Factors That Predict Life Sciences Student Persistence in Undergraduate Research Experiences.

K. Cooper; University of Central Florida, Orlando, FL.

Undergraduate research experiences (UREs) have the potential to benefit undergraduates and longer UREs have been shown to lead to greater benefits for students. However, no studies have examined what causes students to stay in or consider leaving their UREs. In this study, we examined what factors cause students to stay in their UREs, what factors cause students to consider leaving their UREs, and what factors cause students to leave their UREs. We sampled from 25 research-intensive (R1) public universities across the United States and surveyed 768 life sciences undergraduates who were currently

participating in or had previously participated in a URE. Students answered closed-ended and open-ended questions about factors that they perceived influenced their persistence in UREs. We used logistic regression to explore to what extent student demographics predicted what factors influenced students to stay in or consider leaving their UREs. We applied open-coding methods to probe the student-reported reasons why students chose to stay in and leave their UREs. Fifty percent of survey respondents considered leaving their URE, and 53.1% of those students actually left their URE. Students who reported having a positive lab environment and students who indicated enjoying their everyday research tasks were more likely to not consider leaving their UREs. In contrast, students who reported a negative lab environment or that they were not gaining important knowledge or skills were more likely to leave their UREs. Further, we identified that gender, race/ethnicity, college generation status, and GPA predicted which factors influenced students' decisions to persist in their UREs. This research provides important insight into how research mentors can create UREs that undergraduates are willing and able to participate in for as long as possible.

P898/B18

The Impact of Student Research an xiety on Undergraduate Intention to Pursue a Scientific Research Career.

K. Cooper[1], S. Brownell[2]; [1]University of Central Florida, Orlando, FL, [2]Arizona State University, Tempe, AZ.

Participating in undergraduate research is one of the most lucrative activities that a biology student can engage in because of the wide array of benefits that research can provide. Yet, while undergraduate researchers are more likely to persist in science than their peers who do not participate in research, there are still many undergraduate researchers who choose not to pursue a research career. In this study, we explored to what extent research anxiety influences students' intentions to pursue a research career. Specifically, we explored whether demographics predicted student research anxiety and their intention to pursue a research career. We were also interested in whether students' perceived difficulty of their research predicted research anxiety. We sampled from 25 public R1 universities and surveyed 768 biology majors who had participated in a research experience during the academic year. On the survey, we measured student research anxiety, research difficulty, intent to pursue a research career, and demographics. Students also answered open-ended questions about what elements of their research experience affected their anxiety. Using structural equation modeling, and controlling for students' intentions to pursue a science-related research career before they entered their undergraduate research experience, we explored the relationships between student demographics, research anxiety, research difficulty and intent to pursue a research career. We found that females were more likely to have higher research anxiety than males. Additionally, compared to students with low research anxiety, students with high research anxiety were less likely to report intentions to pursue a science-related research career. We also identified that the more difficult a student perceived their research, the more likely they were to express high research anxiety. Finally, using open-coding methods, we coded students' responses to what increased and decreased their research-anxiety. This work identified a novel factor, research anxiety, that influences students' intentions to pursue a science-related research career and identified ways in which research mentors can work to decrease student research-anxiety with the intent to create a more diverse and inclusive scientific community.

P899/B19

The Genomics Education Partnership: a Community of Practice That Enhances Research Opportunities for Students and Faculty at Diverse Institutions.

M. Van Stry; Lane College, Jackson, TN.

Since 2006, the Genomics Education Partnership (GEP) has incorporated authentic genomics research experiences into the undergraduate curriculum, introducing thousands of students to eukaryotic gene structure, comparative genomics, and the evolution of *Drosophila*. Our 100+ participating institutions include community colleges, primarily undergraduate institutions, minority-serving institutions (MSIs), historically black colleges and universities, and research-intensive PhD-granting institutions. For many faculty and their students, the accessible, immersive curriculum and custom bioinformatics tools represent a unique opportunity to participate in research. GEP faculty benefit from membership in a national network of like-minded colleagues and professional development opportunities that include training, research, and publication in peer-reviewed journals. Students who resolve sequencing problems and generate high-quality gene models for GEP analyses are eligible to be co-authors on the scientific publications based on their contributions. GEP has partnered with Galaxy to develop G-OnRamp, an open-source platform for constructing UCSC Assembly Hubs and JBrowse/Apollo genome browsers for eukaryotic genomes, thereby enabling crowd-sourced gene annotation using the GEP curriculum. G-OnRamp allows for more varied research projects to be incorporated into the GEP portfolio, including a current investigation of venom evolution in parasitoid wasps and an investigation of the evolution of insulin pathway genes across 27 *Drosophila* genomes. Our ongoing work in science education finds that a bioinformatics CURE fosters “formative frustration” where students can safely fail in their original analysis, adjust, recover, and succeed. This iterative process allows students to gain deeper insight into annotation and occurs quickly within an inexpensive, online framework. The GEP is actively recruiting additional faculty members, especially from community colleges and MSIs to participate in regional and national professional development to use the GEP curriculum in their classrooms. Further, the GEP is seeking science partners who can collaborate with GEP members to fund and develop additional projects, and science education partners to assist with curriculum development and assessments. Supported by NSF IUSE-1431407 to SCRE, NSF IUSE-1915544 to LKR, and NIH IPERT-1R25GM130517-01 to LKR.

Artlab Vanderbilt: Bringing Together Artists, Scientists, and Designers to Facilitate Science Outreach and Communication.

C. Cencer, E. Moll, J. Chediak, K. Oliver; Vanderbilt University, Nashville, TN.

ArtLab is a campus wide organization exploring the intersection of the arts and the sciences at Vanderbilt University. The goal of ArtLab is to promote discussion of scientific research in an approachable setting that allows people of multiple disciplines to get involved. ArtLab has hosted multiple exhibitions (Ex. ArtLab: Exploring the intersection of art and science, ArtLab Opener 2017, ArtLab at Vanderbilt) that included artistic work by undergraduates, staff, and faculty from across the University community. By forming a campus-wide network with key interest in building an art-science community, we have collected both in-person and online survey data that explores the interest in the program since 2017. The collected data comes from content presented at all exhibitions. We have found an increased interest in these science exhibitions from a wide range of disciplines, supporting our goal.

Most importantly, the exhibitions provided an outlet for both scientists and non-scientists to come together and discuss current topics of research. Surveys provided insight into how attending these events enhanced interest in scientific research discussion. Here we present these findings and suggest possible next steps to perpetuate transdisciplinary interactions across campus and the community focused on public engagement and education of the basic sciences.

P901/B21

The Genomics Education Alliance.

A. Rosenwald[1], V. Buonoccorsi[2], D. Chalker[3], R. Tractenberg[1], J. Williams[4]; [1]Georgetown University, Washington, DC, [2]Juniata College, Huntingdon, PA, [3]Washington University in St. Louis, St. Louis, MO, [4]Cold Spring Harbor Laboratories, Cold Spring Harbor, NY.

The Genomics Education Alliance represents a group of life science educators with experience in engaging students in genomics-based Classroom-based Undergraduate Research Experiences (CUREs). Because we are convinced that CUREs are effective for students to learn both key concepts and the practice of science, we have come together to identify and overcome common barriers to put such experiences within the reach of all life science faculty and students. To achieve this goal, the alliance will curate curriculum and assessment materials, and make them freely available for use on the CyVerse platform. Currently supported by a National Science Foundation Research Coordination Network grant, we are now piloting a set of materials for use by educators in their classrooms in three areas: lessons on examining gene sequence similarities using BLAST, understanding gene structure by using a eukaryotic genome browser, and investigating gene expression by using basic tools for RNA-seq analysis. Eventually, we will curate a wide variety of materials both from our existing genomics CUREs and new resources we create, and make available the appropriate compute resources necessary for use in the classroom. Ultimately, we aim to facilitate efforts by faculty who build their own genomics CURE using our optimized resources. We are currently recruiting faculty to test our pilot resources; let us know if you're interested. Supported by NSF RCN-UBE grant # DBI 1827130

P902/B22

An Integrated Undergraduate Steam Course: the Art and Science of Cell Death.

S. Walsh[1], A. Stewart[2], J. Almond[2], S. Berenguer[2]; [1]Soka University of America, Aliso Viejo, CA, [2]Rollins College, Winter Park, FL.

This fully integrated laboratory-and studio-based course enabled students to visualize apoptosis, design experiments around this basic cell biology process, and then use those experimental data to generate two art pieces. After completing this interdisciplinary course, students fulfilled both their art and science general education requirements. Through short lectures and demonstrations, a mix of thirteen biology and non-science majors were introduced to both the intrinsic pathway of apoptosis and the principles of art and design. Students first learned basic cell culture techniques through a guided experiment expressing Bax-GFP in Omi-RFP HeLa cells. Images were then captured on a confocal microscope and used to thematically inform an exquisite corpse drawing that was digitally rendered using a 3D computer-aided design (CAD) program to create a computer numerical control (CNC) milled wood panel. Following this, students in small groups applied their laboratory experience to design and test their own apoptotic protein using genetic engineering and synthetic biology techniques. Here, we present data generated by two student groups that fused a CARD or a DED domain to GFP to accelerate cell death, as

well as another group that engineered caspase cleavage sites into a dual fluorescent protein to serve as an indicator of apoptosis. Finally, using their personally collected confocal images, students digitally designed and fabricated a 3D printed sculptural form. In the context of this class, students practiced critical thinking and problem-solving skills utilizing both hands-on, novel experiments and computer-aided design.

P903/B23

A Data an alysis and Literature Intensive Undergraduate Course That Positively Impacts Student Ability and Confidence in Scientific Critical Thinking Skills and Increases Post-graduation Success.

K. K. Resendes; Westminster College, New Wilmington, PA.

Bio 404: Nuclear Structure and Function is an advanced cell and molecular biology course taken by junior and senior undergraduates at Westminster College (New Wilmington, PA). While the content of the course focuses on architectural aspects of nuclear cell biology and molecular understanding of gene expression and genome structure, the major objective of the course is to broaden students' skills in content comprehension, data-analysis, modeling, and productive scientific discussion using literature. The design builds upon existing models for using data analysis or individual journal club sessions in order to maximize student gains in ability, confidence, and postgraduate preparation. The four course units (Nuclear Periphery, Nuclear Pore, Chromatin and Nuclear Bodies), are divided into multiple, one-week modules consisting of three one-hour sessions. 1) Secondary article based lecture, introducing a theme. 2) "Work it out Wednesday" where students work in groups of 3-4 answering questions to analyze data and interpret results in order to develop a biological model that links back to lecture. 3) Student-led journal club discussing a theme correlated article. Course evaluations from the 2016 offering indicated that students thought the course was well organized, was a valuable learning experience and that the assignments had instructional value; moreover, exam and course grades in 2016 improved over the 2014 offering, which was structured in a more traditional lecture style. As a result of the positive outcomes with the change in course format a more formalized analysis of student gains and perceptions of the course was performed in the 2018 offering, together with a survey of the 2016 alumni. Student gains in ability and confidence with critical thinking skills were assessed and compared to the pre-requisite course and alumni. Greater gains across several metrics occurred in the advanced course, with students closing the pre-course gap between ability and confidence. Alumni retained gains and reported advantages over peers in postgraduate programs. This presentation will consist of an example of a course module, data from this initial study and ideas for application of the method to a variety of content areas and course sizes.

P904/B24

Improving Awareness About Scientific Rigor and Reproducibility through NIDDK Information Network (dkNET) Tools and Training Resources.

K. Lin[1], A. Bandrowski[1], S. Hagstrom[1], N. McKenna[2], J. Grethe[1], M. Martone[1]; [1]University of California San Diego, La Jolla, CA, [2]Baylor College of Medicine, Houston, TX.

When results of biomedical experiments can not be reproduced, the conclusions are then questioned. Poorly characterized antibodies and cell lines contribute to this problem, as do incomplete reports of materials used, lack of fully documented experimental designs and statistical approaches and the lack of published data. In 2016, NIH announced new guidelines for rigor and reproducibility in grant

applications. The NIDDK Information Network (dkNET; https://dknet.org) is an open community resource portal for researchers in diabetes, digestive, endocrine, metabolic, kidney, and urologic diseases [1]. To enhance the awareness about scientific rigor and reproducibility, dkNET developed tools, resources, and training modules. Based on Research Resource Identifiers (RRIDs), unique identifiers for research resources [2], we developed tools such as Resource Reports and Authentication Reports to assist researchers in the identification and authentication of cell lines and antibodies. These reports provide alerts when the resources have problems and also provide validation information, if available. dkNET also provides informational pages about Rigor and Reproducibility, RRIDs, data management, and suggested data repositories. Building on this material, dkNET has been hosting webinars around these concepts of reproducibility and related dkNET tools. All these recordings are available on dkNET's YouTube channel (https://bit.ly/30Ngyzt). This year we launched the dkNET Summer of Data Student Internship Program to provide students with an opportunity to utilize dkNET tools and resources in their research projects and to learn the basics of rigor, reproducibility and good data management for FAIR (Findable, Accessible, Interoperable, Reusable) data. Students received hands-on training on how to use dkNET to find and evaluate research resources, how to use online data and tools to develop hypotheses to enhance their projects as well as learning the best practices in data management for robust and reproducible research. A course survey indicated that students increased their familiarity with the tools and concepts taught in the course, and are more comfortable with performing reproducible research. In summary, dkNET provides useful online resources and training modules to assist researchers in improving scientific rigor and reproducibility. Graduate program educators can integrate dkNET resources into the research conduct curriculum. References: (1) Whetzel PL et al., PLoS One. 2015; 10(9):e0136206. P905/B25

It's Better Together: Adopting Collaborative Learning Techniques to a Community College Cell Biology Course.

