Radhakrishnan[1], F. E. Ortega[1], J. A. Theriot[2]; [1]Stanford University, Stanford, CA, [2]University of Washington, Seattle, WA.

Listeria monocytogenes is a bacterial pathogen that is able to spread between adjacent cells in an epithelial monolayer without exposure to the extracellular space. While certain bacterial factors that mediate *L. monocytogenes* cell-to-cell spread have been identified, there is little understanding of how host cell factors directly facilitate spread from one cell to the other. The cell junction protein E-cadherin has been shown to strongly enhance cell-to-cell spread for other intracellular pathogens and might play a role in *L. monocytogenes* as well. To study E-cadherin's role in *L. monocytogenes* cell-to-cell spread, we transduced A431D cells, which do not express endogenous E-cadherin, with wild-type E-cadherin or delta cyto E-cadherin that lacks E-cadherin's cytoplasmic domain. Spread efficacy was greater between cells expressing WT E-cadherin than cells expressing delta cyto or no E-cadherin, suggesting that E-cadherin's cytoplasmic domain contributes to spread. Moreover, *L. monocytogenes* spread more efficiently between two neighboring WT E-cad cells than from a WT E-cad donor to a null E-cad recipient

cell. This leads us to conclude that E-cadherin's cytoplasmic domain participates in spread at the recipient side of cell contacts. As EGF enhanced spread in cells expressing WT E-cadherin and not in cells expressing delta cyto E-cadherin, we hypothesized that E-cadherin's contribution to spread might arise from its ability to bind caveolin-1 and undergo endocytosis. In this scenario, donor cell protrusions containing *L. monocytogenes* would be internalized into the recipient cell simultaneous with E-cadherin through a caveolin-dependent process. In support of this hypothesis, we have evidence showing that blocking caveolin-mediated endocytosis with the drug filipin and preventing E-cadherin's interaction with caveolin using the caveolin-scaffolding domain peptide, cavtratin, both reduce *L. monocytogenes* cell-to-cell spread in WT E-cad cells but not delta cyto E-cad cells. We also found that slowing down E-cadherin turnover through an orthogonal method, by expressing a version of E-cadherin that is unable to bind the ubiquitin ligase, hakai, also results in less efficient *L. monocytogenes* cell-to-cell spread. Therefore, caveolin-mediated internalization of E-cadherin is a process used by *L. monocytogenes to* spread between neighboring epithelial cells.

P2598/B857

***L. Pneumophila* Secreted Effector Protein LegC7 Facilitates Fusion of Endosomal and ER-derived Compartments in *S. Cerevisiae*.**

N. K. Glueck, K. M. O'Brien, V. J. Starai; University of Georgia, Athens, GA.

L. pneumophila is an opportunistic bacterial intracellular pathogen and the causative agent of Legionnaires' disease. Inside human alveolar macrophages, *L. pneumophila* secretes >300 effector proteins into the host cell via a Type IV secretion system, thus allowing *L. pneumophila* to avoid lysosomal degradation and recruit host ER-derived vesicles to the Legionella-containing vacuole (LCV). One such effector protein, LegC7, has been previously shown to disrupt normal endosomal traffic when expressed in yeast, although the basis for this activity was not discovered. In this study, we find that CORVET/HOPS tethering complex mutants suppress the LegC7-induced growth inhibition of yeast and that LegC7 appears to strongly colocalize with Vps8p, suggesting a role for CORVET in LegC7 activity in vivo. In addition, LegC7 colocalizes with Sec63p, induces abnormal ER morphology upon expression, and causes the vacuolar protease-dependent degradation of ER luminal protein Kar2p. These phenotypes are suppressed in *vps33Δ* strains, suggesting a role for CORVET/HOPS in the LegC7-dependent disruption of normal ER physiology. Furthermore, flow cytometry analysis of cells expressing an ER lumen-directed, redox-sensitive GFP reveals that LegC7 expression also induces further oxidation of the ER lumen, and a split-GFP study suggests that mixing of ER-derived compartment with endosomes occurs during LegC7 expression. These data provide strong evidence that LegC7 facilitates the fusion of ER-derived vesicles directly with endosomal compartments in yeast, which implicates LegC7 in the recruitment of ER-derived vesicles to the LCV with the help of host membrane tethering machinery in human alveolar macrophages during a *L. pneumophila* infection.

P2599/B858

Identification of Novel *Legionella*-Resistant Genes in *Dictyostelium*.

D. S. Pal[1], T. J. O'Connor[2], P. N. Devreotes[1]; [1]Department of Cell Biology and Center for Cell Dynamics, School of Medicine, Johns Hopkins University, Baltimore, MD, [2]Department of Biological Chemistry, School of Medicine, Johns Hopkins University, Baltimore, MD.

Studies in the social amoeba, *Dictyostelium discoideum*, have led to the identification of a variety of host genes that modulate intracellular growth of several pathogens, including *Legionella pneumophila* and *Mycobacterium marinum.* However, there is a dearth of information regarding molecular mechanisms of host resistance towards these infectious organisms. In this study, we identified several new genes in *Dictyostelium* which confer resistance to infection caused by *L. pneumophila*. To identify resistance-associated genes, we developed a novel 'resistance assay' using the *Legionella*-susceptible wild type and -resistant Nramp1-overexpressing *Dictyostelium* strains as controls. In this assay, at 96 hours post-infection, *Legionella*-infected Nramp1-overexpressing cells could be significantly recovered in liquid culture medium as opposed to infected wild type cells which showed negligible growth. Using this screening assay, we investigated 18 defined, single gene deletion *Dictyostelium* mutants for resistance to *Legionella* infection. Of these, 4 mutants, encompassing defects in phagocytosis, vesicle trafficking, development or chemotaxis, showed 6- to 400-fold increase in resistance to infection, in comparison to wild type cells. Interestingly, resistance to bacterial infection in these mutant strains increased a further 2.5- to 8-fold upon overexpressing the Nramp1 protein in them. These results suggest that aberrations in expression of multiple host genes confer increased host resistance to infection. Encouraged by these results, we are currently attempting to introduce different combinations of these newly identified mutations in *Dictyostelium* for deciphering host mechanisms which provide resistance to *Legionella* and other intracellular bacterial pathogens.

P2600/B859

Characterization of a Ubiquitin-Associated Bacterial Effector Protein.

C. Pike, R. Noll, R. Neunuebel; University of Delaware, Newark, DE.

Many intracellular bacterial pathogens survive within eukaryotic host cells by establishing and maintaining a replication-permissive membrane-bound compartment. *Legionella pneumophila*, the causative agent of Legionnaires' disease, establishes its intracellular niche within phagocytic cells by using a specialized secretion system to translocate over 350 effector proteins that can manipulate various host cell components. However, the majority of these effector proteins have yet to be characterized. Here we report Lpg2411 as a novel ubiquitin-associated effector that is translocated during late stages of macrophage infection. Secondary structure predictions revealed Lpg2411 has limited homology to a ubiquitin C-terminal hydrolase. When ectopically produced in HeLa cells, mCherry-Lpg2411 extensively co-localizes with ubiquitin and a Co-IP of mCherry-Lpg2411 from HEK293T lysates revealed Lpg2411 interacts with poly-ubiquitinated proteins. Lpg2411 displays a dynamic localization pattern when translocated into macrophages. HA-tagged Lpg2411 was observed on intracellular tubular structures and punctae as well as plasma membrane-blebbing structures and cellular extensions of infected host cells. Cellular events that occur during late infection are not well established, thus further studies on Lpg2411 will reveal insight into host-pathogen dynamics during late infection.

Isoform-specific Ras Recruitment to Vacuolar Membranes by the Intracellular Pathogen*Legionella Pneumophila*.

C. Williamson[1], S. Lehman[2], N. Ellis[1], M. Jarnik[1], M. Machner[1]; [1]National Institute of Child Health and Human Development, NIH, Bethesda, MD, [2]National Institute of Child Health and Human Development, NIH, Gaithersberg, MD.

The intracellular bacterial pathogen *Legionella pneumophila* (Lp) is the primary cause of the most common water-borne illness in the US, a severe pneumonia called Legionnaire's disease. Internalized into human host cells by phagocytosis, an Lp bacterium converts the phagocytic vesicle surrounding it during entry into a protective, membrane enclosed, replication compartment called the *Legionella*-containing vacuole (LCV). It achieves this membrane conversion by secreting over 300 bacterial effector proteins into it's host via a type IV secretion system. While characterizing host endolysosomal protein trafficking during Lp infection in live cells, we discovered that the small GTPase NRas, but not its homologs KRas or HRas, is recruited to the *Legionella*-containing vacuole (LCV) by a bacterial effector-dependent mechanism. Once established, NRas recruitment to the LCV was maintained until late times of infection. Ras GTPases are molecular switches that can signal from cellular membranes to regulate a number of fundamental processes involved in growth and survival in all eukaryotes. The essential role of Ras in cell biology makes it a fitting target for pathogens seeking to usurp control of host cell machineries. We sought to define the mechanism and signaling consequences of selective NRas recruitment to the LCV. Human Ras isoforms are targeted to membranes by residues within their C-terminal tails, and differ slightly in their intracellular distribution as well as in their ability to signal on endomembranes. We found the C-terminal tail of NRas was necessary and sufficient for its recruitment to the LCV during infection, requiring both its farnesylation and single palmitoylation site. Interestingly, we could direct HRas recruitment to the LCV by mutating its tail domain to similarly permit farnesylation plus a single palmitoylation. As has been previously reported, this mutation shifts steady state HRas to accumulate more on Golgi membranes compared to wild-type. Selectivity for NRas recruitment to the LCV thus depends on its unique PTM profile, and potentially from the Golgi enrichment afforded by such. A single secreted Lp effector protein, designated Defects in NRas Recruitment (DenR), was found to mediate LCV recruitment of NRas, and partially colocalized on membranes with NRas during ectopic expression in cells. Additionally, both constitutively active NRas as well as an activate-Ras reporter (Halo-Raf-1 Ras-binding-domain) could be detected on LCV throughout infection, suggesting the formation of a presistent NRas signaling compartment. These results provide new insight into the manipulation of Ras GTPases during pathogen infection, and may more broadly offer novel understandings of the differential regulation of Ras protooncogenes in health and disease.

P2602/B861

Discovering the Function of the Phosphoinositide-binding *Legionella* Effector, Lpg0405.

R. Noll, C. Pike, R. Neunuebel; University of Delaware, Newark, DE.

Phosphoinositide (PI) lipids have proven to be a common target for efficient localization of various pathogens' effector proteins in the host cell. As organelle identity is in part dictated by the species of phosphoinositide present, effectors have acquired PI-binding domains to concentrate at specific locations. *Legionella pneumophila*, the causative agent of the potentially fatal pneumonia termed Legionnaires' disease, has been found to encode a number of effectors that contain these lipid-binding domains that contribute to this pathogen's ability to survive inside human macrophages. *Legionella* avoids degradation by using these effector proteins to prevent the host lysosomes from fusing with the *Legionella*-containing vacuole (LCV). We have recently identified, through an in *vitro* lipid binding assay, that an additional *Legionella* effector, Lpg0405, possesses the ability to bind to PIs. In transiently transfected mammalian cells, mCherry-Lpg0405 showed extensive colocalization with GFP-2xFYVE, a PI(3)P biosensor, and but not GFP-P4Mx2, a PI(4)P biosensor. The lipid-binding domain appears to be

present in the N-terminus of the protein since this fragment, but not the C-terminal fragment, shows membrane localization. Upon depletion of PI(3)P by the PI3-kinase inhibitor, wortmannin, mCherry-Lpg0405's localization became cytosolic. Therefore, PI binding is important for localization of Lpg0405 to cellular membranes. Lpg0405 also showed extensive colocalization with a lysosomal marker, LAMP1. The association with these membrane compartments may hint at a role in preventing lysosomal maturation, an important hallmark of *Legionella* infection. Furthermore, Lpg0405 shows interaction with another *Legionella* effector, Lpg2411 and could be functioning together during infection.