N. Minkovsky; Community College of Baltimore County, Essex, MD.

Biology I: Molecules & Cells (BIOL 110) is a gateway course, a prerequisite for science and allied health majors at Community College of Baltimore County (CCBC). It often becomes a "roadblock course" for many of the CCBC students aspiring for a career in STEM or healthcare. The course has a high dropout and failure rate, and while many students repeat the course, the "repeaters" are often less successful at passing the course than the "first time takers". The standard format of the course includes traditional lecture and laboratory. Student participation in the lecture classes is limited to note taking, and clicker questions. Such approach often results in the psychological isolation and alienation of the community college students, who have fewer opportunities for socialization compared to their peers attending a four-year institution. Lack of social interaction negatively impacts performance and persistence in the major. Multiple studies (Johnson et al, 2014; Smith et al, 2009) indicated that collaborative learning contributes not only to the improvements in the overall performance, but also to the college persistence. The number of peer interaction partners in a high enrollment biology classes, termed the *degree of centrality* was positively associated with academic performance measured by GPA (Buchenroth-Martin, DiMartino, & Martin, 2017). Importantly, peer support, which resulted from establishing collaborative networks early in a student's college career, is an important factor contributing to the successful graduation of underrepresented minority STEM students (Lancaster & Xu,

2017). This study was aimed at exploring the effect of various collaborative learning approaches such as permanent or ad-hoc student groups organized for the purpose of short problem-solving sessions and low-stakes formative assessments (group quizzes), and group homework assignments on student engagement, satisfaction, academic performance, lecture attendance and retention. The effectiveness of the techniques was assessed using student surveys to inform and adjust the instruction. The data on student retention, attendance and success-failure rate was also gathered and analyzed. A decrease in the number of students who dropped or stopped attending the class and/or an increase in the passing rate was observed in the test group after the intervention aimed at increase in student interaction was implemented. The overall student satisfaction with the class fluctuated from semester to semester, and reflected conflicting feelings of students toward different types of group assignments. The findings indicate that community college student population respond better to more deliberate choice of instructional methods and faculty adapting instruction based on student feedback.

An Intensive Cellular Engineering Summer Research Course Promoting Interdisciplinary Learning.

S. K. Biswas[1,2], L. Blauch[3,2], B. Graziano[4,2,5], T. Makushok[4,2], V. Pastore[1,2], J. Town[4,2,5], S. Bianco[1,2], W. F. Marshall[4,2], M. Phillips[6,2], S. Tang[3,2], R. Smith[4,2], O. Weiner[4,2,5], **Y. H. M. Chan**[7,2], D. S. Chu[7,2]; [1]IBM Almaden, San Jose, CA, [2]Center for Cellular Construction, Bay Area, CA, [3]Stanford University, Stanford, CA, [4]UC San Francisco, San Francisco, CA, [5]Cardiovascular Research Institute, San Francisco, CA, [6]Phillips and Associates, San Francisco, CA, [7]San Francisco State University, San Francisco, CA.

We report on the Cellular Engineering Summer Research Course offered by the Center for Cellular Construction and hosted at San Francisco State University. This course was designed to provide students an inclusive and intensive research experience on cellular engineering and cellular decision-making. Course goals emphasized development of skills across biology, engineering, and computational disciplines to prepare students to enter into modern scientific research programs. This inaugural course, “Summer of Cells 2019,” included 21 undergraduate, master’s and doctoral students who participated in three research projects during the 2-week course studying various aspects of cellular engineering, leading to discoveries in each area: *(1) Optogenetic control of cell migration*: Students found that immune cells use the rate of polarity factor production to make decisions about when to form protrusions and how frequently to change direction. *(2) Decision-making in Physarum*: Students studied how the morphology of the slime mold *Physarum* and its cytoplasmic flows allow this giant single-celled organism to solve complex optimization problems. *(3) Microfluidic manipulation of Stentor*: Students designed new microfluidic devices to cut single *Stentor* cells into multiple pieces, and they developed staining procedures to visualize *Stentor* structure. Retrospective pre- and post-surveys indicate that students showed growth in self-reported understanding of cellular engineering principles and cross-disciplinary techniques including: cell biology and genetics; optical microscopy; microfluidic design and fabrication; computational analysis; and scientific communication. Student co-authors: J. Aleman[2,7], G. Alvarez-Azanedo[2,7], J. Amatoru[2,7], J. Baker[2,8], A. Barrera-Velasquez[2,7], M. B. de Jesus[2,7], A. Chemel[2,7], G. Hale[2,9], H. Hernandez[2,10], W. Participation in Peer-led Team Learning (PLTL) in an Introductory Cell and Molecular Biology Course Correlates with Enhanced Outcomes for Both Students and Peer Leaders.

K. D. Belanger, G. H. Holm, B. C. Hoopes, J. R. Meyers, K. G. Belanger; Colgate University, Hamilton, NY.

Peer-led team learning (PLTL) is an active learning technique in which students work through complex topical problems in groups facilitated by a more experienced, trained student leader. In this study, we implemented optional, ungraded, out-of-class PLTL sessions in an introductory cell and molecular biology course and assessed outcomes for both students and peer leaders. The PLTL sessions were held nearly weekly for 60-75 minutes and paired groups of 6 - 8 students with one peer leader. The problems presented were related to topics being covered in the regular classroom periods at that time and generally included some interpretation of data from the primary literature, but were not intended to introduce new course content. Students who participated in more than 50% of PLTL sessions scored significantly higher on exams and had lower rates of D and F grades and withdrawals from the course than those who attended half or fewer of the PLTLs. In a post-course assessment, approximately 75% of students gave the peer-led problem sessions “good” or “excellent” ratings and reported that the PLTLs were effective at teaching problem-solving skills, facilitating the learning of course content, and integrating material from across the course. Peer leaders reported perceived gains by PLTL participants in understanding course material, ability to work through complex problems, and understanding data presented in the primary literature. Peer leaders also self-reported gains in their own understanding of course material, ability to work through biology problems, and interest and ability as a teacher. We are continuing to collect and analyze data in an effort to identify factors that enhance or detract from student participation and learning gains associated with PLTLs in this course.

P908/B28

Molecular Case Studies: at the Interface of Biology and Chemistry.

M. Lenahan; Raritan Valley Community College, Branchburg, NJ, NJ.

Title: Molecular Case Studies: at the Interface of Biology and Chemistry Abstract: “Structure and Function”, a biology education core concept, underscores the importance of structural units in defining the functions of living things. At a molecular level, structures of biological macromolecules (e.g., proteins and nucleic acids) define the molecular basis of their cellular functions. Experimentally determined structures of biological macromolecules and various visualization tools are freely available online. However, introducing students to molecular structure visualization, engaging them in structural analysis, and helping them bridge the gap between biology and chemistry to explain structure-function relationships, can be challenging. Case studies have often been used for active learning – to introduce new concepts/skills or to motivate student learning. Molecular case studies can provide contexts for teaching and learning structure-function relationships at the interface of biology and chemistry. A group of seven undergraduate educators from around the nation have formed a network, called Molecular CaseNet. They are collaborating to develop molecular cases for a variety of different courses and at different levels of rigor. These molecular cases provide a platform for integrating interdisciplinary knowledge from biology, biochemistry, chemistry, genetics, and cell biology. In addition, they engage students in “scientific practices” - e.g., introduce them to scientific literature, public biological databases, and bioinformatics tools and resources, many of which are currently underutilized in biology education. Molecular case studies cover a variety of topics. For example, “Nicholas' Story” is focused on

understanding changes in sickle cell hemoglobin leading to severe pain, its treatment using hydroxyurea, and gene therapy trials; while "A Case of Severe Insulin Resistance" explores defects in the insulin signaling pathway resulting in Type II diabetes. The ready to use cases can save undergraduate educators a lot of preparation time. Modular and flexible design of the cases enable students with varied levels of expertise and disciplinary training to explore molecular structure-function relationships, and apply the scientific process to address real-world problems. Over time, by using these case studies the next generation of STEM workers can be trained to creatively apply interdisciplinary approaches in problem-solving.

P909/B29

Perceived Efficacy of an Interactive Quizzing Tool for Learning Cell Biology, Histology and Pathology of George Washington University School by Medicine and Health Sciences (GWU-SMHS) Medical Students.

A. R. Munday, P. S. Latham, R. A. Jurjus; George Washington School of Medicine and Health Sciences, Washington, DC.

A move toward blended teaching in medical school curricula often results in decreased in-class time for disciplines such as Cell Biology, Histology and Pathology, as it has at GWU-SMHS. This study proposes to balance loss of in-class time with a self-study quizzing tool to increase medical student learning and comprehension of these disciplines, which are foundational in preclinical organ system studies. Since many studies have shown that quizzing increases learning, we developed an online, interactive, quizzing tool that allows students to test their ability to recognize visual features and to recall information. This study reports on the perceptions of medical students concerning the effectiveness of this tool as measured by survey. Images for the quizzing tool were derived from the MicroAnatomy and Pathology Atlas (MAPA) currently used by students for studies of histology and pathology (http://microanatomyatlas.com). The on-line quizzing tool was designed to display representative images without annotations or descriptions until activated by the student, allowing students to quiz themselves on the findings. The quizzing tool was provided to students in the class of 2022 near the beginning of each system block and used by them at their discretion. Students were invited to complete a survey asking if and how they used the quiz tool, and feedback about what they liked and did not like about the tool. A Likert scale (1-5) was used to rate the usefulness of the tool for their learning. The survey was given upon completion of the pulmonary organ block and again on completion of their first year. The quiz tool survey was first completed by 29.8% of students (56/188) after the pulmonary organ system block in 2019. The quizzing tool was rated by 60.7% of students at 5 (most useful) on the Likert scale, 30.4% rated it at 4, 7.1% at 3, 1.8% at 2, and 0% at 1. In answering the question 'Did using the quizzes make you more comfortable about answering histology questions on your exam?', 96.4% of respondents answered yes (54/56). After one year, the survey was repeated with a 17% student response rate (32/188), at this time 62.1% of the respondents rated the tool's usefulness at 5, 34.5% rated it at 4, and 3.4% rated it at 3. In answering 'Did using the quizzes make you more comfortable about answering histology questions on your exam?' 92.9% responded yes (26/28). These results indicate that the majority of students who completed the survey perceived that the quizzing tool had a positive impact on learning. The findings suggest that quizzing can enhance learning in cell biology, histology and histopathology, as it has been shown to do in other fields of learning. Future studies will use the quizzing tool to investigate not only perceived learning by students, but also the impact of using the tool on exam performance.

P910/B30

College of Arts and Sciences Faculty and Student Perceptions of Secondary Teaching as a Profession.

K. Baker, K. Stickney, D. Sachs; University of Indianapolis, Indianapolis, IN.

the United States is continuing to face a critical shortage of qualified teachers, particularly in STEM (science, technology, engineering, and mathematics) disciplines. While there are many reasons for this shortage, one of the main factors for the emerging teacher shortage is a decline in enrollments in teacher preparation programs. Since many undergraduate students rely on faculty for career advice, the perceptions of faculty regarding secondary teaching as a career may play a role in either encouraging or discouraging a student's pursuit of teaching as a career. The purpose of this study was to investigate College of Arts and Sciences faculty and students' perceptions of secondary (grades 7-12) teaching as a profession. A survey was used to assess what factors would encourage or discourage STEM undergraduate students (N=271) from choosing a career in secondary teaching. Faculty (N=61) perceptions of secondary teaching were also assessed with the intent of extrapolating how those perceptions might impact recruiting for secondary teacher education programs. The results of this study support the importance of providing undergraduate STEM students and faculty advisors with accurate information about teacher salaries and the positive aspects of secondary teaching in order to encourage students to consider teaching as a career option.

Metadata and Performance Tracking for Fluorescent Microscopes I - Metadata.

M. Hammer[1], A. Rigano[1], F. Farzam[1], M. Huisman[2], D. Grunwald[1], C. Strambio de Castilla[1]; [1]UMASS Medical School, Worcester, MA, [2]UMASS Medical School, WORCESTER, MA.

Microscopy images need to be accompanied by a description of the sample, its preparation and experimental layout as well as technical parameters under which images were taken. The term "metadata" is used to refer to such accompanying information, but the exact meaning of "metadata" frequently varies with context. A major challenge with metadata for technical parameters is the large variability of what is recorded by different microscopes. Metadata can be as simple as the pixel size or as complex as the results of an entire internal instrument calibration routine - and everything in between. To enable full quantitative analysis - to extract the maximal information content of images - and to make images from different microscopes comparable, we propose 1) an OME based, extended metadata model to capture complete hardware and settings used for image acquisition, 2) an extension of metadata to contain optical calibration- and performance documentation and 3) a tier system for metadata requirements that scales the amount of metadata to be reported with the complexity of the

imaging data. Here we present the proposed metadata model and tier system [1] and a tool [2] to collect metadata in a tier dependent manner through a GUI that enables non-experts to be thorough and complete in their metadata documentation of hardware and setting used. This work is accompanied by a second contribution on optical calibration and a third contribution on performance calibration. [1] https://github.com/WU-BIMAC/MicroscopyMetadata4DNGuidelines [2] https://github.com/WU-BIMAC/4DNMicroscopyMetadataTool

P912/B33

Metadata and Performance Tracking for Fluorescent Microscopes II - Optics.