***Ehrlichia Chaffeensis* Trp120 Interacts with Notch Epidermal Growth Factor Domains to Activate Notch Signaling .**

L. Patterson, J. McBride; University of Texas Medical Branch, Galveston TX, Galveston, TX.

Ehrlichia chaffeensis is a small obligately, intracellular gram-negative bacterium, and the etiological agent of human monocytotropic ehrlichiosis (HME), a life-threatening emerging tick-borne zoonosis. Recently, we have shown that the mechanisms whereby *E. chaffeensis* evades host defenses of the macrophage appear to involve activation of Wnt and Notch signaling. Various molecular-based strategies are used by *E. chaffeensis* for intracellular survival, including host-pathogen interactions by secreted tandem repeat protein effectors. Interestingly, TRP120 has been shown to interact with proteins important for activation and regulation of conserved signaling pathways; specifically, Wnt, Notch and Sonic Hedgehog. TRP120 has been shown to directly interact with ADAM17, a Notch metalloprotease, and FBW7, a Notch antagonist. Further, colocalization of TRP120 with both ADAM17 and the Notch-1 receptor has been demonstrated. Ligand-receptor interactions of Notch ligands and Notch-1 occur through direct binding events at epidermal growth factor-like repeats (EGFs) in the extracellular domain (NECD) of the receptor. Importantly the defined ligand binding domain of Notch-1 are EGFs 11-13. Thus, we hypothesize that *E. chaffeensis* TRP120 is a novel non-canonical Notch ligand that activates Notch signaling via tandem repeat amino acids molecularly interacting with NECD-EGF domains 11- 13. We have demonstrated homology of TRP120 and Notch ligands. Specifically, a short motif in TRP120-TR, EDDT, shares homology with Notch ligands. Using surface plasmon resonance, we have determined direct binding of TRP120 and Notch-1 using a Notch-1 recombinant protein containing EGFs 1-13. We have further demonstrated that TRP120-TR and TRP120-NTD are responsible for Notch activation and have currently identified a 32-amino acid motif, inclusive of EDDT, that is required for Notch activation. These results indicate that a specific TRP120-TR sequence is important for the activation of Notch. Understanding the pathobiology of intracellular pathogens may allow for the development of novel therapeutics by targeting host-pathogen protein- protein interactions.

P2604/B863

The Polarity of Epithelial Cells Regulates *Neisseria Gonorrhoeae* Infectivity.

Q. Yu, L. Wang, D. Stein, W. Song; university of maryland college park, College Park, MD.

Neisseria gonorrhoeae (GC) establishes infection in women from the cervix, the gate of the female reproductive tract. To establish infection, GC have to overcome the cervical epithelium. The cervical epithelium is highly heterogeneous, from non-polarized stratified ectocervical epithelial cells to polarized columnar endocervical epithelial cells. Columnar epithelial cells exhibit a polarized distribution of host receptors, the actin cytoskeleton, and form cell-cell junction (the apical junction) supported by

perijunctional actomyosin ring. Stratified epithelial cells display a non-polarized distribution of the actin cytoskeleton and adherens junction. Our previous studies showed that distinct properties of cervical epithelial cells affect GC infectivity in corresponding cervical regions. However, whether the difference in the polarity of cervical epithelial cells, which associates with cell morphology, actin organization, and host receptor distribution, contributes to the differential infectivity of GC in the ectocervix and endocervix is unknown. To address this question, we utilized a non-polarized and polarized epithelial cell model generated from the same cell line on transwells and the human cervical tissue explant model. While GC adhered to both non-polarized and polarized epithelial cells to a similar level, GC invaded into non-polarized epithelial cells more efficiently than into polarized epithelial cells. The expression of phase variable Opa (Opa+) on GC enhanced both GC adhesion and invasion, compared to an Opa deletion mutant (ΔOpa). Inoculation of Opa+ GC induced microvilli elongation in non-polarized epithelial cells, which was concurrent with F-actin recruitment at GC adherent sites. However, we only observed the similar F-actin recruitment in the epithelial cells exfoliated from the ectocervix but not those remained in the ectocervical epithelium. In contrast, inoculation of ΔOpa GC caused a massive disruption of microvilli at the apical surface of polarized epithelial cells, which was concurrent with non-muscle myosin II (NMII)-dependent reduction of F-actin at GC adherent sites of both polarized cell line model and endocervical epithelial cells in tissue explants. GC inoculation only induced intracellular calcium in polarized, but not in non-polarized epithelial cells, which was responsible for NMII activation. Overall, these results suggest that the level of epithelial cell polarity regulates GC infectivity by altering the cytoskeletal and morphological responses of epithelial cells to GC and GC surface molecules.

P2605/B864

Effect of *Helicobacter Pylori O*N the Intercellular Junctions of Pancreatic Cells.

A. Betanzos[1], E. Hurtado-Monzon[1], R. Gaspar-Lino[1], N. Velazquez-Guadarrama[2], J. Espinosa-Rivero[3], C. Bañuelos[1]; [1]Center for Research and Advanced Studies of National Polytechnic Institute, Mexico City, MEXICO, [2]Children's Hospital of Mexico Federico Gomez, Mexico City, MEXICO, [3]Justo Sierra University, Mexico City, MEXICO.

Helicobacter pylori is a gram-negative bacterium known for its damage to the stomach. However, in recent years it has been detected in other human body parts as pancreas, related to different extragastric diseases. *H. pylori* affects the gastric epithelium by damaging the intercellular junctions (ICJs) with the participation of several virulence factors, allowing the long-term infection. The injury on ICJs could be related to the bacterium' ability for invading other organs. Therefore, the aim of this work is evaluating the effect of *H. pylori* on IJCs of pancreatic cells. By using epithelial cells BxPC-3 derived from human pancreatic ductal adenocarcinoma and as control AGS gastric cells, we evaluated the alterations produced by *H. pylori* infection. The cytopathic effect was measured by retention of methylene blue at different MOI (1:50, 1:100, 1:500 and 1:1000), and after 24 h we observed destruction of pancreatic cell monolayers, similarly as control gastric cells in a MOI-dependent manner, reaching up to 22%. Regarding cellular viability, both cell types decreased up to 30% their viability. Despite the significant morphological changes (11%) produced by *H. pylori* on pancreatic cells, they exhibited a scarce hummingbird phenotype (2%), versus the 63% observed by AGS cells. The permeability of pancreatic cells, was evaluated by TEER measurements and results evidenced a TEER decrease of 30% and 37% at MOI 1:500 after 24 h of pancreatic and gastric cells, respectively. In agreement, the occludin expression diminished in pancreatic cells, suggesting that other ICJ proteins could be also modified. Based on those results we conclude that *H. pylori* is capable to infect pancreatic

cells and produce morphological changes, rearranging the actin cytoskeleton and disrupting the epithelial barrier by injuring ICJs, as is has been demonstrated for gastric cells.

ALIS Adventures in Macrophage-land: Functional Characterization of Aggresome-like Induced Structures (ALIS) in Response to Infection.

A. BHATNAGAR[1], S. Raja[2], S. Mahalingam[2], S. Srinivasula[1]; [1]Indian Institute for Science Education and Research (IISER-TVM), Kerala, Thiruvananthapuram, INDIA, [2]Indian Institute of Technology - Madras, Chennai, INDIA.

Recognition of pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns (DAMPs) activate the initial immune response in higher eukaryotes. Macrophages and dendritic cells (DCs) serve as sentinels of host defence against foreign invaders. These cells respond to a repertoire of conserved microbial molecules that are recognized by a collection of pattern recognition receptors (PRRs), like Toll-like receptors (TLRs). PAMP recognition by TLRs induces the accumulation of microtubule-associated protein 1A/1B-light chain 3 (LC3) in punctate structures. Macrophage cells form aggresome-like induced structures (ALIS) in response to lipopolysaccharide (LPS) and *E.coli* stimulation via TLR4 signalling. These are detergent-insoluble, non-membranous, ubiquitin, p62/sequestome1 and LC3-positive bodies. In response to infection, immune cells are known to upregulate the p62 mRNA and protein levels. Thus, the formation of ALIS and the presence of p62 in ALIS indicates their role in host defence. To gain insight into the function and composition of ALIS, we are using cell biology, imaging and biochemical approaches. Apart from LPS, we have observed ALIS formation in response to *E. coli* particles*, Bacillus subtilis and Mycobacterium smegmatis*. This indicates that cells sequester these structures via other PRRs as well. Live-imaging microscopy shows the onset of formation of ALIS upon infection. ALIS also appears to associate with vacuoles formed in response to LPS stimulation and the bacteria containing phagophores. Characterization of ALIS using super-resolution structured illumination microscopy (SIM) provides architectural information. We observed that ALIS is an organized complex. This organization is dynamic and changes with the stage of structural maturity. Biochemical enrichment of ALIS was employed to investigate its components by mass spectrometry. Our data indicate the presence of several immune-related proteins. These results suggest that ALIS assembly is a part of the hitherto unknown immune response.

Genomic Determinants Underlying Rodenticidal Properties of the *Salmonella Enteritidis* Var. Issatschenko.

M. V. Belousov[1,2], A. E. Shikov[1,2], M. E. Belousova[1], A. A. Nizhnikov[1,2], K. S. An tonets[1,2]; [1]ARRIAM, Saint Petersburg, RUSSIAN FEDERATION, [2]St Petersburg University, Saint Petersburg, RUSSIAN FEDERATION.

Different strains of *Salmonella enterica* can infect a wide range of hosts, including rodents, well-known agricultural pests. The losses from rodents in agriculture comprise up to 28% of the potential yield, which forces to constantly undertake measures against them. Several chemical pesticides (rodenticides) are known to control the numbers of these pests. However, these substances can pose danger to warm-blooded animals and humans. At the end of the 19th century, several strains of *Salmonella enteritidis* with rodent-specific action were isolated by the eminent Russian scientist Boris Issatschenko. Despite the wide usage of bacteria var. Issatschenko at the beginning of the 20th century, there is still no

accurate data on the molecular basis underlying specificity of their virulence factors. These strains represent unique model for studying mechanisms of the host specificity, as they can affect only certain species of the order Rodentia. In the present work we assembled the complete genome of *S. enteritidis* var. Issatschenko strains from the ARRIAM collection using the Nanopore long-read and Illumina short-read sequencing technologies. Having compared the *S. enteritidis* var. Issatschenko genome with other publicly available assemblies of *S. enteritidis* we have found a set of unique single nucleotide polymorphisms in protein-encoding genes of the bacterium Issatschenko. Part of these SNPs is located in coding regions of genes whose protein products are known to be involved in the virulence of *Salmonella*. Summing up, our data indicate that mutations in several genes encoding virulence factors of *Salmonella enteritidis* var. Issatschenko are likely to be responsible for highly specific rodenticidal properties of the. This work was supported by the Russian Science Foundation (Grant No 19-76-00026).

P2608/B867

Internalization of *Borrelia Burgdorferi* into Human Cardiomyocyte AC16 Cells.