D. Grunwald, M. Hammer, F. Farzam, M. Huisman; UMASS Medical School, Worcester, MA.

Microscopy images need to be accompanied by a description of the sample, its preparation and experimental layout as well as technical parameters under which images were taken. The term “metadata” is used to refer to such accompanying information, but the exact meaning of “metadata” frequently varies with context. A major challenge with metadata for technical parameters is the large variability of what is recorded by different microscopes. Metadata can be as simple as the pixel size or as complex as the results of an entire internal instrument calibration routine - and everything in between. To enable full quantitative analysis - to extract the maximal information content of images - and to make images from different microscopes comparable, we propose 1) an OME based, extended metadata model to capture complete hardware and settings used for image acquisition, 2) an extension of metadata to contain optical calibration- and performance documentation and 3) a tier system for metadata requirements that scales the amount of metadata to be reported with the complexity of the imaging data. Here we present cooperative data on the use of diffraction limited multicolor beads [1] and a number of imaging and resolution standards for optical calibration of a microscope [2-6]. This work is accompanied by a second contribution on a metadata model and a third contribution on performance calibration. Metadata and Performance Tracking for Fluorescent Microscopes III - Metamax.

M. Huisman[1], C. Smith[2], M. Hammer[3], R. Ulbrich[4], D. Grunwald, 01605[1]; [1]University of Massachusetts Med Sch, Worcester, MA, [2]TU Delft Technology University, Delft, NETHERLANDS, [3]University of Massachusetts Med Sch, WORCESTER, MA, [4]n/a, Worcester, MA.

Microscopy images need to be accompanied by a description of the sample, its preparation and experimental layout as well as technical parameters under which images were taken. The term “metadata” is used to refer to such accompanying information, but the exact meaning of “metadata” frequently varies with context. A major challenge with metadata for technical parameters is the large variability of what is recorded by different microscopes. Metadata can be as simple as the pixel size or as complex as the results of an entire internal instrument calibration routine - and everything in between. To enable full quantitative analysis - to extract the maximal information content of images - and to make

images from different microscopes comparable, we propose 1) an OME based, extended metadata model to capture complete hardware and settings used for image acquisition, 2) an extension of metadata to contain optical calibration- and performance documentation and 3) a tier system for metadata requirements that scales the amount of metadata to be reported with the complexity of the imaging data. However, there are certain crucial pieces of information that simply are not captured in even the most rigorous and precise routines for record-keeping and calibration, as they simply cannot be measured without the aid of (often costly, cumbersome and complicated) external devices. Here, we present an inexpensive, easy-to-use calibration device that, among other things, allows the user to measure excitation power and perform basic detector calibration routines. In doing so, the "MetaMax" tool provides crucial meta-data to evaluate potential photo-toxicity and allows current and future model-based data processing tools to get as much quantitative information as possible out of the images. MetaMax also provides an elegant, possibly automated way to track microscope performance over time. This work is accompanied by a second contribution on a metadata model and a third optical performance calibration. Combining Molecular Beacon and CRISPR Technologies for Sensitive Live-Cell Genomic Imaging.

A. Chen; Peking University, Beijing, CHINA.

The ability to monitor the behavior of single genomic loci in living cells can offer tremendous opportunities for deciphering the molecular basis driving cellular physiology and pathogenesis. Toward this goal, clustered regularly interspersed short palindromic repeats (CRISPR)-based imaging systems have been developed, with tagging of either the nuclease-deactivated mutant of the CRISPR-associated protein 9 (dCas9) or the CRISPR single-guide RNA (sgRNA) with fluorescent protein (FP) molecules currently the major strategies for labeling. Recently, we have demonstrated the feasibility of tagging the sgRNA with molecular beacons (MB), a class of organic dye-based, fluorogenic oligonucleotide probes that have been used extensively for imaging endogenous RNA transcripts in living cells. We showed that, the resulting system, termed CRISPR/MB, enables accurate quantification of genomic loci, measurement of chromosomal dynamics, and dual-color genomic imaging. We should emphasize that, compared with conventional approaches that use FP molecules, CRISPR/MB may offer several advantages including brightness, photostability and reduced background (due to quenching when not bound to target). We are currently optimizing CRISPR/MB for ultrasensitive live-cell genomic imaging.

Development and Application of Designer RNA-binding Protein for Live-cell RNA Imaging and Manipulation of Authentic RNAs in Living Cells.

A. Takai[1], Y. Okada[1,2]; [1]Center for Biosystems Dynamics Research (BDR), RIKEN, Suita, JAPAN, [2]The University of Tokyo, Tokyo, JAPAN.

RNAs do not only serve as the blueprint for the protein assembly, but also play wide variety of essential functions in cells. Furthermore, expression levels of mRNAs can be indicators of cell differentiation and signal transduction. Thus, visualization and manipulation of RNAs in living cells would be beneficial for

both basic and applied sciences. To this end, aptamer sequences such as MS2 stem loop or Broccoli, or synthetized fluorescent oligos such as molecular beacons were developed, however, modification of target RNA sequences and the lack of the method for efficient probe introduction have sometimes been critical problems. That's why fully genetically-encodable probes, which can label authentic, unmodified RNAs were expected to be developed.Here, we report the development of designable RNA-binding protein (dRBP), which is programmable to bind to the RNA of interest. We first established an ELISA-like in vitro assay system using our bright bioluminescent protein, Nano-lantern (Takai et al., *PNAS* 2015), and it was shown that the dRBPs have high affinity (1-10 nM) specifically to the target RNAs. To examine the avidity of our dRBPs to bind to target RNAs in living cells, we designed dRBPs for authentic, unmodified RNAs such as beta-actin mRNA. Immunoprecipitation of the probe followed by quantitative PCR analysis demonstrated that the target, authentic beta-actin mRNA was specifically recognized in vivo. We also showed that our dRBPs were applicable to the visualization of the dynamics of the authentic RNAs including beta-actin mRNA or long non-coding RNA Neat1_2 in living cells. Furthermore, manipulation of the localization of the beta-actin mRNA using the dRBP fused to constitutively active kinesin resulted in the neurite-like elongation of cellular processes. These data collectively suggest that our new probe for RNA would serve as a powerful tool for the imaging and manipulation of unmodified, authentic RNAs in living cells or organisms.

P916/B37

Imaging Endogenous Messenger RNA Expression Dynamics with an RNA Counterpart of a GFP.

T. Ariyoshi[1], Y. Okada[1,2]; [1]RIKEN, Suita, Osaka, JAPAN, [2]Univ. Of Tokyo, Bunkyo-ku, Tokyo, JAPAN.

Single-cell analysis of the transcriptional dynamics gives us plenty of information about how a single cell contributes to the construction and the maintenance of the intricate biological systems. Fluorescent or luminescent protein-based reporters or RNA tagging systems with specific stem-loops that recruit fluorescent fusion proteins are commonly used strategies, but they indicate the transcriptional activity only indirectly. To circumvent this problem, we have recently developed an RNA counterpart of a GFP, Romanesco, which enables the direct and quantitative visualization of mRNA in living mammalian cells. Romanesco-based fluorescent reporter system has been applied to study cell-to-cell variance in transcriptional dynamics, mRNA incorporation into stress granules and RNA translocation during gene expression. However, because the copy number of the mRNA is usually much lower than that of the protein, visualizing mRNA at endogenous levels has been unsuccessful so far. Here we report new methods that enable the monitoring of the endogenous mRNA expression dynamics at single-cell resolution by greatly enhancing the detection sensitivity in Romanesco imaging. Our new methods realize the enhancement of the detection sensitivity by selectively eliminating the background signals derived from cellular autofluorescence and the fluorescence of the residual fluorophore not bound to Romanesco RNA. These methods rely on two photochemical properties of Romanesco: photoswitching and long fluorescence life time. In epifluorescence microscopy, Romanesco-derived fluorescence undergoes multiple rounds of on-off photoswitching whereas background fluorescence does not. Therefore by subtracting off-state images from on-state images background fluorescence is selectively eliminated. In laser-scanning microscopy, time-gated fluorescence lifetime imaging enables selective extraction of the Romanesco-derived fluorescence because Romanesco possesses an order of magnitude longer fluorescence lifetime compared to background fluorescence. By applying these methods to Romanesco imaging, more than 40-fold increase in signal-to-background ratio has been

achieved. We will discuss the details of these methods as well as their applications to the imaging of the endogenous mRNA in immune cells.

P917/B38

A FRET-Based Probe for High Throughput DNA Intercalator Drug Discovery and in Vivo Imaging.

G. T. Shubeita, C. U. Murade, S. Chaudhuri; New York University Abu Dhabi, Abu Dhabi, UNITED ARAB EMIRATES.

Molecules that bind DNA by intercalating its bases remain among the most potent cancer therapies and antimicrobials due to their interference with DNA-processing proteins. To accelerate the discovery of novel intercalating drugs, we designed a Fluorescence Resonance Energy Transfer (FRET)-based probe that reports on DNA intercalation, allowing rapid and sensitive screening of chemical libraries in a high-throughput format. We demonstrate that the method correctly identifies known DNA intercalators in approved drug libraries, and discover previously unreported intercalating molecules. When introduced in cells, the probe rapidly distributes in the nucleus allowing direct imaging of the dynamics of drug entry and its interaction with DNA in its native environment. The combined ability of the single probe to identify intercalators in vitro and follow their function in vivo can play a momentous role in accelerating the discovery of novel DNA-intercalating drugs or repurposing approved ones.

P918/B39

Fluorogen Activating Proteins as a Powerful New Imaging Tool for Quantitative Protein Trafficking Studies in Yeast.

N. A. Hager[1], **C. K. McAtee**[1], J. Warnick[1], M. Bruchez[2], A. Kwiatkowski[1], J. Brodsky[1], A. O'Donnell[1]; [1]University of Pittsburgh, Pittsburgh, PA, [2]Carnegie Mellon University, Pittsburgh, PA.

Recent advantages of genetically encoded fluorescent probes have led to the development of fluorogen activating proteins (FAPs). This technology has two components: a non-fluorescent single chain antibody (SCA) that can be fused to a protein of interest and fluorogens, which are non-fluorescent when free in solution. When the SCA and fluorogen bind, there is a 20,000-fold fluorescent increase relative to unbound dye. This level of fluorescence is comparable to GFP and other standard fluorescent proteins. However, the FAP-technology has two major advantages; (1) using either a membrane-permeant or impermeant fluorogen dye we are able to selectively label intracellular proteins from proteins at the permeable membrane and (2) since the fluorogen does not fluoresce when it is not bound by SCA, we are able to eliminate possible background fluorescence. Although developed in yeast, this technology had surprisingly not been used to detect localization in this model system until our recent work looking at the residence of membrane proteins at the cell surface. In order to make this technology more readily available to the yeast community, we have first optimized the SCA sequence for expression in yeast, then created a series of FAP tagging constructs for making FAP-tagged fusions to your favorite protein of interest, and finally have made a suite of FAP-tagged markers to be used as co-localization markers for the cell biology and yeast research communities. These tools will allow scientists to quantitatively analyze protein dynamics, minimize the effects of background, and selectively illuminate the surface or intracellular population of a tagged protein.

Live-cell an alysis of ER and Golgi Enzyme Activities in Gaucher Disease.

J. J. Naleway, L. C. Woods, F. K. Harlan, E. M. Swanson; Sonas BioPharma, Eugene, OR.

TITLE: Live-Cell an alysis of ER and Golgi Enzyme Activities in Gaucher Disease INSTITUTION: Sonas BioPharma, 1850 Millrace Drive, Eugene, OR 97403 the Endoplasmic Reticulum (ER) and Golgi Apparatus are dynamic organelles that contain metabolic and regulatory enzymes involved in the ordered synthesis and processing of nearly all proteins, lipids, and carbohydrates in the cell. Functional deficiencies or mutations in these enzymes are indicative of a number of disease states, particularly those that affect the nervous system including the Lysosomal Storage Diseases and Parkinson's Disease. Methods to analyze Golgi and ER enzyme function within living cells have been hampered by the inability to monitor activity within individual organelles. We developed new, organelle-targeted, live-cell fluorogenic substrates for Golgi, ER and lysosomal enzymes that can be used for in *situ* analysis of changes in their metabolic activity and intracellular trafficking for the Lysosomal Storage Diseases. Staining with these new probes was shown to co-localize with known markers of lysosomal, ER and Golgi morphology. We have now utilized these targeted fluorogenic substrates to perform a pilot screen with a focused library of compounds known to modulate protein transport, act as pharmacological chaperones or otherwise alter enzyme levels or trafficking in the ER, Golgi and lysosome. Using both fibroblasts and B-lymphoblast cells derived from Gaucher I patients alongside control cells from healthy individuals we were able to compare the GCase activity in the ER and the lysosome in response to drug application by staining with the targeted substrates. We identified a new, potential hit from this screen, compound SB1282. Application of 10 uM SB1282 to Gaucher I cells for 72 hours resulted in a 92% decrease in GCase β-glucosidase activity in the ER with a corresponding greater than 50% increase in enzyme activity in the lysosome as compared to untreated controls, indicating improved intracellular trafficking of the enzyme from the ER to the lysosome. We are currently performing SAR studies to develop analogs of SB1282 with improved efficacy, employing intracellular enzyme activity analyses with our targeted fluorogenic substrates, as well as by monitoring ER stress (UPR) utilizing antibody co-staining (ASK1 CHOP, GRP78, or XBP1: Abcam) and measuring total lipid burden changes by HPLC analysis. Our screening methodology is being similarly employed with existing larger libraries to elucidate additional potential hits. This work was funded in part by NIH-NIGMS grant 5R44GM108137-03.

CatCh-ER: an Endoplasmic Reticulum Membrane-Localized Optogenetic Channel for the Manipulation of ER Calcium.

L. J. Shumway[1], L. V. Fortuno[1], C. J. Obara[2], C. T. Richie[1], J. Lippincott-Schwartz[2], B. K. Harvey[1];
[1]NIH/NIDA, Baltimore, MD, [2]HHMI Janelia, Ashburn, VA.

The endoplasmic reticulum (ER) is the site of protein synthesis, lipid metabolism, cellular signaling, and calcium storage for the cell. Its role as a calcium store greatly facilitates and is indeed necessary for its other functions. Dysregulation of ER calcium homeostasis has been implicated in numerous human diseases, ranging from neurodegenerative to metabolic to infectious. In order to better understand the role of ER calcium in disease pathogenesis, I present here the development and characterization of CatCh-ER, a modified optogenetic channel with increased calcium permeability compared to ChR2 and localized to the ER membrane. CatCh-ER provides increased spatiotemporal control of modulating ER calcium, allowing for more precise study of the role of ER calcium dysregulation in disease.

P921/B42

Brief Calcium Influx through Membrane Channels Transiently Stabilizes Pip2and Recruits Actin in the Inner Plasma Membrane Leaflet of Intact Cells.

M. Zucker, W. JIn, **A. Pralle**; SUNY-Buffalo, Buffalo, NY.

Calcium entering the cell through ion channels acts as fast diffusion signal molecule. However, local calcium levels near the membrane can reach several hundred micromoles, sufficiently high to act electrostatically. The inner membrane leaflet contains various negatively charged lipids, such as phosphatidylinositol 4,5- bisphosphates (PIP2) and Phosphatidylinositol (3,4,5)-trisphosphate (PIP3). These modulate protein function and recruit specific proteins to the plasma membrane. In model membrane systems it has been shown that Calcium ions induce clusters of PIP2. Hence, we have investigated whether Calcium influx modulates the lateral PIP3 and PIP3 distribution in intact cells. This could cause very quick rearrangements during cell signaling and modulate the bilayer to cytoskeleton linkage, and hence be important for mechanosensitive channels, such as Pieoz1. However, it makes imaging the membrane faithfully very challenging. We employed fluorescent correlation spectroscopy (FCS) measuring diffusion on multiple length scales simultaneously, to show that the transient calcium in flux leads to a transient clustering of PIP2 and PIP3 on the inner membrane leaflet. To study the formation of PIP2 clusters in the plasma membrane we use GFP-PHPLCdeltaand Halo-PHPLCdelta labelled with the JaneliaFluor647; as marker for PIP3 PH-AKT-GFP; and for cholesterol-stabilized nano-domains Lck-mGFP. We find that opening TRPV1 or Piezo1 channels leads to a transient rise in calcium as imaged using GCaMP5G, transiently stabilizes PIP2 and PIP3 with PIP3 following a slower kinetics. It also increases the interaction between the Lck-mGFP and cholesterol domains. Using an ionophore to clamp the calcium level to a fixed value, we determine the threshold for these effects. We find that vinculin in rest cells stabilizes PIP2 clusters. In vinculin knockdown cells the calcium induced clustering and redispersion are accelerated. These results suggest a concentration dependence of calcium-induced PIP2 clusters and cholesterol- stabilized nano-domains in the PM at calcium levels, which may be reached in intact cells locally by opening of ion channels.

P922/B43

Comparative an alysis of Taxol-derived Fluorescent Probes to Assess Microtubule Network Organization in Drosophila Egg Chambers.

G. Logan, B. McCartney; Carnegie Mellon University, Pittsburgh, PA.

Drosophila oogenesis is an excellent in vivo model for investigating cytoskeletal dynamics because of the rapid cytoskeletal remodeling that occurs at the end of stage 10. While there are several genetic tools to fluorescently label the actin cytoskeleton with minimal artifacts, there are few robust tools for detecting microtubules in live complex tissues. The recent development of membrane permeable microtubule binding taxol-based fluorescent probes is significant technical progress; however, the effectiveness of these probes and the potential stabilizing effects of the taxol derivative have not been well characterized in vivo. Here, we compared ViaFluor (Biodium), Tubulin Tracker (ThermoScientific), and SiR-Tubulin (Spirochrome), three commercially available taxol-derived microtubule probes coupled to far red emitting dyes to determine their efficacy and potential artifacts. We assessed whether the three probes labeled microtubules with differences in the speed of penetration, brightness, and signal to noise ratio. Like taxol, however, all of the probes disrupted the actin cytoskeleton in a concentration

dependent manner. The manufacturer's instructions for SiR-tubulin recommend using the efflux pump inhibitor, verapamil. We found that verapamil increased both the brightness for SiR-Tubulin, and the severity of the actin artifacts. In the Drosophila ovary, Tubulin Tracker was the brightest of the three dyes, and we demonstrated that washing out the dye after a 30 minute incubation maintained sufficient signal brightness over the 90 minute imaging period and significantly reduced the actin artifacts. Together these data suggest that careful optimization including a taxol control is essential to ensure that signal is optimized while minimizing artifacts due to unintentional microtubule stabilization.

P923/B44

Engineering Biologically-relevant Boundaries: Optochemical Patterning of a Synthetic Cell Boundary to Probe Spindle Positioning.

J. G. Bermudez, 19104, M. C. Good; University of Pennsylvania, Philadelphia, PA.

In all multicellular organisms, proper development and adult tissue renewal rely on precise cell divisions. Cell division defects are associated with developmental disorders, neurological defects, and cancer, and they are linked to mispositioning of the mitotic spindle during anaphase. Mutations have been identified in a suite of proteins, including tumor suppressors Adenomatous polyposis coli (APC) and p53, that are thought to function in spindle positioning. This suggests that disruption of spindle positioning can lead to cell division defects and subsequent disease. However, a major challenge has been characterizing the functional roles of these proteins and how their mutation contributes to disease pathology. Studies in living cells are confounded by the presence of tens of thousands of distinct macromolecules and the complex nature of their interactions. An approach that overcomes these hurdles is to characterize minimal components in emulsion systems, which match the geometry of cells. I encapsulated recombinant optochemical proteins and microtubules inside water-in-oil emulsions. The optochemical system consists of FRB and FKBP fusion proteins and a photocaged dRap. Upon 405 nm laser illumination, dRap is uncaged and free rapamycin promotes dimerization of FKBP and FRB, thereby translating an optical input to a biochemical output. After 1 second of illumination, GFP-FRB protein is quickly relocalized to the boundary to generate an anisotropic boundary. I light-inducibly recruited microtubule adapter proteins (i.e., LGN) and GFP-FRB fusion proteins in a similar manner to examine their effects on spindle microtubule position in a minimal context. An additional advance is that we can incorporate cell-free systems that can carry out aspects of the cell cycle in *vitro*, including spindle assembly. By leveraging emulsion, cell-free extract, and optochemical approaches, we can pattern a synthetic boundary and build spindle interactions from the bottom-up to characterize the dynamics and spatial patterning of molecular factors required for proper cell division. This platform will provide new insights into the molecular mechanisms underlying spindle positioning, and ultimately generate paradigms to explain how defects arise in cell division and contribute to disease.

EGFP Is a Lifetime Highlighter for Fluorescence Lifetime Imaging (FLIM).

A. Holoubek[1], B. Brodska[1], D. Strachotova[2], **P. Herman**[2]; [1]Institute of Hematology and Blood Transfusion, Prague, CZECH REPUBLIC, [2]Faculty of Mathematics and Physics, Charles University, Prague, CZECH REPUBLIC.

Enhanced green fluorescence protein (eGFP), a successor of the wild type GFP from *Aequorea victoria*, is a popular and trusted fluorescent tag extensively used in biological and biomedical research. Over the

years researches gathered extended collections of cell lines bearing specific eGFP-tagged proteins. Surprisingly, some photochemical properties of eGFP have remained unexplored. We report on a lifetime-based photoconversion of eGFP especially usable in fluorescence lifetime imaging. Our results document that eGFP can be permanently photoconverted to a short-fluorescence-lifetime form (PC-eGFP) either by intense blue irradiation or by a two-photon process. PC-eGFP exhibits the same spectral emission compared to the unconverted form. Fluorescence of PC-eGFP is pH-independent and the photoconversion efficiency depends on the solvent viscosity and presence of external redox agents. Besides potential FLIM artifacts caused by an unintended photoconversion, the controlled process turns eGFP to an excellent tool for kinetic FLIM applications. This is demonstrated by tracking of a nucleophosmin in live cells during its cytoplasm-nuclear relocalization induced by external drugs. Since the photoconversion occurs in the lifetime domain, PC-eGFP is easily distinguishable from the unconverted tag by time-resolved detection. All other spectral detection channels stay free for multicolor labeling. Reported properties line up eGFP with other photoconvertible fluorescent proteins with special advantage in FLIM where lifetime-photoconvertible labels are scarce. (This work was supported by the Czech Science Foundation, grant 19-04099S).

***In Vivo* Multiplexed Bioimaging of Intrinsic and Extrinsic Biomarkers.**

H. J. Chiang, E. S. Koo, S. Cai, W. Shi, P. Wang, L. A. Trinh, S. E. Fraser, **F. Cutrale**; University of Southern California, Los an geles, CA.

There is a complex relationship between signaling pathways, extracellular microenvironment, different tissues and metabolic requirements of the cell. These intertwined factors contribute to an orchestrated communication across scales, from cells to tissues, which plays an important role during development and in a wide range of diseases. The palette of fluorescent proteins has been expanded, covering a wide range of colors. However, the time course of dynamics remains unclear due to a technological imaging gap. To study these multiplexed processes, imaging techniques need to simultaneously satisfy multiple opposing needs: capability to separate spectrally overlapping fluorophores, sufficient sensitivity to image at single-cell resolution without perturbing the process under study, and fast enough to capture the 3-dimensional volume within which the cell is interacting. Spectral imaging has the potential to fulfill this need by offering an increased informational domain that can capture the intertwined multi-scale complex biological interactions. In this work, we report our novel methods for analyzing fluorescent data in the multi-spectral domain. Using novel implementation of Machine Learning, denoising, unmixing and phasors, we enable rapid lossless denoising of spectral data and enable parallel observation of multiple intrinsic and extrinsic biomarkers.

P926/B47

DISC: Quantitative Light Sheet Fluorescence Microscopy with Minimal Shadowing.

T. C. Fadero, P. S. Maddox; UNC-Chapel Hill, Chapel Hill, NC.

Live-cell fluorescence microscopy has enabled biologists to observe subcellular dynamics at high spatial resolution. However, traditional fluorescence microscopy modes introduce unnecessary photodamage to the fluorescent sample. A recent revolution in fluorescence microscopy, Light Sheet Fluorescence Microscopy (LSFM), drastically decreases the rate of photodamage to live organisms by illuminating the sample from the side. Unfortunately, this illumination scheme introduces shadowing artifacts in the final

image, complicating any quantitative analysis of fluorescence intensity. To address the shadowing problem inherent in LSFM, we propose DISC (Diametric Illumination for Sheet Consistency) microscopy. DISC microscopy uses a parabolic mirror to illuminate fluorescent samples with a converging light sheet from every angle, rather than a single light sheet from one angle. The 360º illumination reduces shadowing to its theoretical minimum, making DISC microscopy ideal for maintaining a consistent excitation intensity while still spatially confining the excitation light to a single plane. Additionally, DISC microscopy is compatible with coverslip-mounted samples to maximize fluorescence detection efficiency with high-numerical aperture objectives. Thus, DISC microscopy nearly eliminates shadowing artifacts in LSFM while reducing photodamage in live-cell fluorescence microscopy.

P927/B48

Mapping Protein Counts in Live Cells.