B. L. Clarke, S. RedBrook; University of Minnesota-Duluth, Duluth, MN.

In this study, we tested if *Borrelia burgdorferi* (Bb), an obligate parasitic spirochete that causes Lyme disease, can enter into cardiomyocytes. Approximately 4% of advanced Lyme disease cases exhibit carditis involving an atrioventricular blockade and the development of dilated cardiomyopathy. Bb endocytosed by phagocytic cells are not dependent on serum complement; and proceeds by a non-conical internalization process known as “coiling phagocytosis”. We tested for Bb internalization into several different cell types to determine if penetration is restricted to professional phagocytic cells. Our objective was to determine if entry results from spirochetal penetration, or as a consequence of host-cell phagocytosis. We tracked the entry of spirochetes into the human cardiomyocyte AC16 and mouse fibroblasts 3T3 cell lines by confocal microscopy using a recombinant Bb (B31-strain) engineered to express green fluorescent protein (GFP-Bb). Internalization studies were performed on cells adherent to coverslips. Cells were incubated in RPMI1640 plus 5% FCS at 37^{o}C in 5% CO_2 for 60 min. Cover slips were washed with ice cold PBS three times, fixed with 1% PFA, washed again, and stained with DAPI to label the nuclei. Labeled cells were inspected for internalized GFP-Bb spirochetes. These experiments were replicated in parallel using RAW 264.7 macrophage and JAWSII dendritic cells to demonstrate the processing of intracellular GFP-Bb by professional phagocytic cells. Cell surface labeling used anti-CD44 for AC16 and 3T3 cells, anti-CD86 for macrophage, and anti-CD11c for dendritic cells to demarcate intracellular regions. The fluorescence from GFP-Bb was identified at the cell surface and within internal compartments showing various stages of internalization. Incubation of the cells at 4^{o}C blocks internalization, and incubation at 16^{o}C permits a lower rate of internalization but halts intracellular membrane fusion events. A second experimental series was performed to monitor the processing of internalized GFP-Bb by professional phagocytic cells. After 60 min, cells with internalized GFP-Bb were washed with ice cold media to remove unbound motile extracellular spirochetes and either returned to 37^{o}C to sustain processing of internalized spirochetal cargo, or 16^{o}C to prevent phagosomal hydrolysis. The appearance of fluorescence was detectable following the 60 min incubation at 37^{o}C that was comparable to 16^{o}C, suggesting that low-pH associated processes within the host phagolysosomal compartments were compromised by Bb. These results support the model of intracellular parasites modulating intracellular functions to acquire a “safe-harbor” within host compartments, providing insight into a putative cellular mechanism for persistent borreliosis.

P2609/B868

Subversion of Host Endocytic Trafficking Pathway by the *Legionella Pneumophila* Effector Protein an kx.

B. Romero Duenas, R. Neunuebel; University of Delaware, Newark, DE.

The intracellular bacterium *Legionella pneumophila* proliferates within amoebae and human alveolar macrophages, and it is the causative agent of Legionnaires' disease, a life-threatening pneumonia. During infection, *L. pneumophila* remains enclosed in a membrane-derived vacuole, *Legionella*-containing vacuole (LCV) and survives by translocating effector proteins into the host cytosol. Several of these effectors manipulate Rab GTPases to disrupt vesicular trafficking pathways. The *Legionella* effector protein an kX is a phosphocholine transferases that covalently modifies Rab35 and facilitates avoidance of pathogen degradation. We hypothesize that an kX manipulates host endocytic trafficking pathways to prevent fusion of the LCV with endocytic compartments, to avoid degradation via phagosome maturation. We determined an kX's subcellular localization to the plasma membrane and tubular membrane compartments in mammalian cells by using superresolution microscopy and immunogold transmission electron microscopy. We observed that an kX colocalizes with Rab35, a Rab GTPase in charge to regulate the recycling of cargo back to the plasma membrane in the fast recycling pathway. We quantified the levels of an kX's disruption of endocytic trafficking by using the DQ Red BSA assay. Furthermore, we determined an kX's localization after translocation during infection of amoeba, *Legionella's* natural host. Finally, we investigate an kX's mechanism to disrupt endocytic trafficking and help prevent degradation in amoeba.

Studying Pericyte-endothelial Interaction during an giogenesis in Medium Throughput Microfluidic Culture Platform.

J. Joore, B. Kramer, A. Stuber, B. de Wagenaar, A. Nicolas, D. Kurek, H. Lanz, L. J. van den Broek; Mimetas B.V., Leiden, NETHERLANDS.

The transition from 2D to 3D cell culture and co-cultures of more relevant cell types are the first steps towards more physiological relevant models in *vitro*. Previously we showed that a standardized microfluidic 3D tissue culture platform, called OrganoPlate® can be used to generate precisely controlled gradients, pump-free and in medium throughput (n=40) for growing blood vessels and inducing controlled 3D angiogenic sprouting [1]. Here we integrated pericytes into the vascular model to look at cell-cell interaction during angiogenesis. Endothelial cells are grown against an extracellular matrix gel and form a vessel/tubule due to the flow. Pericytes are seeded in the ECM or co-seeded with the endothelial cells. The blood vessel is exposed to angiogenic compounds to direct sprouting into the ECM gel. When pericytes were co-seeded with endothelial cells sprouts with a perfusable lumen were formed. In contrast pericytes in the ECM inhibited sprouting. Pericytes in the parental vessel also started to express high levels of α-sma. This model can be used as an in *vitro* screening platform to unravel the important drivers in angiogenesis and vasculogenesis and the involvement of pericytes in these processes. Profilin1 Is an Important Regulator of Developmental and Pathological Retinal Neovascularization.

D. Gau[1], L. Vignaud[2], D. Koes[1], D. Boone[1], X. Guillonneau[2], P. Roy[1]; [1]University of Pittsburgh, Pittsburgh, PA, [2]Institute de la Vision, Paris, FRANCE.

Angiogenesis is an essential process of neovascularization during development and tissue repair. However, aberrant angiogenesis exacerbates many diseases including proliferative diabetic retinopathy (PDR), a leading cause of blindness worldwide. Our bioinformatics analyses revealed that actin-binding protein Profilin1 (Pfn1), an important regulator of actin cytoskeleton, is transcriptionally upregulated in vascular endothelial cells (EC) derived from retina of PDR patients prompting us to explore the role of Pfn1 in developmental and pathological angiogenesis in the retina. To this end, we generated for the first time an inducible vascular EC-selective Pfn1 knockout mouse model to demonstrate that post-natal deletion of the *Pfn1* gene in EC leads to prominent reduction in endothelial F-actin abundance, vascular density and branching during developmental angiogenesis in the retina. By computationally guided biochemical screen, we further identified novel small molecule antagonists of Pfn1:actin interaction that are non-cytotoxic, inhibit EC migration and proliferation (key features of angiogenesis) and exhibit anti-antigenic activity on various types of vascular EC, regardless of their tissue of origin, in *vitro*, *ex vivo* and in *vivo. To* model pathological neovascularization in the retina as occurs in PDR, we subjected newborn mice to oxygen-induced retinopathy (OIR) where hyperoxic-to-normoxic transition (mimics a hypoxic shift) elicits strong VEGF-driven pathological neovascular response in the retina. We provide evidence for transcriptional upregulation of Pfn1 in the OIR retina, and further demonstrate that small molecule intervention of Pfn1:actin interaction through intravitreal administration attenuates pathological retinal neovascularization. In summary, these findings provide the first direct evidence of Pfn1's indispensable role in mammalian developmental angiogenesis in *vivo* and a proof-of-concept of susceptibility of pathological angiogenesis to small molecule intervention of Pfn1, laying a conceptual foundation for targeting Pfn1 in angiogenesis-dependent diseases.

The Concept of Personalized Cell-mediated Gene Therapy Using Gene Modified Leucoconcentrate (GML) Prepared from the Patient's Peripheral Blood.

M. E. Sokolov[1], R. R. Islamov[1], A. A. Izmailov[1], F. V. Bashirov[1], A. R. Khamitov[1], I. A. Munasipov[1], I. F. Galyautdinov[1], M. A. Davleeva[1], O. V. Zubkova[2], M. M. Shmarov[2], D. Y. Logunov[2], B. S. Naroditskiy[2], R. G. Turaev[3]; [1]Kazan State Medical University, Kazan, RUSSIAN FEDERATION, [2]Gamaleya Research Institute of Epidemiology and Microbiology, Moscow, RUSSIAN FEDERATION, [3]The Republican Blood Center of the Ministry of Health of the Republic of Tatarstan, Kazan, RUSSIAN FEDERATION.

Previously we have shown that umbilical cord blood mononuclear cells transduced with adenoviral vectors carrying recombinant human genes is the promising therapeutic approach for cell-mediated gene therapy. Herein for the first time we propose the usage of the peripheral blood leucoconcentrate as a cell system for temporary production of the recombinant biologically active molecules for correction of certain pathological conditions. The mini-pig's peripheral blood was collected into the plastic blood bag. Preparation of the leucoconcentrate and transduction of WBC with chimeric

adenoviral vector (Ad5/35) carrying reporter green fluorescent protein (GFP) gene was performed in the plastic bag. After transduction for 12 hours gene modified leucoconcentrate (GML) was washed out with saline and the plastic bag was kept at room temperature before usage. At the next day after blood donation the mini-pigs were underwent to spinal cord injury and four hours after surgery were injected intravenously with GML. A week after surgery fluorescent microscopy study of the spinal cord sections at the site of injury and the white pulp of spleen revealed WBC expressing GFP. Thus the efficacy of transduction, migratory potential and secretory activity of WBC suggest their usage for temporary production of the specific recombinant biologically active molecules for pathogenetic therapy of the varied nosological form, such as trauma, ischemic, degenerative, autoimmune, infection and other diseases. Results of this study present a simple, safe and effective approach for personalized ex vivo gene therapy based on autoinfusion of GML. This study was supported by the grant of Russian Science Foundation No 16-15-00010.

The Role of Transglutaminase 2-ROS Vicious Cycle in Hyperglycemic Memory-mediated Vascular Dysfunction in Diabetic Aorta.

J. Lee[1], Y. Lee[1], H. Jeon[1], Y. Kim[1], K. Ha[1,2]; [1]Department of Molecular and Cellular Biochemistry, Kangwon National University school of medicine, Chuncheon, KOREA, REPUBLIC OF, [2]Scripps Korea antibody Institute, Chuncheon, KOREA, REPUBLIC OF.

Clinical trials suggest that hyperglycemic memory (HGM) is defined as the long-term diabetic vascular complications even after glycemic control in Type 1 and 2 diabetes ; However, the mechanisms underlying the cellular HGM induced by high glucose remain unclear. We hypothesized that a vicious cycle between transglutaminase 2 (TGase2) and intracellular reactive oxygen species (ROS) plays a key role in HGM-induced vascular dysfunction. We found that hyperglycemia induced persistent oxidative stress, expression of inflammatory adhesion molecules, and apoptosis in the aortic endothelium of HGM mice whose blood glucose levels had been normalized by insulin supplementation. TGase2 activation and ROS generation were in a vicious cycle in the aortic endothelium of HGM mice and also in human aortic endothelial cells after glucose normalization, which played a key role in the sustained expression of inflammatory adhesion molecules and apoptosis. Our findings suggest that the TGase2-ROS vicious cycle plays an important role in HGM-induced endothelial dysfunction.

P2614/B874

Regulation of Endothelial-derived *Pseudomonas Aeruginosa*-induced Secreted Beta Amyloid by Cystatin C.

R. Balczon[1], T. C. Stevens[2], S. Weintraub[3], T. Stevens[1]; [1]University of South Alabama, Mobile, AL, [2]Vanderbilt University, Nashville, TN, [3]University of Texas Health Science Center, San an tonio, TX.