D. Thirstrup, **W. Wiegraebe**, A. Institute for Cell Science Team; Allen Institute for Cell Science, Seattle, WA.

Calibrating Fluorescence Microscopes allows estimates of the number of proteins in each pixel of a 3D image stack from living human induced Pluripotent Stem Cells (hiPSC). We applied this method to several cell lines from the Allen Cell Collection expressing monomeric enhanced Green Fluorescence Protein (mEGFP) tagged proteins that highlight major structures[1]. To determine protein counts from fluorescence intensities, we imaged mEGFP solutions at six concentrations (from 22-1787nM) using settings optimized for cell imaging on the Zeiss spinning disk (Zeiss Cell Observer SD) and super-resolution microscopes (Zeiss LSM 880 Airyscan Fast). We confirmed the mEGFP concentrations using Fluorescence Correlation Spectroscopy (FCS) and then fitted linear regression to intensity data from solution images and FCS determined concentrations. We applied this calibration curve to fluorescence images of cells to estimate protein count per pixel. To ascertain that fluorescence properties of mEGFP are identical in cells and calibration solutions, we used number & brightness (N&B) analysis. The brightness parameter of this fluctuation-based method is proportional to quantum efficiency of the dye, given fixed imaging parameters. Since most of the Allen Cell Collection have one allele tagged with mEGFP, we measured the relative amount of mEGFP labeled protein and endogenous, unlabeled protein using immunoblotting for the protein and mEGFP. The relative level of tagged to non-tagged protein is close to 50% for most cell lines; however, there are outliers (e.g., NPM1 (22%), LMB1(33%))[2]. We corrected these calibration curves using the ratio of tagged to non-tagged protein. To validate the method, we used cell lines expressing cytosolic mEGFP, estimating the concentration of mEGFP with point-FCS and quantitative immunoblots from cell extracts. In general, the data are within a factor of 2, e.g., 68±35nM for FCS measurements in the cytosol, 117±18nM from the immunoblots from cell extracts, and 73±24nM by our method. In summary, we have developed an image-based, sub-cellular protein count method that can be easily applied to proteins through three orders of expression levels and multiple microscope modalities. FCS measurements were not greatly limited by cell movement, bleaching, and phototoxicity, thus allowing robust fitting and higher concentrations. However, for microscopes without FCS capability, the measurements can be calibrated using solutions of known concentration. [1)] https://www.allencell.org/cell-catalog.html [2)] Roberts, B., et al. (2017). Mol Biol Cell 28(21): 2854-2874.

New Non-curing Mounting Media Couples Improved Axial Resolution with Cross-spectrum Photobleach Protection Enabling High Quality Deep Tissue Imaging.

A. V. Dix, 97402, D. Cash, L. Webber, L. Poliak; Thermo Fisher Scientific, Eugene, OR.

Fluorescence microscopy offers unparalleled insight into the inner workings of specimen tissue by illuminating sub-cellular structures. The ability to visualize and interrogate specimen tissue is complicated by factors including photostability and tissue thickness. These factors are more pronounced when imaging thicker tissue, >30 microns, which is often of greater interest than thinner tissue samples. The longer signal acquisition times required for thicker tissue place increased demand on the signal-generating fluorphores leading to a greater potential for photobleaching. Fluorophore photobleaching occurs after repeated excitation cycles and results in the loss of signal. To mitigate photobleaching, reagents such as free-radical scavengers and antioxidants are included in the mounting media to minimize fluorophore degradation. Image distortion is caused by poor optical matching between the lens objective, glass cover slip, and the sample itself. The refractive index (RI) is a characterization of how materials in the signal path interacts with light, and any mismatch in this pathway limits the axial resolution and focal depth of the imaging process. Cover glass and immersion oil objectives (RI=1.52) minimize refraction of light traveling to and from the sample. Most commonly used mounting media have a RI near 1.45 resulting in a mismatch. In thicker biological samples it is vital to match the refractive indexes of your materials to acquire a high-quality image. Images acquired with mismatched materials are blurry, distorted, and lack the desired focal depth. Presented here is a new mounting media formulation with an RI=1.52 developed to provide both protection against photo-degradation and RI-matching in a non-curing format. To demonstrate resolution improvement with RI-matching, point spread functions of sub-resolution microspheres were measured to quantitatively compare samples mounted with the new mounting media and current alternatives. Images of 100 micron thick tissues were mounted with the new formulation and compared to non-curing mounting media with RIs=1.45. The ability to look deeper into samples and cross-spectrum photobleach protection enables acquisition of high-resolution images of thick tissue specimens. These experiments seek to educate and empower microscopy users with additional considerations when choosing antifade mounting media.

Best Practices at the National Center for Cryo-EM Access and Training.

E. Eng, E. Kopylov; National Center for CryoEM Access and Training, New York, NY.

Advances in cryo-electron microscopy (cryo-EM) imaging technology and data processing have resulted in the recent growth of single particle structures, which extend to near-atomic resolution. To broaden biomedical scientists' access to cryo-EM the NIH Common Fund's Transformative High Resolution Cryo-Electron Microscopy program has created three national service centers to provide access to the technology and the development of training curricula to build a skilled workforce. The mission of the NCCAT (National Center for Cryo-EM Access and Training) service center is twofold: to provide nationwide access to advanced cryo-EM technical capabilities, and to assist users in the development of cryo-EM skills needed for independent research. NCCAT provides access to state-of-the-art equipment required to solve structures to the highest possible resolution using cryo-EM methods. By implementing

the most current best practices users are able to optimize different experimental parameters on-the-fly, thereby allowing reconstructions to be determined from images collected in a single day. Our objective is to enable biomedical researchers from all fields to make use of these cryo-EM techniques and methodologies in their research programs.

The Allen 3d Live Cell Imaging Pipeline: Automation, Standardization and Quality Control.

.Allen Institute for Cell Science Team; Allen Institute for Cell Science, SEATTLE, WA.

The Allen Institute for Cell Science combines 3D live cell imaging of cellular spatial and temporal organization with genomics to identify and define cell states and to unlock how cells transition among various normal and pathological states. We do this using a collection of genome-edited human induced pluripotent stem cell (hiPSC) lines expressing green fluorescent protein tagged to proteins identifying specific cellular organelles and structures (**The Allen Cell Collection at Allencell.org**). Using these cells, we visualize the 3D organization and dynamics of cellular structures under diverse and defined conditions, creating a holistic picture of the changes in cellular organization. To collect and process these data we developed a highly standardized, quality controlled and automated 3D live cell imaging pipeline. Here, we describe the standardization and automation of our imaging workflow, which includes 5 distinct steps: 1) Imaging sample preparation, 2) sample & region of interest selection, 3) high resolution image acquisition, 4) post-acquisition processing, and 5) 3D image segmentation. Each step is optimized and automated to increase reproducibility and minimize error introduced by repetitive manual tasks. We first developed a robotic human iPSC culture platform to generate uniform and reproducible imaging plates. Each plate is ranked based on confluency and cell morphology using an algorithm that segments and classifies cell colonies. Coordinates from the center and edge of each colonies are selected and 3D images automatically captured from this position list using Zeiss spinning disk confocal microscopes operated with Zen Blue software and open-application development scripts. The data flows through an image processing pipeline to generate individually segmented 3D cells and is stored in a data management system built to manage the high volume of data produced. To maintain quality, we implemented rigorous quality control over cell morphology, microscope optics, image data and segmentations. The laser power at the objective, field homogeneity and point-spread functions are measured daily to ensure optimal performance. Image and cell qualities are curated using criteria like cell and colony morphology, absence of debris, whole cell integrity and signal-to-noise ratio. Algorithms are now being developed to further automate these final processes.

Supporting New Technology Development to Accelerate the Pace of Cancer Research: the Innovative Molecular an alysis Technologies (IMAT) Program.

K. Crotty, A. Dickherber; NATIONAL CANCER INSTITUTE, Bethesda, MD.

The National Cancer Institute (NCI) established the Innovative Molecular an alysis Technologies (IMAT) Program in 1998 to support the development of technologies to accelerate the pace of discovery and address challenges facing basic and clinical cancer researchers. The program has become a technology development pipeline that supports the genesis, technical maturation, and dissemination of novel next-generation technologies through an approach of balanced but targeted innovation. Among the strengths of the IMAT Program is the diversity of disciplines from which potentially transformative technologies

are solicited, including technologies to advance research in cancer etiology, epidemiology, cellular mechanics, biophysics, biospecimen science, and the analysis of cancer development and progression. Technology development is supported at several levels, from early conceptual stages to technique validation to commercialization. The IMAT Program empowers translational research by taking risks on early stage technologies, many of which have matured into methods widely applicable across research disciplines. Some of these include elegant molecular biology tools to detect the presence of proteins, biomarkers, and miRNAs with high sensitivity as well as novel biosensors and imaging tools to observe cellular features in real time. The IMAT Program supports the implementation of these novel technologies through additional funding opportunities for researchers with active NCI grant awards to integrate these tools into their ongoing basic and clinical research projects. The IMAT Program's support for the development of research tools and platforms accelerates basic cancer research and translates these discoveries into tomorrow's patient care.

3d Image-based Data Generation Pipeline: Effect of Drug Perturbations on the Allen Cell Collection.

N. Gaudreault,.Allen Institute for cell science team; Allen Institute for Cell Science, SEATTLE, WA.

The Allen Institute for Cell Science combines 3D live cell imaging of cellular spatial and temporal organization with genomics to identify and define cell states and to unlock how cells transition among various normal and pathological states. We do this using a collection of genome-edited human induced pluripotent stem cell (hiPSC) lines expressing green fluorescent protein tagged to proteins identifying specific cellular organelles and structures (**Allen Cell Collection at allencell.org**). In addition to normal and pathological organization, the Institute is also interested in developing a holistic 3D image database of cellular responses to a variety of perturbations including well-characterized drugs commonly used to perturb specific cellular processes, structures, or pathways. This database is being used to study and elucidate inter-dependency among cellular structures, train models to identify perturbed cell states, and identify likely pathways influenced by mutations. Our cell culture and imaging pipeline workflow has been fully automated using a Hamilton star robotic platform and a spinning disk confocal microscopy platform. The workflow also includes semi-automated quality control processes. Phenotypes observed in the images are first qualitatively described, and subsequently, 3D image segmentation and feature extraction are performed and used for quantitative analysis. Here we present a growing 3D image-based dataset matrix to include multiple drug perturbations collected at 3 different time points (2, 4 and 24 hrs post-perturbation) over different cell lines of the Allen Cell Collection. Through the parallel use of qualitative and quantitative methods, we plan to create a 3D image-based map of cell structure co-variation. Ultimately, the perturbation signature and structure co-variation will allow us to propose candidate cell structure inter-dependency and predict the directionality of these relationships.

Identification of Biosamples Using NIDDK Information Network (dkNET) Resource Reports: an Integrated Resource Network Platform That Helps Improve Rigor and Reproducibility.

K. Lin, A. Bandrowski, V. Guo, C. Hsu, I. Ozyurt, J. Grethe, M. Martone; University of California San Diego, La Jolla, CA.

Awareness of problems with scientific reproducibility has risen in recent years. A survey of 1576 researchers showed that more than 70% of researchers failed to reproduce experiments done by other

scientists [1]. To improve reproducibility, the National Institutes of Health announced new guidelines for rigor and reproducibility in grant applications in 2016. The identification of research resources is an essential step to enhance reproducibility. For example, without a unique identification system for biosamples, one cannot cross-reference the source of biosamples across experiments between different projects or organizations. Research Resource Identifiers (RRIDs), unique identifiers for research resources, help improve identification of research resources in the biomedical literature [2]. As of August 2019, there are more than 600 Journals that have RRID citations, including endocrinology society journals. Utilizing RRIDs, dkNET(NIDDK Information Network; dknet.org)[3] created Resource Reports to help researchers identify key resources such as digital tools, antibodies, cell lines, and organisms, and track resource use and performance. Using text mining and data aggregation technologies, the reports provide detailed information about research resources along with citation metrics from the biomedical literature, community feedback, alerts when the resources have problems, and information about who is using the resource. In this project, we expanded the resource types to include biosamples. To identify the human pancreatic islets used by the Integrated Islet Distribution Program (IIDP) researchers, the Resource Identification Initiative worked with the BioSample databases in the EU and the US and the IIDP team to develop a registration pipeline. Biosamples are registered with the NCBI Biosample database to obtain BioSample SAM* identifiers which are used as RRIDs. Researchers can now easily find useful resource information on pancreas islets and track their usage via dkNET Resource Reports. RRIDs improve the identification of biosamples and researchers can cite the RRIDs when publishing papers. Researchers can not only pool or re-analyze the data across experiments and studies, but can aggregate data from different biosamples from the same donor. Two diabetes relevant journals, Diabetologia and Diabetes, now require researchers to cite biosamples using unique identifiers. Researchers are encouraged to contact distributor programs to register their biosamples. Based on RRIDs, we can also integrate more data to provide updated information. References: (1) Baker M. The NIH Common Fund's Extracellular RNA (exRNA) Communication Program.