Patients who survive hospital-acquired (nosocomial) pneumonia have elevated death rates in the first year following hospital discharge and exhibit additional deficiencies, including decreased memory function. These observations suggest that long-lived deleterious molecules may be produced during the initial infection. Using *Pseudomonas aeruginosa* as a model for nosocomial pneumonia, we demonstrated that infection of pulmonary microvascular endothelial cells (PMVECs) by *P. Aeruginosa* led to the release of cytotoxic oligomeric tau and beta amyloid by the PMVECs. Attempts to deplete the cytotoxins by ultracentrifugation demonstrated an initial increase in cytotoxic activity (one hour of

centrifugation at 150,000 x g) followed by a rapid depletion of cell killing activity at longer periods of centrifugation. Likewise, immuno-depletion of beta amyloid caused increased cytotoxic activity in the residual supernatant. Collectively, these results suggested that cytoprotective forms of beta amyloid, in addition to cytotoxic amyloids, are released during infection processes. To identify possible modulators of beta amyloid activity, mass spectrometry was performed of proteins secreted from PMVECs following infection by *P. Aeruginosa*. These analyses identified three potential regulators of beta amyloid in the secreted material, including gelsolin, clusterin, and cystatin C. Each of these proteins was immuno-depleted individually from bacterial-induced PMVEC secreted supernatant, and the depleted supernatants were added to cultured cells. No change in cytotoxic behavior was observed following depletion of either clusterin or gelsolin. However, supernatants depleted of cystatin C exhibited increased cytotoxic behavior demonstrating that secreted cystatin C has a protective effect. Subsequently, co-immunoprecipitation of cystatin C and beta amyloid was demonstrated. Moreover, cystatin C and beta amyloid pelleted during the first hour of centrifugation at 150,000 x g. Collectively, these data demonstrate that cystatin C is a negative regulator of beta amyloid-induced cytotoxicity following *P. Aeruginosa* infection and identify cystatin C as a potential target for intervention to alleviate the long-term consequences of nosocomial infection.

P2615/B875

Dissecting the Roles of Notch Receptors in Human Haematopoietic Stem Cells.

J. Carmelo[1,2], A. De Soure[2,3], F. Lampreia[1], F. An jos-Afonso[1]; [1]European Cancer Stem Cell Research Institute, Cardiff, UNITED KINGDOM, [2]Institute for Bioengineering and Biosciences, Lisbon, PORTUGAL, [3]Cancer Research UK, London, UNITED KINGDOM.

Haematopoietic stem cells (HSCs) reside at the top of the haematopoietic cells hierarchy and have the highest self-renewal and differentiation capacities, giving rise to more committed progenitors (HPCs) that become progressively more restricted in terms of their differentiation and self-renewal capacities. The Notch signalling pathway has been linked to cell fate decisions in haematopoiesis, although its role in the regulation of steady-state human HSCs is still largely unexplored. Activation of Notch signalling in *vitro* has been shown to promote self-renewal of HSPCs and has been explored for protocols of *ex vivo* expansion. Nonetheless, a more comprehensive study is necessary to clearly identify the functions of the different Notch receptors in HSPCs regulation.The expression of Notch receptors, NOTCH1 (N1) and NOTCH2 (N2), and their respective activation in UCB HSPCs were quantified at protein level. Both N1 and N2 receptors were found to be highly expressed on HSPC and HSC populations, with higher activation in HSCs. The roles of N1 and N2 receptors were evaluated through lentiviral shRNA-mediated gene silencing in UCB HSPCs, with average knockdown efficiencies of 72% and 89% (at the protein level) achieved for N1 and N2 receptor, respectively. In a long-term culture model to detect HSCs and immature progenitors, we observed that the number of primitive cells was not affected by either knockdown. However, N2 receptor silencing promoted a decrease in HSCs frequency while with N1 receptor silencing only an increase in immature progenitors was observed. In accordance, in a xenotransplantation assay we observed that, although the total human engraftment was not largely affected in primary transplants, N1 and N2 receptor silencing in the transplanted HSPCs promoted different phenotypic outcomes in *vivo*. N1 receptor silencing favoured myeloid over lymphoid differentiation and increased frequency of haematopoietic progenitors but had no effect in HSCs, whereas N2 receptor silencing significantly decreased HSCs frequency, had no effect in progenitor populations and a milder effect on differentiation.These results suggest that, although extracellular N1

and N2 receptors are both highly expressed on HSCs, activation of N2 receptor has a more determinant role in the fate of HSCs than N1 receptor and the respective genetic programs are under evaluation.

Heparin Blocks Foam Cell Formation and Reverse Cholesterol Transport.

M. Mori, A. Sato, M. Hikosaka, R. Motohashi, S. Kikuchi, M. Takahashi; Chiba Inst Sci, Cyoshi CHIBA, JAPAN.

[Objective] Heparin is a potent drug to inhibit blood coagulation. The property of this drug, it contains a lot of negative charged residue. To clear the effect of negative charged material against foarm cell formation and reduce proceeding atherosclerosis, foam cell formation and reverse cholesterol transport with /without Heparin , several PPAR agonists, ARB and vascular statins can be examined as positive and negative effertors to ABCA1 transcription and translocation **[Method]** LDL and sdLDL were prepared from human plasma by KBr density gradient separation. AcLDL and OxLDL were prepared by Acetic anhydrate treatment , CuSO4 oxidation respectively. Foam cells were prepared by J774 cells incubating with these modified LDL for 24-72hr, and cultured up to 3-6 days in the presence of LPDS +/- HDL and Heparin, PPAR agonists, ARB or statin. FC(Free cholesterol) rich lipid droplets were detected by Filipin staining. **[Results & Discussion]** FC-rich Lipid droplets were detected by Filipin staining in these modified LDL induced foam cells. Foam cell formation reduced markedly in the presence of Heparin. HDL, a potent material to remove FC from foam cell via ABCA1, ABCG7 pathway, did not affect to reverse cholesterol transport in heparin treated foam cells. However, Vascular statin molecules (Simvastatin, Atorvastatin) were well known as a potent activator of ABCA1 translocation in foam cells, also reduced FC-rich lipid droplet formation, and increase ABCA1 expression level in AcLDL, OxLDL induced foam cells. These materials did not recover FC translocation activity to HDL in Heparin treated foam cells. Considering FC rich lipid droplet formation, ARB molecules (Angiotensin II AT1 receptors blockers; Losartan, Irbesartan, Telmisartan) had a potent activity as well as PPAR alfa, gamma agonists, and reduce FC-rich lipid droplet formation, However, in the presence of Heparin, ARB did not affect on this activity. These significantly relationship of Heparin against AcLDL induced foam cells, among the FC-rich lipid droplet formation, reverse cholesterol transport and foam cell death may reflect to development of atherosclerosis correlated in IHD patients. Exogenous Mitochondria Regulate Intrinsic Apoptosis Pathway and Oxphos Function in Acute Hindlimb Ischemia.

J. Hwang, J. Lee, J. Kim, Y. Choi, M. Kim, Y. Choi; CHA University, Seongnam-si, KOREA, REPUBLIC OF.

Mitochondria, the critical role of survival and death in mammalian cells, are involved in such as calcium homeostasis, biogenesis, and regulation of apoptosis, reactive oxygen species production. As ischemic damage has been reported to be involved in mitochondrial dysfunction, new treatment of transplanting exogenous mitochondria into ischemic heart tissue before ischemic reperfusion have recently been reported. However, the therapeutic mechanism of transplanted mitochondria is still controversial. In this study, we determined whether transplanted mitochondria contribute to angiogenesis and oxidative phosphorylation (OXPHOS) via inhibition of the apoptosis pathway in acute ischemic hindlimb model. One week after mitochondria transplantation, blood flow was assessed by laser Doppler imaging. Ischemic limb significantly increased blood flow as well as skeletal muscle mass. The ischemic muscles

were harvested for detection of mitochondrial apoptotic markers and mitochondrial OXPHOS proteins. Consequently, the expression of OXPHOS protein was increased in the group injected with exogenous mitochondria. On the other hand, all expressions of Bcl-2, Bax, cytochrome c, caspase 3 and cleaved caspase 3 were decreased compared to the sham control group. Based on our results, new findings revealed that transplanted mitochondria inhibit cellular apoptosis and promote angiogenesis.

P2618/B878

Stromal Cells Promote Neovascular Invasion Across Tissue Interfaces.

H. A. Strobel[1], S. Labelle[2], L. Krishnan[3], J. Dale[3], A. Rauff[2], A. M. Poulson, IV[2], K. Aliaj[2], J. A. Weiss[2], J. B. Hoying[1]; [1]Advanced Solutions Life Sciences, Manchester, NH, [2]University of Utah, Salt Lake City, UT, [3]University of Louisville, Louisville, KY.

Rapid vascularization is essential for the survival of implanted and repairing tissues. Via angiogenesis, neovessels grow through tissue interfaces and create a network that is fully integrated with the existing microvasculature. Understanding the mechanisms that guide vessels across the interface between two tissues is essential for effectively supporting tissue vascularization. Towards this, we used an experimental tissue interface model involving a “core” plug of collagen gel embedded in a “field” of fresh collagen, resulting in two distinct regions separated by a thin, high-density layer of collagen as determined by second harmonic generation imaging (SHG) and scanning electron microscopy (SEM). In this model, we incorporate whole isolated microvessel fragments (intact capillaries, arterioles, venules) isolated from adipose tissue. We have previously shown that microvessels spontaneously sprout, grow, and connect when embedded in collagen. To model growth across the interface, microvessels were incorporated into the core region with or without stromal cells. Crossing events, where angiogenic neovessels grew across the interface, were counted, then normalized to both interface length and overall microvessel density. Microvessel density was quantified from images taken using a GE in cell 6500 confocal scanner. Without the additional stromal cells, neovessels grow and sprout within the core, but rarely cross this high-density interface; instead growing parallel to collagen fibrils of the interface. When stromal cells were incorporated into the core, neovessels crossed the interface and began to populate the field. When stromal cells were instead incorporated into the field (with microvessels in the core), even more crossings were recorded. SEM imaging indicated that crossing events do not grossly alter or degrade the interface structure. In the presence of a VEGF-A trap, neovessel crossing events were significantly reduced. However, VEGF-A alone was insufficient to stimulate crossing, suggesting a stromal cell-mediated, but VEGF-A dependent mechanism. Finally, we determined that macrophages are necessary for this process. Microvessels were incorporated with the complete stromal cell fraction or with stromal cells lacking CD11b/c^{+}. An increase in crossings was visible only when CD11b/c^{+} cells were present. This indicates that stromal cells, particularly tissue-resident macrophages, play a critical role in guiding neovessel growth during angiogenesis across tissue interfaces. We propose that these cells create a spatiotemporal gradient of VEGF, guiding neovessels across the interface. This suggests that inclusion of macrophages within a fabricated tissue would promote engraftment following implantation and accelerate graft perfusion

Lysyl Oxidase and MMP12 Directionally Regulate Age-associated Arterial Stiffening.

K. Bruun, R. Von Kleeck, I. Roberts, S. Brankovic, E. Hawthorne, R. Assoian; University of Pennsylvania, Philadelphie, PA.

Arterial stiffening is a hallmark of aging and a risk factor for cardiovascular disease (CVD). We have previously shown that arterial stiffening in mice develops between 12 to 24 months of age. In the premature aging disease Hutchinson-Gilford Progeria Syndrome (HGPS), patients display arterial stiffness at an early age, and typically die in their teenage years as a consequence of CVD. Here we have compared the process of arterial stiffening in normal and premature aging using carotid arteries isolated from WT and HGPS (LMNA608G/608G) mice. Pressure myography showed that carotid arteries of 2-month HGPS mice stiffened prematurely, with a circumferential stiffness similar to 24-month WT controls. Transmission electron microscopy (TEM) revealed increased amounts of collagen within the elastin folds of both 2-month HGPS and 24-month WT carotid arteries relative to 2-month WT controls. Additionally, immunostaining and RT-qPCR revealed increased expression of Lysyl oxidase (LOX) in young HGPS arteries, and an incremental increase of arterial LOX expression at 12-24 months in WT arteries. Moreover, treatment of HGPS mice with the pan-Lox inhibitor β-aminopropionitrile (BAPN) restored near-normal circumferential arterial mechanics to HGPS carotid arteries. LOX covalently crosslinks the newly synthesized fibrillar collagens and elastin to regulate their tensile strength, but since new elastin synthesis ends early in life, the LOX effect on arterial stiffness is probably restricted to collagen. Although similarly stiff circumferentially, the arteries of 24-month WT mice differed from young HGPS arteries in two ways. They displayed additional stiffening in the axial direction, and this correlated with a high prevalence of elastin breakage not seen in HGPS or the 2-month WT controls. Previous work in our lab showed that the abundance of MMP12, a potent elastase, increases as arteries stiffen with age. The deletion of MMP12 in mice significantly reduced the axial stiffening seen in normal aging whereas the circumferential stiffening of these arteries persisted. The arteries from 24-month MMP12 null mice also had a significant reduction in elastin breakage when compared to age-matched WT controls. These results associate age-dependent circumferential stiffening with Lox-mediated collagen crosslinking and axial stiffening with MMP12-mediated elastin degradation. Role of Liver Dysfunction in Blood Brain Barrier and Consequences to Alzheimers Disease.

P. Ahumada[1], D. Cabrera[1,2], J. Leon[3], M. Freire[3], R. Morales-Loyola[4], **L. Estrada**[1]; [1]Universidad Bernardo O Higgins, santiago, CHILE, [2]P. Universidad Catolica de Chile, Santiago, CHILE, [3]P. Universidad Catolica de Chile, santiago, CHILE, [4]The University of Texas Health Science Center, Houston, TX.

Alzheimers disease (AD) is the most common cause of dementia in older-aged people. During the last decade, it has become been clear that the synaptic loss and neuronal degeneration underlying cognitive impairments are caused by small aggregates termed Abeta oligomers. One key pathway that may underlie Abeta accumulation is dysfunction of the blood brain barrier (BBB). The BBB is a layer of tightly packed cells that regulates the flow of molecules between the brain and blood. There is evidence of BBB impairment and dysfunction in AD research models and patients. It remains unclear whether Abeta oligomer clearance through the BBB is affected by this impairment. The liver is a key organ mediating the clearance of Abeta from the circulation; thus, dysfunction of these organs can impair Abeta

clearance. Liver dysfunction occurs in multiple contexts, including nonalcoholic fatty liver disease (NAFLD), a common condition that is associated with obesity and inflammation. We hypothesize that NAFLD can intensify the AD-related BBB impairment to exacerbate AD pathology. The aim of our research was to evaluate the impact of NAFLD in AD pathology, specifically in Abeta-oligomer dynamics, BBB integrity, and LRP-1 levels. We used mice fed with a high fat diet as models of NAFLD/NASH. AD pathology was determined through histological staining with Thioflavin S, and Aβ-specific and GFAP antibodies. BBB integrity was followed by penetration studies and immunofluorescence for tight junctions proteins, and LRP-1 levels was determined by immunohistochemistry. We found that Abeta plaques and Abeta oligomers are increased in brain of NAFLD/NASH mice, while levels of occluding and ZO1 are decreased in BBB. LRP1 levels were reduced in liver of NAFLD/NASH affected mice. Altogether our results indicated that liver damage in the context of NAFLD/NASH, impairs liver Abeta clearance, and affects BBB integrity, with the involvement of LRP1. We anticipate NAFLD will exacerbate contribute to a vicious cycle that perpetuates the imbalance in peripheral Aβ-oligomer clearance as a result of liver dysfunction and chronic inflammation. Human Peripheral Blood Mononuclear Cell Expression of Stimulated by Retinoic Acid 6.

D. Duriancik; University of Michigan - Flint, Flint, MI.

Coined as the anti-infective vitamin, vitamin a has pleiotropic roles in immunity. Vitamin a deficiency results in impaired innate immunity and skewed adaptive immune responses towards inflammatory T helper type one responses at the expense of T helper type two responses. The objective of this study was to characterize the expression of the receptor for holo-retinol binding protein, stimulated by retinoic acid 6 (STRA6), which facilitates cellular retinol uptake. Holo-retinol binding protein also activates STRA6-dependent Janus kinase (JAK) 2 and signal transducer and activator of transcription (STAT) 5 signaling with eventual transcriptional up-regulation of suppressor of cytokine signaling (SOCS) 3. Multicolor flow cytometry and confocal microscopy was used to determine expression of STRA6 on human peripheral blood mononuclear cells. Expression of STRA6 was determined by median fluorescence intensity of STRA6 in B lymphocytes, T lymphocyte subsets, natural killer cell subsets, monocyte subsets, and dendritic cell subsets. Monocytes expressed significantly higher STRA6 than any mononuclear subset and B lymphocytes expressed significantly lower STRA6 than any mononuclear cell subset. T helper cells (CD4+) expressed significantly higher STRA6 than T cytotoxic cells (CD8+). The CD14-dim/CD16+ monocyte subset expressed significantly higher STRA6 than CD14+/CD16- and CD14+/CD16+ monocytes. There was no significant difference in STRA6 expression on natural killer cell subsets or dendritic cell subsets. The cell line retinal pigmented epithelial - 19 (ARPE-19) cells expressed high amounts of STRA6. However, confocal microscopy showed punctate intracellular staining of STRA6 in ARPE-19 cells instead of plasma membrane-associated staining. It is unknown if STRA6 is expressed on the plasma membrane or intracellularly in human peripheral blood mononuclear cells. Determining cellular localization of STRA6 in peripheral blood mononuclear cells is a future direction as well as mechanisms of regulation of STRA6 expression. These data provide a characterization of STRA6 expression by human immune cells which provide baseline data to investigate cellular uptake of vitamin A, as well as JAK-STAT-SOCS axis, in inflammatory and homeostatic conditions. The implications of the

data are an understanding of the vitamin a transport and STRA6 signaling in relation to immune cell energy metabolism as the JAK-STAT-SOCS signaling can reduce insulin sensitivity.

Effect of BIA 10-2474 in Salt-loaded Stroke-prone Spontaneously Hypertensive Rats.

N. M. Pires[1], K. Weber[2], P. Moser[1], M. Bonifácio[1], **P. Soares-da-Silva**[1,3,4]; [1]BIAL-Portela & Cª, S.A., Coronado, PORTUGAL, [2]Anapath GmbH, Oberbuchsiten, SWITZERLAND, [3]Faculty Medicine, University Porto, Porto, PORTUGAL, [4]MedInUP-Center for Drug Discovery and Innovative Medicines, University of Porto, Porto, PORTUGAL.

In 2016 one person died and four others had mild-to-severe neurological symptoms during a phase I clinical trial of the fatty acid amide hydrolase inhibitor BIA 10-2474, with reports that the subject who died, after receiving the 50 mg dose for 5 days in the clinical trial, showed evidence of severe brain microhemorrhage and several of the surviving subjects also showed evidence of mild to moderate microhemorrhage. To determine if BIA 10-2474 might contribute to cerebral blood vessels rupturing, the effects of the compound were explored in stroke-prone spontaneously hypertensive rats (SHRSP) by evaluating mortality rate and examining cerebrovascular damage.Male SHRSP were 60-day-old at the start of the study. Ten SHRSP received standard rodent diet and regular tap water (control group). The remaining 60 rats were placed on a stroke-prone rodent diet and given 1% NaCl to drink. Rats on the stroke-prone diet and high-salt were divided into two groups receiving either vehicle (0.2% HPMC) or BIA 10-2474 (30 mg/kg p.o.). Treatments were administered daily until approximately half the rats in either the vehicle or BIA 10-2474 group had died or euthanized for ethical reasons. At the end of the study, surviving animals were euthanized and brains were removed, fixed and embedded; seven cutting levels were taken from the brains, whenever possible, and stained by H&E. Histological changes were described according to distribution, severity and morphologic character. Lesion area was measured, whenever possible, for hemorrhage, edema, inflammation and necrosis.The study was terminated after 45 days when 53.3% (16/30) of the animals receiving vehicle and 43.3% (13/30) of animals receiving BIA 10-2474 had died. No deaths were recorded in the control group. Log-rank test revealed no effect of BIA 10-2474 treatment on mortality rate compared with vehicle in animals on stroke-prone diet and high-salt intake (P=0.1882). In those rats surviving at the end of the study, histological lesions consisted of hemorrhage, edema and inflammation; necrosis was not observed. In rats on high-salt intake and receiving vehicle or BIA 10-2474, the type of lesion, location, number and size was similar comparing affected animals. Daily treatment with BIA 10-2474 at the dose of 30 mg/kg did not affect mortality rate in this model and, in surviving animals, did not increase the incidence of hemorrhage or edema.

Exocrine and Endocrine Organs

P2623/B883

Effect of Human Placenta-derived Mesenchymal Stem Cells on Antioxidant Factors of Ovary in Taa-injured Rat Model.

J. Na[1], J. Song[2], H. Kim[3], J. Seok[4], G. Kim[4]; [1]University of Pennsylvania, Philadelphia, PA, [2]University of California San Diego, San Deigo, CA, [3]Northfield Mount Hermon School, Lamplighter Way, Gill, MA, [4]CHA University, Seongnam, KOREA, REPUBLIC OF.

Ovary is a very important organ for female reproductive system as well as health. Reactive oxygen species (ROS) are generated as by-products during ovarian physiological metabolism and their unbalance between ROS production and clearance induce ovarian dysfunction such as infertility, polycystic ovarian syndrome (PCOS) and early menopause. In previous reports, placenta-derived mesenchymal stem cells (PD-MSCs) promotes folliculogenesis in ovariectomized rat model. However, there is no evidence that placenta-derived stem cells (PD-MSCs) have can preserve ovary function of ovarian dysfunction model via antioxidant effect. So, the objectives of the present study are to analyze the effect of human placenta-derived mesenchymal stem cells on the antioxidant factors in the ovary of thioacetamide (TAA) injured rat models by measuring folliculogenesis factors. In vivo experiment was designed by injecting 300mg/kg of TAA every week for 12 weeks in 7-week-old female Sprague-Dawley rats. Human PD-MSC (PD-MSCs Tx) and saline (Non-Tx) injected at week 8 via tail vein. Explant culture experiment was designed by culturing a half-cut ovary in a 24-well-plate treated with 70mM of TAA for 24 hours. First treatment group received $1x10^4$ PD-MSCs and second treatment group received $5x10^4$ PD-MSCs per each well for 24 hours. Ovaries were collected in each experiments and analyzed for ROS and antioxidant factors (NOX4, CAT, HO-1, SOD), folliculogenesis factors (Lhx8, Lin28a, Nanos3, Nobox) and E2 levels. Expression of antioxidant factors increased and ROS factors significantly decreased in in vivo ovaries after PD-MSC Tx. ($p<0.05$). Ex vivo ovaries showed enhancement in antioxidant activities correlated with amount of PD-MSCs co-cultivated. E2 production level in ex vivo ovaries increased as amount of PD-MSCs co-cultivated increased compared to control group. Both samples showed increase in folliculogenesis factors in RNA levels after PD-MSCs co-cultivtion. Based on these results, PD-MSC Tx effectively enhances ovarian function in TAA-treated rat models by regulating ROS and antioxidant factors and increases folliculogenesis activity. These findings lead to the potential of new therapeutic strategies of PD-MSCs in reproductive medicine. **Funding Source**: This research was supported by a grant from the National Research Foundation of Korea (NRF) funded by the Ministry of Science, ICT & Future Planning, Republic of Korea (grant number : NRF-2017M3A9B406)

The Constitutive Formation of USP8-STAM1 Complex Plays an Important Role in the Onset of Cushing's Disease.