L. Kuo; National Institutes of Health (NIH), Bethesda, MD.

The NIH Common Fund's Extracellular RNA (exRNA) Communication Program was developed to address critical issues in exRNA research. The overarching objective is to generate a multi-component community resource for sharing fundamental scientific discoveries, protocols, and innovative tools and technologies. Key components of the first stage of the exRNA Communication Program include (a) generating a reference catalogue of exRNAs present in human body fluids, (b) defining the fundamental principles of exRNA biogenesis, distribution, uptake, and function (c) identifying exRNA biomarkers of diseases, (d) demonstrating clinical utility of exRNAs as therapies, and (e) developing a resource to provide the scientific community access to exRNA data, standardized protocols, and other tools and technologies. The second stage of the exRNA Communication Program will address specific technological challenges including (a) the development of molecular tools, methods and technologies for single-vesicle characterization and (b) scalable methods for separation and analysis of exRNA carrier subclasses. Ongoing outreach efforts will provide the greater scientific community with these exRNA resources, novel tools and technologies. Recent progress to be presented include showcasing new community-wide tools for researchers. ExRNA data sets are being generated and shared to be findable,

accessible, interoperable and reusable (FAIR). New exRNA tools and technologies to be presented include the Extracellular RNA Communication Consortium's Virtual Biorepository, the miRDaR web application for RNA isolation, the ExceRpt small RNA-seq analysis pipeline, and the exRNA Atlas. Cryoem-101: a Media-rich Online Curriculum for Learning About the Cryo-em Workflow.

J. Iwasa, P. Shen; University of Utah Sch Med, Salt Lake City, UT.

Cryo-EM has emerged as a powerful tool for the high-resolution determination of macromolecular structures. We have created a media-rich online curriculum, called CryoEM 101, to aid the training efforts of newcomers to the field. Using videos, animations, and interactive simulations, CryoEM 101 provides self-paced learning material that introduces students to the protocols, expectations, limitations and troubleshooting of standard procedures of a typical cryo-EM project. The course is divided into five chapters: (1) sample purification, (2) cryo-EM grid preparation, (3) cryo-EM grid screening, (4) data collection, and (5) image processing and analysis. All material will be made freely available at http://cryoem101.org.

The NIH Common Fund Human Biomolecular Atlas Program (HuBMAP): Building a Framework for Mapping the Human Body.

D. C. Procaccini, R. S. Conroy; Common Fund, NIH, Bethesda, MD.

Normal 0 false false false EN-US X-NONE X-NONE /* Style Definitions */ table.MsoNormalTable {mso-style-name:"Table Normal"; mso-tstyle-rowband-size:0; mso-tstyle-colband-size:0; mso-style-noshow:yes; mso-style-priority:99; mso-style-parent:""; mso-padding-alt:0in 5.4pt 0in 5.4pt; mso-para-margin-top:0in; mso-para-margin-right:0in; mso-para-margin-bottom:8.0pt; mso-para-margin-left:0in; line-height:107%; mso-pagination:widow-orphan; font-size:11.0pt; font-family:"Calibri",sans-serif; mso-ascii-font-family:Calibri; mso-ascii-theme-font:minor-latin; mso-hansi-font-family:Calibri; mso-hansi-theme-font:minor-latin; mso-bidi-font-family:"Times New Roman"; mso-bidi-theme-font:minor-bidi;} Understanding how tissue organization influences a cell's molecular make-up, interactions, and history is vital to elucidating variation in organ function across lifespan and health-disease continuum. Even with cutting edge imaging and omics technologies, current knowledge of how tissues are organized is restricted to a small number of microscopic structures. Better insights into principles governing organizational and functional relationships will potentially provide a better understanding of inter-individual variability, lifespan changes, tissue engineering approaches, and the emergence of disease at the biomolecular level. However, high throughput integration of imaging and omics analysis to comprehensively profile biomolecular distribution and morphology in tissues is challenging. Further, placing this information on 3D tissue maps amenable to modelling and molecular perturbation has yet to be fully realized. HuBMAP, in conjunction with many single-cell consortia doing single-cell work, is working to catalyze the development of a comprehensive atlas of cellular organization in humantissues to meet this challenge.

Actin and Actin-Associated Proteins 2

P937/B59

Role of Cyclase-associated Protein in Actin Dynamics.

T. Kotila[1], H. Wioland[2], G. Enkavi[3], K. Kogan[1], I. Vattulainen[4], A. Jégou[2], G. Romet-Lemonne[2], P. Lappalainen[1]; [1]University of Helsinki / Institute of Biotechnology, Helsinki, FINLAND, [2]Institut Jacques Monod, CNRS, Université de Paris, Paris, FRANCE, [3]University of Helsinki / Department of Physics, Helsinki, FINLAND, [4]Computational Physics Laboratory, Tampere University, Tampere, FINLAND.

The most prominent force-producing machinery in eukaryotic cells is the actin cytoskeleton. It powers diverse cellular processes through rapid polymerization of actin filaments at their barbed ends that is balanced by filament disassembly at pointed ends. While much is known about how actin filaments grow, we know substantially less about mechanisms of their disassembly. The best known actin disassembly factors are the cofilin family proteins, which increase cytoskeletal dynamics by severing actin filaments. However, the mechanism by which severed actin filaments are recycled back to monomeric form to fuel actin filament growth has remained enigmatic. Here we determined the molecular mechanism of actin filament pointed end depolymerization. We show that a ubiquitous actin regulator, cyclase-associated protein (CAP), binds actin filament pointed ends through its HFD domains, and works in synergy with cofilin to increase actin filament pointed end depolymerization by nearly 100-fold. By determining the crystal structure of HFD domain in complex with actin, combined with single filament imaging and atomistic molecular dynamics simulations, we revealed that CAP depolymerizes actin filaments by destabilizing the interface between the two terminal actin subunits at filament pointed end. Moreover, we show that the HFD domain can deliver the newly depolymerized actin monomer to the C-terminal half of CAP, which subsequently recharges the monomer with ATP. Our work establishes CAP as a molecular machine that accelerates actin monomer dissociation from filament pointed ends, and subsequently recycles actin monomers for new rounds of filament assembly. Together, these findings unveil that rapid actin dynamics relies on both actin filament severing and pointed end depolymerization, and explain why CAP is critical for dynamic actin-dependent processes in all organisms ranging from unicellular eukaryotes to multicellular plants and animals.

Metabolic Alterations in the Hearts of Cyclase Associated Protein 2 Mutant Mice.

S. Gurunathan, Y. Xiong, B. Attipoe, J. Field; University of Pennsylvania, Philadelphia, PA.

Cyclase associated proteins (CAPs) are actin binding proteins that regulate the cytoskeleton and associated signaling pathways such as SRF. The CAP2 isoform is expressed mainly in heart, skeletal muscle and brain. Loss of CAP2 causes dilated cardiomyopathy (DCM) and conduction delays, but the effects of CAP2 loss on metabolism has not been studied. We performed a metabolomics analysis to investigate the effects of CAP2 loss on energy metabolism in mouse hearts. Female mice (n=4/group, 1-year old) from CAP2 KO and age-matched control mice (n=4/group) were analyzed for acyl carnitines (fatty acids) and organic acids (lactate, pyruvate and TCA cycle intermediates) in heart tissue. CAP2 KO mice exhibited a strikingly different metabolic signature in their fatty acid and organic acids profile. Fatty acid profiling showed a significant increase ($p<0.05$) in long-chain fatty acids in CAP2 KO mice compared with controls and a trend towards increased levels of short chain fatty acids between the groups. Lactate and pyruvate levels were also increased ($p<0.05$), but the lactate/pyruvate ratio was decreased

in CAP2 KO mice in comparison to control mice. In addition, all the intermediates of the TCA cycle were significantly increased (except for citrate, being increased) in CAP2 KO mice. RNAseq data also showed significant decrease in genes (*Ech1, AcadM, Acaa2, Slc27a1, Acsl6,* etc.) associated with fatty acid oxidation, uptake, transport and lipid modifications. Decreased citrate levels associated with increased pyruvate and lactate levels suggest the flux of glycolysis towards lactate formation instead of the TCA cycle in CAP2 KO mice. However, increased levels of other intermediates of TCA cycle and accumulation of fatty acids might be due to anaplerotic reactions to refuel TCA cycle and decreased fatty acid oxidation respectively as supported by RNA seq data. Therefore, CAP2 mutation leads to strikingly different metabolic signature characterized by a surge towards anaerobic glycolysis and decreased fatty acid oxidation. This metabolic signature could be an additional factor aggravating the pathology in DCM patients.

Small Cofilin Clusters Sever Actin Filaments and Grow Preferentially at the Pointed End Independent of Filament Tension.

J. Bibeau, E. De La Cruz; Yale University, New Haven, CT.

Actin filaments comprise force generating networks that facilitate various cellular functions such as migration and division. Filament network turnover is accelerated by members of the ADF/cofilin family of regulatory proteins that sever filaments and increase the concentration of filaments ends available for growth and disassembly. Cofilin severs filaments at junctions, or “boundaries”, between bare and cofilin-decorated segments. Pulling forces have been used to visualize cofilin binding and investigate force sensitivity, but have yielded conflicting behaviors. We used microfluidics to apply tension on actin filaments and directly visualized cooperative cofilin binding, cluster formation and filament severing with TIRF microscopy. We observed preferential cofilin cluster growth toward filament pointed ends. Small clusters (less than three cofilin) displayed severing activity. Filament bending, flow-induced tension, and attachment conditions did not substantially affect cofilin association kinetics. This work addresses the discrepancies in the field on cofilin force sensitivity, cluster growth, and severing.

P940/B62

Diversification in the ADF-H Domain Family of Actin Regulatory Proteins.

R. M. Aguilar, S. Guo, B. L. Goode; Brandeis University, Waltham, MA.

Cofilin and Abp1 are ubiquitous, abundant actin-binding proteins that both use Actin Depolymerizing Factor Homology (ADF-H) domains to bind the sides of actin filaments, yet have highly distinct regulatory effects on F-actin. Cofilin severs and depolymerizes filaments, whereas Abp1 instead promotes Arp2/3 complex-dependent actin nucleation and stabilizes branch junctions. This raises important questions, including: Do these ADF-H proteins compete for binding to F-actin? Can they co-exist on filament sides at the same time? Do they interfere with each other’s functions? to begin to address these questions, we performed in *vitro* multi-wavelength TIRF imaging using labeled yeast Cofilin (Cof1) and Abp1. We found that Cof1 and Abp1 each bind to filaments with similar affinities (Kd ~ 0.5 μM), but highly distinct kinetics. Cofilin binds and dissociates slowly, whereas Abp1 binds and dissociates rapidly (sub-second time scale). Even though these proteins compete for overlapping binding sites on F-actin, when mixed at their normal cellular ratio and concentrations, they do not interfere with each other functionally. Abp1 initially coats filaments in a non-cooperative manner, then Cofilin slowly

binds, in a cooperative manner, to form spots and induce severing. Thus, the unique kinetic properties of these two ADF-H proteins allow them to sequentially perform their functions in each other's presence. Our observations predict that mutating Cofilin in *vivo* to reduce its dwell time on filaments will result in defects caused by Abp1 competition and interference. Indeed, we found that *cof1-22*, which weakens F-actin binding, causes cellular defects in actin organization and function that are suppressed by *abp1Δ*. These results shed new light on the diversification of ADF-H family proteins, and how complex systems in cells have evolved to employ multiple proteins with a related binding module, tuning their properties so that they perform distinct functions while working in harmony with each other.

P941/B63

Actin-binding Proteins Modulate the Activity of Actin-specific Adp-ribosylating Toxins.

S. Dong[1,2], E. Kudryashova[1], D. B. Heisler[1,2,3], D. S. Kudryashov[1,2]; [1]Department of Chemistry and Biochemistry, the Ohio State University, Columbus, OH, [2]Ohio State Biochemistry Program, the Ohio State University, Columbus, OH, [3]University of Texas Southwestern Medical Center, Dallas, TX.

Bacterial pathogens have developed multiple strategies to disrupt the actin cytoskeleton, and thereby compromise numerous cellular processes assisted by actin. Several actin-targeting ADP-ribosylating toxins (ARTs) from various pathogens covalently modify one of two residues on actin - R177 or T148. ADP-ribosylation at R177 converts actin monomers (G-actin) into non-polymerizable species, leading to the cytoskeleton disruption. In contrast, modification of T148 supports actin polymerization and stabilizes filamentous actin (F-actin), resulting in abnormal actin dynamics and accumulation of F-actin aggregates. ADP-ribosylation by ARTs has classically been studied using G-actin as a substrate, however, under physiological conditions, G-actin is typically partnered with thymosin β4 (TMSB4) or profilin (PFN1). In this study, our goal was to evaluate the activity of ARTs with physiologically relevant G-actin substrates. In this study, ADP-ribosylation was monitored by following either changes in fluorescence of etheno-NAD^+ or via a shift in actin mobility on the native-PAGE upon its modification by ARTs. We found that among three R177-ARTs from different bacterial species, PFN1-actin complex is a preferred substrate for *Salmonella enterica* ART SpvB; whereas *Aeromonas hydrophila* VgrG1 and *Clostridium perfringens* Iota toxins showed no substantial preference toward PFN1-actin or TMSB4-actin. Deletion of the poly-proline rich motifs from SpvB and VgrG1 toxins reduced the PFN1's effect on the efficiency of the enzymes, in agreement with the hypothesis that poly-proline regions contribute to the binding of these ARTs to the actin-PFN1 complex. R177 modification caused no effect on the affinity of TMSB4 or PFN1 to G-actin. Given the fast exchange of actin between TMSB4- and PFN1-bound complexes, the substrate preference should not selectively affect PFN1-dependent or -independent actin polymerization pathways. Surprisingly, accumulation of R177-ADP-ribosylated-actin in cells inhibited the mDia1-controlled actin polymerization substantially faster than the leading-edge retrograde flow of actin controlled by the Arp2/3 complex and myosin contractility. For *Photorhabdus luminescens* T148-ART TccC3, F-actin and G-actin were modified with similar rates, but the presence of TMSB4 or PFN1 prevented modification of G-actin, suggesting that F-actin is the physiological substrate of TccC3. We confirmed previous reports that T148-ADP-ribosylated actin is resistant to severing by another essential actin binding protein cofilin and demonstrated a stoichiometric character of this resistivity. The multifaceted roles of actin binding proteins in the toxicity mechanisms of ARTs and other actin-specific toxins remain to be elucidated.