T. Fukushima, Y. Madoka, A. Endo, K. Kawaguchi, S. Arakaki, M. Komada; Tokyo Institute of Technology, Yokohama, JAPAN.

Ubiquitin-specific protease 8 (USP8) deubiquitinates and stabilizes some receptors for growth factors and hormones, thereby regulating the receptor-mediated signaling. USP8 interacts with 14-3-3 proteins. We had reported that missense mutations of the 14-3-3 binding motif in USP8 very frequently occur in pituitary tumors in Cushing’s disease. In this disease, pituitary tumors secret excess

adrenocorticotrophic hormone (ACTH), leading to the onset of hypercortisolism symptoms. Here we show the pathogenic mechanisms by which USP8 mutation leads to the onset of Cushing's disease. We focused on STAM1, one of USP8 binding proteins. STAM1 harbors ubiquitin-binding domains and can help USP8 to recognize substrate proteins. Firstly, we analyzed USP8-STAM1 interaction in HEK293 cells. Wild-type USP8 ($USP8^{wt}$) interacted with STAM1 in an EGF-dependent manner, whereas the Cushing's disease-associated mutant USP8 ($USP8^{mut}$) constitutively interacted with STAM1. USP8 harbors three putative STAM binding motifs (SBMs), and we found that the region aa 738-747 (SBM3) in USP8 interacts with STAM1. Interestingly, the SBM3 is in close proximity to the 14-3-3 binding motif (aa 715-720). Overexpression of difopein, a peptide that inhibits the interaction of 14-3-3 and the binding proteins, increased the interaction of $USP8^{wt}$ with STAM1. It indicates that the dissociation of 14-3-3 may make the SBM3 available to STAM1. We tried to identify substrate protein(s) of $USP8^{mut}$-STAM1 complex. The vasopressin V1b receptor is a GPCR that is specifically expressed in pituitary corticotrophs, and mediates vasopressin-induced ACTH secretion. We found that $USP8^{mut}$-STAM1 complex binds to ER-residing immature V1b. The treatment with proteasome inhibitors increased immature V1b, indicating that immature V1b is unstable and degraded through the ubiquitin-proteasome pathway under basal condition. Overexpression of $USP8^{mut}$ reduced ubiquitinated V1b. Overexpression of $USP8^{mut}$, not $USP8^{wt}$, increased immature V1b as well as mature V1b. The increase in V1b was inhibited by amino acid substitution of the SBM3 in $USP8^{mut}$, confirming the importance of $USP8^{mut}$-STAM1 interaction. Finally, we observed that overexpression of $USP8^{mut}$, not $USP8^{wt}$, enhanced vasopressin-induced inositol phosphate production. Taking these data together, we conclude that 1) the Cushing's disease associated mutation of USP8 leads to the constitutive formation of $USP8^{mut}$-STAM1 complex; 2) $USP8^{mut}$-STAM1 complex binds to and deubiquitinates immature V1b, thereby preventing its degradation; 3) through these mechanisms, $USP8^{mut}$-STAM1 complex increases cell surface V1b levels and vasopressin signaling, possibly leading to excess ACTH secretion and the onset of Cushing's disease.

P2625/B885

Cortactin Deficiency Causes Pancreatic Epithelial Dysfunction.

J. Espinosa-Rivero, F. Samaniego, A. Romero-Fabela, M. Schnoor, A. Betanzos; CINVESTAV Del IPN-44533066, Ciudad de Mexico, MEXICO.

Cortactin is a multifaceted actin-binding protein containing several domains allowing for interaction with other proteins, thus enabling cortactin to fulfill essential roles in diverse actin-related cellular processes including adhesion and migration. Moreover, homeostasis maintenance of the intestinal barrier is regulated by cortactin; since in *cortactin*-KO mice colon epithelial permeability is increased and expression and localization of intercellular junction (ICJs) proteins is altered. However, it remains unknown whether absence of cortactin causes also damage in other epithelia such as in the pancreas. Therefore, the aim of this work is to analyze the effect of cortactin deficiency on pancreatic IJCs proteins, as well as on epithelial permeability of a cortactin-depleted ductal pancreatic cell line.Histologically, the pancreas of KO-mice looks apparently normal compared with those from wild-type animals. However, western blot and immunofluorescence analyses of pancreatic tissue revealed that cortactin-deficiency provoked a decrease of filamentous actin, and reduced expression of the IJC proteins occludin, claudin-1 and ZO-1. Moreover, these IJS relocalized from cellular borders to the cytosol in the absence of cortactin. By contrast, only a slight decrease of E-cadherin was detected, with similar location in WT and KO tissues. To investigate the effect of cortactin on pancreatic epithelial permeability, cortactin-depleted BxPC-3 cells were generated using shRNA and their transepithelial

electrical resistance (TEER) was monitored. Cortactin-KD cells exhibited 45% lower TEER than control cells. Accordingly, ICJs proteins were also less expressed and mis-localized.In conclusion, our results demonstrate that in the pancreas, cortactin also participates in the regulation of proper IJC architecture and epithelial permeability. Thus, cortactin seems to be a critical regulator of epithelial homeostasis in many organs.

P2626/B886

Haemoglobin Expression in Prostate Cells: Hypoxia and Dht Signalling?

H. E. Carvalho, 13083-863, I. Barbutti; State University Campinas-UNICAMP, Campinas, BRAZIL.

Haemoglobins are expressed in erythroid cells. We found haemoglobin expression in prostate cells and aimed at characterizing whether haemoglobin expression in prostate cells is due to hypoxia or DHT signalling. *HBA1* and *HBE* were found in 2D cultured RWPE1, and its expression increased in 3D cultured RWPE1, regardless of the presence/absence of dihydrotestosterone (DHT). In 2D cultured cells HBA was found in the nucleus. In 3D, however, the lack of DHT changed HBA subcellular localization: cells in the center of the spheroid presented higher amounts of HBA, localized mainly on the cytoplasm, whereas cells in the periphery presented the same nuclear localization as 2D cells. DHT treatment abolished HBA cytoplasmic localization. Interestingly, 2D cells cultured under hypoxia had increased *HBA2*, *HBA1* and *HBE* expression (51-, 119- and 450-fold, respectively) compared to 2D cells not submitted to hypoxia. $CoCl_2$ treatment also increased *HBA2*, *HBA1* and *HBE* expression, (9-, 7- and 16-fold, respectively). *HBA2*, *HBA1* and *HBE* are expressed in RWPE1 cells, and their expression increase in 3D culture. Spheroids untreated with DHT presented both cytoplasmic (center cells) and nuclear (peripheric cells) localization of HBA. **Financial support:** FAPESP

Murine Model of Chronic Prostatitis Involves the Mtor Pathway.

P. Thumbikat, K. E. McKenna, A. J. Schaeffer, **K. Roman**; Northwestern University, Chicago, IL.

Patients with chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS) suffer from chronic pelvic pain. Surveys conducted by the National Institute of Health (NIH) reported a significant impact on the quality of life of CP/CPPS patients with chronic symptoms due to few viable therapeutic targets. Studies using fMRI showed that various cortices in the brain (e.g., prelimbic, anterior cingulate cortex, and insular cortex) are altered in patients diagnosed with CP/CPPS after several years. Interestingly, a strong link between mTOR signaling in the anterior cingulate cortex and the development of neuropathic pain has emerged in several rodent models. Therefore, we seek to examine whether the mTOR pathway plays a key role in anterior cingulate cortex sensory processing in mice with chronic pelvic pain in a model of CP/CPPS called experimental autoimmune prostatitis (EAP). Our experiments were performed on male C57BL/6J (B6) mice (6-8 weeks old). To elicit EAP, the experimental group received a subcutaneous injection of rat prostate antigen (1 mg/ml). We conducted behavioral pain testing (via von Frey filaments) on all mice to assess the development of pelvic tactile allodynia on days 0, 7, 14, 20, and 30. On day 30, mice were perfused and the anterior cingulate cortex and spinal cord lumbosacral region were excised from mice with EAP and respective control cohorts. The anterior cingulate cortex and spinal cord were processed for either immunofluorescence or immunoblots. Our behavioral measurements verified that mice with EAP develop pelvic pain at day 7 thru day 30. Moreover, the immunofluorescence and immunoblot data showed that the lumbosacral region of the spinal cord

collected from mice with EAP had increased phosphorylation of ribosomal S6 (S40/244), a substrate site for S6K1 and downstream of the mTOR cascade, in neurons compared to control cohorts at day 30. Similarly, the anterior cingulate cortex from B6 with EAP showed elevated levels of phosphorylated S6 (240/244) proteins compared to control. Altogether, this study interconnects the development of chronic pelvic pain to the activation of the mTOR signaling cascade in regions of the spinal cord and brain relevant to CP/CPPS. More importantly, the data presented in this study suggests that the mTOR pathway at specific brain sites may signal neuroplastic changes in higher-order neurons that hinder the long-term effectiveness of current treatment options.

Targeting MT1-MMP: Therapeutic Opportunities in Obesity, Type 2 Diabetes and Other Associated Diseases.

H. Wong; Hong Kong Baptist University, Hong Kong, HONG KONG.

Obesity and diabetes are major causes of morbidity and mortality. Obesity is known to be the main risk factor for various non-communicable diseases, in particular type 2 diabetes. There is an ongoing need to identify non-invasive therapeutic approaches for the management of obese patients with type 2 diabetes to achieve their glycemic and weight loss goals.Recently, mutations in MT1-MMP (MMP14), a membrane bound metalloproteinase responsible for extracellular matrix remodeling and pericellular proteolysis, have been associated with human obese and diabetic traits. In this talk, the role of MT1-MMP in energy and glucose homeostasis and the molecular mechanism by which MT1-MMP regulates body weight and insulin sensitivity will be discussed. MT1-MMP contributes to the development of metabolic disorders through increasing energy intake and impairing insulin sensitivity. We found that MT1-MMP is a suppressor for GDF15-GFRAL signaling pathway, a newly identified central nervous system circuit that regulates metabolism and food intake in response to stress. In addition, MT1-MMP also impairs insulin signaling in the control of peripheral insulin sensitivity and glucose metabolism. These results indicate that MT1-MMP constitutes an important modulator of insulin sensitivity and energy homeostasis. Thus, targeting MT1-MMP represents potential therapeutics for the management of obesity and type 2 diabetes, two diseases with a need for combined treatment strategies.

Investigating Abnormal Gene Expression in Zebrafish Ciliopathy Models.

C. Zhang[1], Y. Li[2], N. Semanchik[2], Z. Sun[2]; [1]Millsaps College, Jackson, MS, [2]Yale University School of Medicine, New Haven, CT.

Polycystic kidney disease (PKD) is a medically important disorder that is characterized by the formation of multiple epithelium-lined, liquid-filled cysts in the kidney. Affecting one in 1000 live births, autosomal dominant polycystic kidney disease (ADPKD) is among the most common monogenetic disorders in humans (Gabow and Grantham, 1997). Over-proliferation of renal epithelial cells contributes to PKD pathogenesis (Nadasdy et al., 1995). Moreover, the cilium is thought to play a central role in the etiology of PKD (Ong and Wheatley, 2003). However, the precise role of cilia in PKD pathogenesis is not well understood. In previous studies, we identified zebrafish mutants of *arl13b*, a cilia biogenesis gene, and *pkd2*, a causal gene of ADPKD. To identify downstream targets of ciliary and Polycystin defects, we performed transcriptome analysis using RNA-seq and identified hundreds of genes with changed expression levels. To validate the RNA-seq results, we performed qPCR for four of the hits that are

changed in both mutants. We utilized *pkd2 and arl13b* genes as the internal comparisons between both mutants to ensure experiment accuracy. As expected, our qPCR results showed that *pkd2* mRNA level is decreased in *pkd2* mutants, while *arl13b* mRNA level is decreased in *arl13b* mutants. Moreover *tcap and ntd5* RNA are significantly elevated in both mutants, while *glis3 and klf4* RNA is significantly elevated in *arl13b* mutants. We hope to expand our analysis in the future to fully validate the RNA-seq results and to perform pathway analysis to identify key signaling events affected by ciliary and Polycystin defects.

Molecular Mechanisms of Prolactin in the Scented Glands of the Male Muskrats (*Ondatra Zibethicus*).

W. Xie, H. Zhang, Y. Han, Z. Yuan, M. Xu, Q. Weng; Beijing Forestry University, Beijing, CHINA.

Prolactin (PRL) production in mammals has been demonstrated in extrapituitary gland, which can activate autocrine/paracrine signaling pathways to regulate physiological activity. The muskrat (*Ondatra zibethicus*) is a medium-sized semiaquatic rodent that is native to North America and has been introduced to China since 1957. The muskrat is a seasonal breeder with sexually active period of about 8 months from March to October. The muskrat has a pair of scented glands near its tail that give off a musky odor to attract females. The object of our study is to investigate the expression of prolactin (PRL), prolactin receptor (PRLR) and signal transducers and activators of transcription 5 (STAT5) in the scented glands of the breeding and non-breeding seasons and to determine the levels of prolactin (PRL) in the sera and scented glands of the muskrats. We found that the weight and volume of the scented glands in the breeding season were significantly higher than those of the non-breeding season. Immunohistochemical data showed that PRL, PRLR and STAT5 were found in the glandular cells and epithelial cells of the scented glands in both the seasons. Furthermore, we found that PRL, PRLR and STAT5 had higher immunoreactivities during the breeding season when compared to those of the non-breeding season. With parallel expressions of PRL, PRLR and STAT5 at the protein and mRNA levels were significantly higher in the scented gland during the breeding season than those of during the non-breeding season. The concentrations of PRL in scented glandular tissues and sera were measured by enzyme-linked immunosorbent assay (ELISA), and their levels were both notably higher in the breeding season than those of in the non-breeding season. These findings suggested that the scented glands of the muskrats were capable of extrapituitary synthesis of PRL, which may attribute PRL to an endocrine or autocrine/paracrine mediator. The current study showed that the scented glands of the muskrats were capable of extrapituitary synthesis of PRL which may attribute PRL a specific function as an endocrine or autocrine/paracrine mediator.

Analysis of the Impact of P21 Dependent G2 Cell Cycle Arrest on Renal Fibrosis.

T. Koyano[1], M. Namba[1], T. Kobayashi[1], M. Fukushima[1,2], M. Matsuyama[1]; [1]Shigei Medical Research Institute, Okayama, JAPAN, [2]Shigei Medical Research Hospital, Okayama, JAPAN.

The progression of renal fibrosis is correlated with kidney function. Although several processes are implicated in the regulation of renal fibrosis, including the epithelial-mesenchymal transition (EMT) and cell cycle arrest, the underlying molecular mechanisms are largely unknown. Here, by using in vivo and

in vitro models, we have examined the impact of renal tubular cell-cycle arrest on the progression of renal fibrosis. To induce renal fibrosis in mice, we have conducted unilateral urinary obstruction (UUO) into male mice. We have found the proximal tubular cells arrested at the G2 of the cell cycle under the obstructed condition, especially in the early stage of the damage where fibrotic features was not seen clearly. Interestingly, the G2 arrest partially dependents on p21, which is a cyclin dependent kinase (CDK) inhibitor. The newly constructed monoclonal antibody against p21 revealed that the protein levels of p21 were sharply upregulated in response to the damage during the initial stage, but dropped down toward the later stage. To investigate the requirement of p21 for the progression of renal fibrosis, we constructed the novel *p21* deficient mice by *i*-GONAD method. Compared with wild-type mice, *p21* deficient mice showed the exacerbation of the fibrosis. Thus, the G2 arrest in early stage of the damage have a protective role in the progression of renal fibrosis.

Extracellular Vesicles from Senescent Cholangiocytes Differentially Affect Target Cells Via Epidermal Growth Factor Receptor Activation.

M. Al Suraih, S. P. O'Hara, C. E. Trussoni, P. L. Splinter, N. F. LaRusso; Mayo Clinic, Rochester, MN.

Primary Sclerosing Cholangitis (PSC) is a chronic, cholestatic liver disease of unknown etiology characterized by peribiliary inflammation and fibrosis. We reported that cholangiocyte senescence (a state of cell cycle arrest, apoptosis resistance, and hypersecretion of bioactive molecules) is a prominent feature of PSC. Extracellular vesicles (EVs) have emerged as prominent mediators of cell signaling. Thus, we tested the hypothesis that EVs from senescent cholangiocytes have a unique proteomic profile and influence biliary and peribiliary target cell phenotype. EVs were isolated by ultracentrifugation from cultured normal human cholangiocytes (NHCs), cultured cholangiocytes from PSC patients, and NHCs experimentally induced to senescence with LPS (donor cells). NHCs, malignant human cholangiocytes (MHCs), and monocytes (target cells) were exposed to 10^8 EVs from each donor cell population and assessed for proliferation, MAPK activation, and migration. Additionally, we isolated EVs from plasma of wild-type and $Mdr2^{-/-}$ mice (a murine model of PSC), and assessed mouse monocyte migration and activation. EVs exhibited the size (40-150nm) and protein markers (CD63) of exosomes. The number of EVs released from senescent human cholangiocytes (both experimentally induced or PSC patient derived) was increased (~6-fold); similarly, the EVs in plasma from $Mdr2^{-/-}$ mice were increased (~2-fold). Additionally, EVs from senescent human cholangiocytes were enriched (~2-fold) in multiple growth factors, including EGF, as assessed by growth factor array. NHCs exposed to EVs from senescent human cholangiocytes showed increased NRas and ERK1/2 activation (~4 and ~8-fold, respectively). Moreover, EVs from senescent human cholangiocytes promoted proliferation (~40% increase) of NHCs and MHCs, findings that were blocked by Erlotinib, an EGF receptor inhibitor. Furthermore, EVs from senescent human cholangiocytes induced EGF-dependent Interleukin 1-beta and Tumor necrosis factor-alpha expression (~4-fold) and migration (~2-fold) of human monocytes (THP-1); similarly, $Mdr2^{-/-}$ mouse plasma EVs induced activation (~4-fold) of mouse monocytes. In summary, senescent human cholangiocytes, both PSC-derived and LPS- induced, secrete increased numbers of EVs with the characteristics of exosomes. These EVs are enriched in growth factors, including EGFR ligands, and mediate EGF-dependent cellular responses in target cells. The data continue to support the importance of cholangiocyte senescence in PSC pathogenesis, directly implicate EVs in cholangiocyte proliferation, malignant progression, and immune cell activation and migration, and identify novel therapeutics approaches for PSC.

Clearance Or Prevention of P16ink4a-associated Cholangiocyte Senescence Improves Inflammation and Fibrosis in the Mdr2-/- Mouse Model of Primary Sclerosing Cholangitis.

M. Al Suraih, **P. S. Tietz Bogert**, N. E. Pirius, S. P. O'Hara, N. F. LaRusso; Mayo Clinic, Rochester, MN.

Primary sclerosing cholangitis (PSC) is an idiopathic, progressive disease of the bile ducts. We reported that biliary epithelial cell (cholangiocyte) senescence, characterized by cell cycle arrest and apoptosis resistance, is important in PSC pathogenesis. Moreover, we demonstrated that the cyclin dependent kinase inhibitor, CDKN2A (p16), a central mediator of senescence, is increased in cholangiocytes of PSC patients and in a PSC mouse model ($mdr2^{-/-}$). Here, we use genetic approaches to determine whether targeted removal or genetic deletion of p16 positive cells improves biochemical markers of liver injury, portal fibrosis and inflammation in the $mdr2^{-/-}$ mouse. We employed two novel genetic murine models to assess the role of p16 in the pathophysiology of PSC. The INK-ATTAC mouse allows for the selective apoptotic removal of p16 expressing cells following administration of the dimerizing molecule, AP20187. Hence, we generated double homozygous INK-ATTAC X $mdr2^{-/-}$ mice and treated the experimental group with AP20187. Additionally, we generated a mouse deficient in both $p16^{-/-}$ and $mdr2^{-/-}$ ($p16^{-/-}$ X $mdr2^{-/-}$ mouse). Following AP20187 treatment (INK-ATTAC X $mdr2^{-/-}$) or aging ($p16^{-/-}$ X $mdr2^{-/-}$), we assessed severity of portal inflammation and hepatic fibrosis via hydroxyproline assays and siruis-red staining of liver sections. We also measured monocyte chemoattractant protein-1 (mcp-1), a key regulator of macrophage infiltration, and senescence markers, p16 and p21, by real-time PCR in rodent livers. In the AP20187 treated INK-ATTAC X $mdr2^{-/-}$ mice, fibrosis decreased by 50%, mcp-1 was reduced by 60%, and p16 and p21 were reduced by ~35% and ~70%, respectively. In the $p16^{-/-}$ X $mdr2^{-/-}$ mice, fibrosis was reduced by 25-50%, and Mcp-1 and p21 were each reduced by 90%. We have now shown in two novel genetic mouse models of PSC that removal or prevention of cholangiocyte senescence improves portal fibrosis and inflammation. Together our data continue to support an important pathophysiologic role of senescence in the progression of PSC and suggest that the targeted removal of senescent cholangiocytes (senolytic therapy) is an attractive therapeutic approach.

Anti-cancer Potential Of*Fagonia Indica*Against Hepatocellular Carcinoma through Expression Regulation of Cytochrome P450 Pathway.

F. Azam[1], A. Tayyeb[2], **N. Sheikh**[1]; [1]Department of Zoology, University of the Punjab,, Lahore, PAKISTAN, [2]School of Biological Sciences, University of the Punjab, Lahore, PAKISTAN.

Background: Hepatocellular carcinoma is one of the most frequent death causing cancers worldwide. The incidence of HCC is growing at an exponential rate in Pakistan with more cases seen in male gender. HCC involves multiple alterations in large number of molecular pathways that lead into cancer progression and malignancy. Objectives: Present study aimed to investigate the anti-cancer effects of medicinal plant *Fagonia indica*against hepatocellular carcinoma. In addition, the potential molecular mechanisms regulated were also analyzed. Methodology: Liver carcinoma cell line, Huh7 was used. $IC_{50}$was determined by using different concentrations of plant extract and comparison with control. Cell Cytotoxicity analysis and DNA fragmentation were performed. PCR was performed for the analysis of regulation of cytochrome P450 pathway. Results: Cell cytotoxicity assay showed significant reduction in cell viability with even low doses of plant extract. DNA fragmentation and down regulation of cancer

markers further confirmed the anti-cancer effects of the plant. On the other hand, regulation of various genes of cytochrome P450 depicted an involvement of the pathway in occurrence and cure of hepatocellular carcinoma. In conclusion, with further detailed experiments, current study proposes *Fagonia indica*as a promising anti-cancer drug against hepatocellular carcinoma.

Anti-fibrotic and Pro-angiogenic Effects of WKYMVm Peptide in a Rat Model of Bile Duct Ligation.

J. Jun[1], J. Kim[1], S. Park[1], J. Seok[1], J. Cho[1], S. Jun[1], Y. Kwon[2], J. Kim[2], J. Choi[3], S. Bae[4], G. Kim[1]; [1]CHA University, Seongnam, KOREA, REPUBLIC OF, [2]Pusan National University, Yangsan, KOREA, REPUBLIC OF, [3]Gangneung-Wonju National University, Gangneung, KOREA, REPUBLIC OF, [4]Catholic University Medical College, Seoul, KOREA, REPUBLIC OF.