P942/B64

Dissecting Profilin Mediated Actin-microtubule Interactions by Storm.

M. L. Pimm, J. L. Henty-Ridilla; SUNY Upstate Medical University, Syracuse, NY.

Super-resolution microscopy methods are powerful tools that break the diffraction barriers of conventional light microscopy, allowing for higher spatial resolution and visualization of cellular structures in greater detail (typically expanding resolution from microns to nanometers). We used Stochastic Optical Reconstruction Microscopy (STORM) and ThunderSTORM software to visualize actin, microtubules, and cytoskeletal regulatory proteins, specifically Profilin-1 and Profilin-2. Our most optimal imaging conditions permitted ~10-fold increase in resolution of actin filaments from ~200 nm obtained using conventional TIRF and/or confocal microscopy to ~20 nm with STORM. Here we show optimized conditions to visualize these proteins in mouse Neuroblastoma 2A (N2A) cells. While each Profilin isoform associated with both actin and microtubules, Profilin-1 was more strongly colocalized with the actin-rich regions of the cell and Profilin-2 more prevalent on the sides of microtubules. We are currently investigating how these localizations change with specific mutations in Profilin-1 and Profilin-2 that disrupt actin and microtubule-binding.

P943/B65

Profilin-1 Controls Actin Network Assembly, Organization, and Homeostasis.

K. Skruber, J. Henty-Ridilla, E. A. Vitriol; University of Florida, Gainesville, FL.

An increasingly important question for the field is how actin binding proteins coordinately regulate the cytoskeleton. Yet the rules that determine how complex networks form from multiple assembly factors remain poorly understood. Profilin-1 (PFN1) buffers the actin monomer pool and promotes polymerization through interactions with polymerases, allowing it to bias assembly of specific types of actin networks. In this study, we sought to understand how PFN1 controls actin assembly, organization, and homeostasis in the elaborate environment of mammalian cells. In PFN1 knock-out (KO) cells, the ability to polymerize actin through Arp2/3 and formins is partially lost, while assembly by Mena/VASP is completely inhibited. We also found PFN1 is necessary to maintain monomer/filament homeostasis, even when Arp2/3 or formins are inhibited. PFN1 KO cells also have depleted lamellipodia actin and a loss of Arp2/3 localization to the leading edge. By reintroducing discrete amounts of PFN1 protein, we identified a concentration-dependent relationship of PFN1 to lamellipodia architecture. Lower profilin concentrations stimulate the formation of filipodia and linear filament arrays and allow Arp2/3 to re-localize to the leading edge, while higher concentrations stimulate dendritic network assembly. These findings demonstrate a nuanced, coordinate action of PFN1 with other actin binding proteins, and suggest that filaments generated through PFN1 create the majority of Arp2/3 binding sites. This study provides new insight into how PFN1 controls the assembly of complex actin networks.

P944/B66

Gelsolin-Mediated Actin Filament Severing in Crowded Environments.

J. B. Heidings, B. Demosthene, T. Merlino, N. Castaneda, E. H. Kang; University of Central Florida, Orlando, FL.

Actin is an essential cytoskeletal protein that plays a key role in several cellular functions such as phagocytosis and cell motility with the help of actin binding proteins (ABPs). Gelsolin is a calcium

regulated ABP that severs and caps actin filaments. These two proteins control actin assembly and disassembly, dynamic processes that are required for cell survival. The majority of in *vitro* studies of gelsolin and actin have been performed in dilute buffer conditions that do not properly model the intracellular environment which is crowded with high concentrations of macromolecules. These macromolecules induce depletion forces and excluded volume effects. We hypothesize that gelsolin and actin filaments present in crowded environments will lead to greater severing activity due to the excluded volume effects. To test this hypothesis, co-sedimentation assays were performed in order to determine the effect of macromolecular crowding on the binding affinity of gelsolin to actin. We have directly visualized actin filament severing by gelsolin in solution including macromolecular crowders utilizing total internal reflection fluorescence (TIRF) microscopy. Steady-state average filament lengths as well as filament length distributions were analyzed to determine the effect crowding has on gelsolin-mediated filament severing. Real-time filament severing assays allowed us to estimate the filament disassembly rates in the presence of macromolecular crowding. Taken together, this study demonstrates that macromolecular crowding modulates gelsolin-mediated actin filament severing activities and offers insights into the function of both actin and gelsolin inside the cell.

P945/B67

Regulation of Inf2-mediated Actin Polymerization through Site-specific Lysine Acetylation of Actin Itself.

M. A, 03755; Dartmouth college, hanover, NH.

INF2 is a formin protein that accelerates actin polymerization and also severs actin filaments. A common regulatory mechanism for formins is autoinhibition, through interaction between the N-terminal diaphanous inhibitory domain (DID) and C-terminal diaphanous autoregulatory domain (DAD). We recently showed that INF2 utilizes a variant of this mechanism which we termed ‘facilitated autoinhibition’, whereby a complex consisting of cyclase-associated protein (CAP) bound to lysine-acetylated actin (KAc-actin) is required for INF2 inhibition, in a manner still requiring DID. We also showed that de-acetylation of actin in the CAP/KAc-actin complex activates INF2. Here, we use lysine-to-glutamine mutations as acetyl-mimetics to map the relevant lysines on actin for INF2 regulation, focusing on three positions: K50, K61 and K328. Biochemically, purified K50Q-, K61Q and K328Q β-actin polymerize with similar equilibrium and kinetic properties to WT β-actin or rabbit skeletal muscle (RSK) actin, both in the absence and presence of INF2. When complexed with CAP2, however, K50Q- and K61Q- inhibit RSK-actin polymerization by full-length INF2, but not by INF2 lacking DID. When expressed at low levels in U2OS cells, K50Q- and K61Q-actin inhibit INF2-mediated actin polymerization. Direct binding studies show that the CAP WH2 domain binds INF2-DID with sub-micromolar affinity but has weak affinity for actin, while INF2-DAD binds CAP/K50Q-actin 5-fold better than CAP/WT-actin, suggesting an inhibition model whereby CAP/KAc-actin serves as a bridge between INF2 DID and DAD. In U2OS cells, INF2 is 70 and 8-fold less abundant than CAP1 and CAP2, respectively, suggesting that there is sufficient CAP for full INF2 inhibition.

P946/B68

Cellular Mechanisms Controlling *S. Cerevisiae* Formin Displacement from Barbed Ends.

A. C. E. Wirshing, B. Turegun, B. Goode; Brandeis University, Waltham, MA.

Formins are highly processive actin machines, and in the absence of other cellular factors stay attached to growing barbed ends for minutes, assembling filaments that are 50-100 times longer than those found in vivo. This raises an important question: how do cells tune the duration of formin activity to control filament length? Recently, we showed that mammalian capping protein forms 'decision complexes' with formins at barbed ends, catalyzing formin displacement to limit growth. Here we asked whether related mechanisms are used in *S. cerevisiae* to control the activities of its two formins (Bni1 and Bnr1). Bni1 and Bnr1 have distinct biochemical properties, localize to different cellular sites, and assemble distinct sets of actin cables, suggesting that these two formins may be differentially regulated in vivo. We show that *bni1Δ* (but not *bnr1Δ*) displays strong synthetic growth defects with loss of Cap1/2, suggesting that Cap1/2 plays an important role in regulating Bnr1 in vivo. Microfluidics-assisted TIRF microscopy further revealed that Bnr1 can be readily displaced from barbed ends by Cap1/2, or by the Bnr1-binding partner Bud14, and that *bud14Δ* and *cap2Δ* mutants display strong synthetic defects in cell growth and actin organization. Taken together, our results suggest that Bnr1 can be displaced from barbed ends by two distinct and genetically complementary mechanisms, and that formin displacement may be more critical for controlling cable formation by Bnr1 than Bni1. Currently, we are using single molecule imaging to determine whether Cap1/2 and/or Bud14 join Bnr1 at barbed ends in decision complexes, and to define the similarities and differences in their displacement mechanisms.

P947/B69

Fhod-1 and Muscle Cell Size in *Caenorhabditis Elegans*.

C. Yingling, D. Pruyne; SUNY Upstate Medical University, Syracuse, NY.

Formins are cytoskeletal proteins best known for their ability to nucleate actin and to remodel the actin cytoskeleton within cells. A mammalian formin, FHOD3, is required for cardiac muscle cell maturation in mice. In neonatal rat cardiomyocytes, activated FHOD3 leads to hypertrophy, whereas knockdown of FHOD3 leads to disrupted sarcomere formation. In humans, FHOD3 variants have been linked to an increased incidence of hypertrophic cardiomyopathy. However, how FHOD3 contributes to muscle cell size remains unknown. Using a simple genetic model, *Caenorhabditis elegans,* we are investigating how FHOD-1, a homolog of FHOD3, contributes to muscle cell size. Our lab has shown that in *C. elegans,* loss of FHOD-1 is not lethal, unlike the loss of FHOD3 in mice. Worms lacking FHOD-1 develop striated muscles that are thinner beginning in mid-larval stage and never recover. We have shown that loss of FHOD-1 leads to the reduction of muscle-specific myosin heavy chain 3 (MYO-3) protein expression. Previous work has shown that formins regulate muscle gene expression indirectly through enhancing transcription in mammalian systems. To determine if FHOD-1 promotes MYO-3 mRNA or muscle gene expression, we preformed qRT-PCR and mRNA sequencing. However, our qRT-PCR and mRNA sequencing results showed that MYO-3 mRNA and muscle-specific genes were not downregulated in worms lacking FHOD-1. Thus, removing transcription as a means of FHOD-1 regulating muscle cell size. To determine if MYO-3 protein is being degraded, we pharmacologically inhibited two protein degradation pathways: calpains and the proteasome. Preliminarily, we have seen calpains have no effect on MYO-3. However, the proteasome appears to degrade MYO-3 protein. It is our hope that by

determining the role of FHOD-1 in the regulation of muscle protein expression, we might better understand how FHOD3 contributes to hypertrophic cardiomyopathy.

P948/B70

FHOD-1 Is the Only Formin That Contributes Directly to the Development of Body Wall Muscles in *Caenorhabditis Elegans*.

S. Sundaramurthy, S. Votra, A. Laszlo, D. Pruyne; SUNY Upstate Medical University, Syracuse, NY.

The striated body wall muscles (BWMs) of *Caenorhabditis elegans* are a simple model system with well-characterized sarcomeres that have many vertebrate protein homologs. Previously, we observed that the deletion mutants for two formin genes, *fhod-1* and *cyk-1,* had thinner BWMs compared to wild type. We wanted to more fully characterize how FHOD-1 and CYK-1 contribute to BWM development. However, CYK-1 is essential for cytokinesis during embryonic development, so homozygous *cyk-1(Δ)* progeny are derived from a heterozygous parent from which they receive a maternal contribution of CYK-1. We suspected that the presence of maternal CYK-1 in homozygous *cyk-1(Δ)* renders it partially functional and contributes to the development of BWMs. To test the complete loss of CYK-1 and avoid the issue of maternal CYK-1, we used a fast-acting temperature sensitive *cyk-1(ts)* mutant. Surprisingly, post-embryonic loss of CYK-1 had a minimal effect on larval BWM growth whereas loss of FHOD-1 has a more major effect. Additionally, only loss of FHOD-1 caused dispersed dense bodies which are Z-line analogs. During embryonic sarcomerogenesis, we observed that acute loss of CYK-1 did not cause any gross BWM defects, but the loss of FHOD-1 caused the F-actin striations to appear frayed. To test for cell autonomous roles in BWM development, we created mosaic formin expression strains by re-expressing either full-length FHOD-1 or CYK-1 in *fhod-1(Δ) and cyk-1(Δ)* mutants, respectively. We observed that individual BWM cell size and dense body morphology in *fhod-1(Δ)* mutants were rescued by re-expressing FHOD-1 in BWM cells. However, there was no similar rescue in *cyk-1(Δ)* mutants. This suggests that FHOD-1 promotes muscle cell growth cell-autonomously, whereas CYK-1 functions in a non cell-autonomous manner likely during embryonic development and its effect on BWMs could be indirect.

Mdia1/3 Facilitate Lat Phosphorylation by Zap70 Via the Spatiotemporal Control of F-actin Polymerization at the Immune Synapse.

D. Thumkeo[1], Y. Katsura[1], Y. Nishimura[2], P. Kanchanawong[2], N. Watanabe[3], M. F. Krummel[4], S. Narumiya[1]; [1]Department of Drug Discovery Medicine, Kyoto University, Kyoto, JAPAN, [2]Mechanobiology Institute, National University of Singapore, Singapore, SINGAPORE, [3]Department of Pharmacology, Kyoto University, Kyoto, JAPAN, [4]Department of Pathology, UCSF School of Medicine, San Francisco, CA.