Hepatic failure, chronic liver injury, is one of the diseases related to difficult-to-cure liver diseases and it has shown high morbidity and mortality. The chronic liver disease involves inflammation, activation of hepatic stellate cells (HSCs) resulting in fibrogenesis, necrosis of hepatocytes caused by vascular blockade. Fibrogenesis in hepatic failure impairs vasculature of the liver simultaneously dysfunction of liver sinusoidal endothelial cells (LSECs). WKYMVm peptide, which is composed of Trp-Lys-Tyr-Met-Val-D-Met, is a strong agonist of formyl peptide receptor 2 (FPR2). Recently, WKYMVm peptide has been reported as the therapeutic factor in several diseases such as ischemic and wound healing models through migration and proliferation of angiogenic cells. However, the effects of WKYMVm peptide in chronic liver disease have not been elucidated. Therefore, our objectives of this study were to evaluate the condition of hepatic fibrosis and vascularization and analyze the expression of key factors related to hepatic fibrosis and angiogenesis through treatment of WKYMVm peptide in bile duct ligation (BDL) rat model and in *vitro* model. Collagen accumulation using Sirius Red staining in rat liver tissues of BDL was alleviated in WKYMVm treated groups compared with non-treated group (p<0.05). Also, the fibrotic markers (Collagen I and α-SMA) were significantly down-regulated in WKYMVm treated groups versus non-treated groups (p<0.05). While the hepatic fibrosis was drastically declined, the mRNA level of angiogenic factors such as VEGF and Endoglin were dramatically increased in WKYMVm treated groups (p<0.05). In *vitro* model damaged by transforming growth factor-β (TGF-β) in rat HSCs, the area of α-SMA in cytoplasm were significantly decreased in WKYMVm peptide treated group by immunofluorescence (p<0.05). Furthermore, WKYMVm peptide significantly up-regulated hepatic function through hepatocyte proliferation and albumin expression (p<0.05). These findings suggest that WKYMVm peptide mitigates hepatic fibrosis and regenerates damaged vasculatures. Therefore, the WKYMVm peptide has therapeutic potential for anti-fibrosis and hepatic regeneration. This research was supported by a grant of the Korea Health Technology R&D Project through the Korea Health Industry Development Institute (KHIDI), funded by the Ministry of Health & Welfare, Republic of Korea (HI17C1050020017) and the National Research Foundation of Korea Grant funded by the Korean Government (F19SN22T1305).

Human Placenta-derived Mesenchymal Stem Cells Enhance Hepatocyte Regenerationvia Antioxidant Effect in Taa Injured Rat Model.

J. Song[1], J. Na[2], H. Kim[3], J. Kim[4], J. Kim[4], G. Kim[4]; [1]University of California San Diego, San Diego, CA, [2]University of Pennsylvania, Pennsylvania, PA, [3]Northfield Mount Hermon, Gill, MA, [4]CHA university, Seongnam, KOREA, REPUBLIC OF.

Mesenchymal stem cells (MSCs) has been a new trend of cell therapy in regenerative medicine, including liver disease. Liver fibrosis is induced by imbalance between reactive oxygen species (ROS) and antioxidant factors, and lead to irreversible stage, cirrhosis. However, there is no evidence that placenta-derived stem cells (PD-MSCs) have can reverse early stage of liver cirrhosis model via antioxidant and hepatocyte regeneration effect. We therefore compared the expression of reactive oxygen species factor and antioxidant factor in TAA-injured rat model in which PD-MSC was transplanted. Additionally, we verified the hepatocyte regenerative function of the stem cell by measuring the albumin expression. In serum level, liver damage marker aspartate aminotransferase (AST), Alanine aminotransferase(ALT) and bilirubin increased in TAA-injured model and showed a significant decrease in PD-MSC treated model ($p<0.05$). On other hand, albumin and Nox4 the liver regeneration marker, decreased in TAA treated model and showed a significant increase in PD-MSC treated model ($p<0.05$). The expression of genes involved in antioxidant factors such as SOD1 and catalase in TAA-injured rat liver were increased in PD-MSC transplanted group. The dominant antioxidant factor which determines the final step in antioxidation, catalase, shows an equitable pattern in which decreases in TAA treated model and increases in PD-MSC transplanted model. These findings lead to the potential of the therapeutic effect of PD-MSCs in liver cirrhosis.

P2637/B897

Regional Calcium Dynamics in *Drosophila* Adult Midgut.

A. A. Kim[1,2,3], D. Montell[1], B. L. Pruitt[1], L. E. O'Brien[2]; [1]UC Santa Barbara, Santa Barbara, CA, [2]Stanford University, Stanford, CA, [3]Uppsala University, Uppsala, SWEDEN.

Although calcium dynamics are widely studied in cell culture, little has been reported on the topic for adult organs. We find striking regional and cell-type specific differences in calcium dynamics in the three major cell types of the adult *Drosophila* intestine. The adult fruit fly intestine is a compelling platform for studying intercellular dynamics and interactions. This stem cell-based epithelium is a reductionist model system of the mammalian small bowel with conserved features. The multi-cellular epithelium consists of three major cell types: progenitor cells that give rise to new cells (including stem cells), enteroendocrine cells that are hormone signaling cells, and enterocytes that are large absorptive cells. We find regional and cell-type specific variations in calcium signaling dynamics within this functionally compartmentalized organ, using confocal imaging of *ex vivo* cultured fly intestines. Progenitor and enteroendocrine cells indicate oscillatory intracellular calcium dynamics of slower and faster frequencies respectively, and enterocytes demonstrate the presence of traveling calcium waves. Our findings may establish a novel model for studying spatio-temporal organization of cellular to organ-level calcium dynamics in a renewable adult organ.

P2638/B898

Factors That Dysregulate Pannexin 1 Channel Expression in the Diabetic Bladder Urothelium.

S. Solouki[1], M. M. Urban-Maldonado[2], M. M. Thi[3], M. A. Laudano[2], **S. O. Suadicani**[2]; [1]Department of OB/GYN, Albert Einstein College Medicine and Montefiore Medical Center, Bronx, NY, [2]Department of Urology, Albert Einstein College Medicine and Montefiore Medical Center, Bronx, NY, [3]Department of Orthopaedic Surgery, Albert Einstein College Medicine and Montefiore Medical Center, Bronx, NY.

Pannexin 1 (Panx1) channels are essential components of the urothelial mechanosensory-transduction system and play important roles in sensation of bladder distention. Our studies with diabetic mice have shown that urothelial Panx1 expression changes with disease progression and correlates with bladder transition from a compensated overactive to decompensated underactive state. Hyperglycemia and polyuria are viewed as main factors leading to emergence and temporal progression of diabetic bladder dysfunction (DBD). Moreover, tissue hypoxia caused by polyuria-induced bladder overdistension is also proposed as a factor in DBD. However, the individual contribution of hyperglycemia, polyuria and hypoxia to DBD has yet to be determined. Our objective is to evaluate the role played by each of these factors in dysregulating Panx1 expression in urothelium. In this study, we used immortalized human and mouse urothelial cell cultures that were submitted to three conditions: (1) High extracellular glucose (HG; 450 mg/dL glucose) or control glucose level (100 mg/dL) for 8, 12, 24 hours, 4 and 8 days; (2) hypoxia (1% oxygen) or normoxia (21% oxygen) for 1, 4, 6 and 8 hours, and (3) mechanical stimulation by cyclic uniaxial stretch (5 min at 10% strain with 5 min rest intervals) for 2 and 5 hours or non-stimulated. Total RNA was extracted from these cells and processed for Panx1 mRNA analysis by qRT-PCR. Short-term exposure to HG increased Panx1 expression (12 hours: 1.20±0.03; N=3; $p<0.05$), whereas prolonged exposure downregulated Panx1 expression (8 days: 0.83±0.04; N=3; $p<0.01$) relative to controls. Exposure to hypoxic conditions induced a progressive increase in Panx1 expression (8 hours: 1.63±0.21; N=3; $p<0.01$) relative to controls. Prolonged cyclic-stretch downregulated Panx1 expression (5 hours: 0.66±0.07; N=3; $p<0.05$) relative to non-stimulated controls. These findings indicate that each of the factors normally encountered in the diabetic bladder environment, i.e. high extracellular glucose levels, prolonged polyuria-induced mechanical stimulation and hypoxia, can individually contribute to dysregulate Panx1 expression in the bladder urothelium and thereby, impair urothelial function and bladder sensation in diabetes.

Serum Gamma-Glutamyl Transpeptidase in Normal Physiology and Pathology.

M. H. Hanigan, M. B. West; University of Oklahoma Health Sciences Center, Oklahoma City, OK.

The level of the enzyme gamma-glutamyl transpeptidase (GGT, aka gamma-glutamyl transferase) in the serum has long been used clinically as marker of liver disease. The role of GGT in tissues is well known including its role in cysteine homeostasis. But what role, if any, GGT activity in the serum plays is unclear. GGT is a cell surface enzyme anchored to the membrane by a single transmembrane domain. The mechanism by which it is released from the cell membrane and enters the serum has not been determined. The objective of this study was to investigate differences between the serum versus tissue GGT. We examined the data for insight into the possible roles of serum GGT activity in the progression of liver disease. In humans, serum GGT activity of 0 to 60 U/L is considered within the normal limits. We examined GGT in bile and in serum from healthy patients and those with liver disease. The GGT in bile was observed as a smear at the top of a native polyacrylamide gel suggesting a hydrophobic form of the

enzyme with the transmembrane domain intact. Treatment of the sample with papain, which cleaves the transmembrane portion of the GGT protein, yielded a form of GGT that ran as a single sharp band in a native polyacrylamide gel, indicating a single hydrophilic form of the enzyme. The very low level of GGT in serum from healthy individuals migrates within the gels predominantly as a single hydrophilic form. GGT in the serum of patients with hepatitis or hepatocellular carcinoma migrates as multiple bands and smears revealing a mixture of hydrophobic and hydrophilic forms. High serum GGT is associated with cholestasis suggesting that in many liver disorders GGT on the bile canalicular membrane of the hepatocytes is solubilized by bile acids. Our data indicate that high levels of GGT activity in serum can reveal a heptobiliary pathology, but the activity is unlikely to contribute to the disease. Consistent with our conclusion is a recent report of two families with mutations in GGT. The mutations eliminate the transmembrane domain of the enzyme. The activity of GGT in the serum is very high but these individuals have no liver or other pathology, further indicating that highly elevated levels of serum GGT can identify liver disorders, though this biomarker is not specific and does not play a role in liver pathology.

P2640/B900

Novel Insights into the Crosstalk between Mineralocorticoid Receptor and Extracellular Vesicles in Kupffer Cells Activation in Nash.

D. Cabrera; Universidad Bernardo O Higgins, Santiago, CHILE.

Patients with Non-alcoholic steatohepatitis (NASH) exhibit increased local cortisol production and portal hypercortisolism and a dysregulation of the mineralocorticoid receptor (MR) expression(1,2). Notably, MR has recently been identified as a regulator of macrophage polarization. Kupffer cells (KCs), liver resident macrophages, undergo fundamental changes during the development of NASH and are critical in initiating liver damage and inflammation(3,4). The accumulation and inflammatory polarization (M1) of hepatic macrophages is considered a hallmark feature of progressive disease in NASH patients(5). The purpose of this study was to assess whether MR inhibition specifically in KC prevents M1 polarization and thus ameliorates NASH progression. The role of the MR was studied in myeloid cell-targeted MR knockout mice (MyMRKO)(6). Three-month-old animals were fed with methionine and choline deficient (MCD) diet as experimental NASH model, for 3 weeks. Livers were weighed, fixed and stained with hematoxilin/eosin and oil red. NAS score system was used. As an in *vitro* approach, a primary culture of Kupffer cell was treated with EVs isolated from steatotic hepatocytes and Aldosterone. MR modulation was assessed using eplerenone and siRNA transfection. Pro-inflammatory response was evaluated via real-time PCR (IL-1b, CD68, CD206, CD80, TNF-α, IL4, IL6). Our results showed that in a murine NASH model myeloid-specific deletion of MR ameliorated inflammatory foci induction and steatosis in MyMRKO+MCD compared to WT+MCD. EVs and Aldosterone induced KC M1 polarization, since the expression of IL-1b and CD68 were increased after EVs and Aldosterone incubation. In contrast, the induction of KCs M1 polarization was prevented in MyMRKO KCs. In addition, we found that aldosterone, synergized with EVs in the activation of KCs and this effect was abolished in MyMRKO. Our results indicate that MR contributes to KCs activation and M1 polarization in the development of the inflammatory response in NASH progression in a mechanism that involves a crosstalk between EVs derived from steatotic Hepatocytes and Aldosterone.This work was partially funded by grants from the Fondo Nacional de Desarrollo Científico y Tecnológico (FONDECYT 1191145 to MA, FONDECYT 11171001 to DC), the Center for Aging and Regeneration [CARE PFB12/2007 (M.A.), and the grant from Millennium Institute on Immunology and Immunotherapy (No P09/016-F to AK).