The mechanism by which the cytosolic protein Zap70 physically interacts with and phosphorylates its substrate, the transmembrane protein LAT, uponT cell receptor (TCR) stimulation remains largely obscure. In this study, we found that the pharmacological inhibition of formins, a major class of actin nucleators, suppressed LAT phosphorylation by Zap70, despite TCR stimulation-dependent phosphorylation of Zap70 remaining intact. High resolution imaging and 3D image reconstruction revealed that localization of phosphorylated Zap70 to the immune synapse (IS) and subsequent LAT phosphorylation are critically dependent on formin-mediated actin polymerization. Using knockout mice, we identify mDia1 and mDia3, which are highly expressed in T cells and which localize to the IS

upon TCR activation, as the critical formins mediating this process. Our findings therefore describe previously unsuspected roles for mDia1 and mDia3 in the spatiotemporal control of Zap70-dependent LAT phosphorylation at the IS through regulation of filamentous actin, and underscore their physiological importance in TCR signaling.

P950/B72

Effect of Arpc1b Deficiency on Neutrophil Directed Migration.

A. N. Peterson, D. A. Bennin, J. Chini, A. Huttenlocher; University of Wisconsin-Madison, Madison, WI.

Neutrophils are primary cells of the innate immune system that mediate host defense. Neutrophils exhibit rapid, directed migration in response to chemoattractants and tissue damage. We have shown that the Arp2/3 complex is critical for neutrophil directed migration in vivo. We have also found that Arp2/3 inhibition impairs neutrophil directed migration in microfluidic systems in vitro. Here, we characterize the role of the ArpC1b, a WD40 repeat containing protein and regulatory component in the Arp2/3 complex on neutrophil directed migration. Previous studies have described patients with inflammation and allergy induced by Arpc1b deficiency. We modeled this disease in neutrophil-like PLB-985 cells using CRISPR/Cas9 to deplete Arpc1b. We found that Arbc1b depletion severely impaired neutrophil directed migration in 2D, and moderately impaired migration in a 3D matrigel environment. Expression of Arpc1b-GFP in the deficient line rescued cell migration. Taken together, these findings suggest that Arpc1b is necessary for efficient directed migration of neutrophil-like cells.

Capping Protein Insulates Arp2/3-assembled Actin Patches from Formins.

I. Billault-Chaumartin, S. Martin; UNIL, Lausanne, SWITZERLAND.

How actin structures of distinct identities and functions co-exist within the same environment is a critical self-organization question. Fission yeast cells have a simple actin cytoskeleton made of four structures: Arp2/3 assembles actin patches around endocytic pits; the formins For3, Cdc12 and Fus1 assemble actin cables, the cytokinetic ring during division, and the fusion focus during sexual reproduction, respectively. The focus concentrates the delivery of hydrolases by myosin V to digest the cell wall for cell fusion. We discovered that cells lacking capping protein, a heterodimer that blocks barbed-end dynamics and associates with actin patches, exhibit a delay in fusion. Consistent with capping protein-formin competition for barbed-end binding, Fus1, F-actin and the linear filament marker tropomyosin hyper-accumulate at the fusion focus in cells lacking capping protein. Capping protein deletion also rescues the fusion defect of a mutation in the Fus1 knob region. However, myosin V and exocytic cargoes are reduced at the fusion focus and diverted to ectopic foci, which underlies the fusion defect. Remarkably, the ectopic foci coincide with Arp2/3-assembled actin patches, which now contain low levels of Fus1. We further show that capping protein localization to actin patches is required to prevent the formation of ectopic foci and promote efficient cell fusion. During mitotic growth, actin patches lacking capping protein similarly display a dual identity, as they accumulate the formins For3 and Cdc12, normally absent from patches, and are co-decorated by the linear filament binding-protein tropomyosin and the patch marker fimbrin. Thus, capping protein serves to protect Arp2/3-nucleated structures from formin activity.

Structure-activity Relationships and Mechanism of the Formin Inhibitor Smifh2.

M. Landis, A. Klestzick, K. G. Song, V. Huang, S. Liu, J. Vadakkan, C. M. Rojas, **C. L. Vizcarra**; Barnard College, New York, NY.

The small molecule drug SMIFH2 was discovered in a biochemical screen for inhibitors of formin-stimulated actin polymerization (Rizvi, et al. 2009). While the original in *vitro* screen was carried out against the mouse formin mDia1, SMIFH2 was also found to be a cell permeable inhibitor that targeted both yeast and mammalian formins. Since then, SMIFH2 has been used widely to investigate formin function in diverse cellular contexts. However, the molecular mechanism of inhibition remains mysterious, and it is unknown whether the drug effects formin-mediated actin-microtubule crosstalk. In this study, we measured the affinity of SMIFH2 for purified C-terminal fragments from a range of human formins. SMIFH2 was found to have broad activity against human formins. To explore the relationship between chemical structure and biological activity, we generated analogs that vary in each ring of the molecule. Consistent with published data, a sulfur carbonyl on the central ring is essential for high-affinity binding. Our analog series also shows that the oxygen in the furan ring is essential and that halogenation but not methylation of the furan is tolerated. Neither INF2 or FMNL3 are able to bind to microtubules when bound to SMIFH2. Together our data support a model of SMIFH2 as a pan-formin inhibitor that blocks both actin and microtubule binding. Rizvi, S. A., Neidt,E.M., Cui, J., Feiger, Z., Skau, C.T., Gardel, M.L. Kozmin, S.A., Kovar D.R., Chemistry & Biology 2009, 16: 1158-1168.

Wiskott-Aldrich Syndrome Protein (wasp) Is Critical in Regulating Actin Reorganization Upon BCR Activation in Germinal Center B Cells.

Y. Li[1,2], A. Bhanja[1], X. Zhao[2], W. Song[1]; [1]University of Maryland, college park, MD, [2]Children's Hospital of ChongQing Medical University, ChongQing, CHINA.

B-lymphocytes are responsible for generating antibody responses against pathogens. B-cell receptors (BCRs) sense antigen and initiate B-cell activation. Activated B-cells form germinal centers (GC), where B-cells with high-affinity BCRs were selected through their competitive ability to engage and capture antigen on antigen-presenting cells. Actin plays a critical role in BCR activation in naïve B-cells. Actin drives B-cell spreading and subsequent contract on antigen-presenting cells, enhancing and attenuating BCR signaling, respectively, by reorganizing receptors. How actin works during the selection of GC B cells (GCBs) remains unclear. The hyperactivity of GCBs in Wiskott-Aldrich syndrome protein (WASP)-deficient mice supports a distinct role for actin in GCBs. Using WT and WASP knockout (WKO) mice expressing Lifeact-GFP or GFP-non-muscle myosin II as models, this study examined actin's role in BCR activation in GCBs. We quantitatively analyzed the dynamics of actin reorganization, cell spreading, and BCR clustering in GCBs interacting with antigen on planar lipid bilayers (PLBs) using live-cell imaging by total internal reflection fluorescence and interference reflection microscopy. We found that WT GCBs rapidly accumulate F-actin at the contact zone upon binding the stimulatory PLB. After the accumulation reached a plateau, a central actomyosin ring structure formed. Concurrently, GCBs spread rapidly and symmetrically. Upon reaching a plateau, the contact area was maintained. The periphery area of the contact zone bound to the PLB much stably than the central area. As GCBs spread, BCRs rapidly accumulated and formed microclusters in the contact zone. Upon forming, BCRs microclusters did not grow or merge. Compared to WT GCBs, both the kinetics and the maximal levels of F-actin accumulation

in the contact zone of WKO GCBs were significantly reduced. There was also no central actomyosin ring structure. WKO GCBs took a longer time to take foothold to the PLB. Upon binding, WKO GCBs spread asymmetrically in a slower rate than WT GCBs and could not maintain the stably bound periphery and the active center in the contact area. Consequently, BCRs clustered at a slower rate and a reduced level in the contact zone of WKO GCBs, which reduced the kinetics and levels of signaling. Our results suggest that actin in GCBs is not only responsible for driving cell spreading and BCR clustering, but also for maintaining the sizes and organization of BCR microclusters for optimal signaling.

P954/B76

The Actin Regulatory Protein WASp Control Activation of Nucleic Acid Innate Sensors.

G. M. Piperno[1], A. Naseem[1], N. Liv[2], J. Klumperman[2], F. Graziano[3], P. Benaroch[4], R. Hanna[5], F. Benvenuti[1]; [1]ICGEB, Trieste, ITALY, [2]University Medical Center, Utrecht, NETHERLANDS, [3]Institute Curie Laboratoire Immunité et Cancer, paris, FRANCE, [4]Institute Curie Laboratoire Immunité et Cancer, Paris, FRANCE, [5]MedImmune LLC, Gaithersburg, MD.

Wiskott-Aldrich syndrome protein (WASp) is an actin nucleation promoting factors (NPFs) specifically expressed in cells on the hematopoietic lineage that controls multiple immune related functions. Mutations is WASp are linked to a rare immune deficiency, Wiskott-Aldrich syndrome (WAS), that manifests with frequent autoimmune manifestations and increased inflammatory responses to self-DNA in myeloid cells. At present the exact molecular link between actin regulation and excessive activation of inflammatory genes is not fully understood. Here we show that endosomal F-actin nucleation by Wiskott-Aldrich syndrome protein (WASp) is required for endosomal sorting and fusion with lysosomes in dendritic cells. Lack of WASp induces stalling and accumulation of ingested immunogenic cargo in maturation-defective organelles enhancing their immunogenicity. Moreover, defective endosomal maturation is accompanied by increased membrane fragility and leakage of endocytosed material to the cytosol, favoring activation of cytosolic innate sensors. These findings identify WASp as critical to set the threshold of innate sensors and unveil the mechanism underlying excessive inflammatory responses in WAS disease.

Elucidating Mechanisms Contributing to Actin Meshwork Formation.

M. T. Panzica, M. Quinlan; University of California, Los an geles, Los an geles, CA.

Temporally and spatially controlled actin filament assembly and disassembly is essential for a wide range of cellular processes. In *Drosophila* oogenesis, two actin nucleators, Spire and Capu (FMN-formin family member), are critical for meshwork formation. The mammalian homologs of Spire and Capu (FMN2) are required for a similar meshwork in mouse oocytes, along with the GTPase Rab11 and the actin motor protein MyosinV (MyoV). Recently, MyoV was shown to recruit Spire to Rab11-positive vesicles through a direct interaction in mouse. Not only do Spire, Rab11 and MyoV form a tripartite complex, this complex also recruits FMN2 and provides the first model of coordination between cytoskeleton assembly and transport. However, the ability of Spire or FMN2 to assemble actin filaments while part of this complex remains to be tested. To investigate the significance of Spire-MyoV binding in *Drosophila,* we first examined their binding in *vitro* and have identified key residues for their interaction. We report the effects of MyoV binding on Spire actin assembly in *vitro.* Together, these data form the basis for further studies in *Drosophila* oocytes to understand actin meshwork formation.

P956/B78

Inhibition of Arp2/3-mediated Actin Nucleation Alters Membrane Dynamics but Does Not Block Pigment Granule Aggregation Or Dispersion in Isolated Fish Retinal Pigment Epithelial (RPE) Cells.

T. Tashiro, C. King-Smith; Saint Joseph's University, Philadelphia, PA.

Actin filaments support organelle transport in numerous cell types by serving as tracks for multiple classes of myosin motors. In addition, non-muscle myosin II has been shown to power endosome, mitochondria, and actin patch movement in budding yeast indirectly, by moving actin cables to which organelles are attached. A similar mechanism has been proposed for aggregation of pigment granules through apical projections of fish retinal pigment epithelial (RPE) cells. Dissociated RPE cells cultured in vitro, having their apical projections attached to the substrate can be triggered to aggregate pigment granules towards the cell body through the application of cAMP. Aggregation of pigment granules requires an intact actin cytoskeleton and non-muscle myosin II. To further investigate the mechanism of pigment granule aggregation, and determine the role of actin nucleation in pigment granule motility, we treated isolated cells with the Arp2/3 complex inhibitor, CK-666. Time lapse videos revealed that in control cells, RPE apical projections are very dynamic, often exhibiting random protrusions of membrane and cytoplasm that extend laterally from RPE cell projections, then move in a retrograde direction, towards the cell center. Treatment with 100 uM CK-666 rapidly stopped formation and movement of these membrane protrusions. However, aggregation of pigment granules in RPE cells treated with CK-666 occurred as in control cells, even after a 30 minute pre-treatment with the drug. Similarly, CK-666 did not block dispersion of pigment granules out of the cell body. These results suggest that although membrane dynamics in RPE apical projections is affected CK-666, pigment granule motility persists, and is independent of actin filament nucleation.

Arp2/3 Nucleates Conventional and Divergent Actin Networks In*Chlamydomonas Reinhardtii*.

B. M. Bigge[1], D. Sept[2], C. Schroeder[3], P. Avasthi[1]; [1]University of Kansas Medical Center, Kansas City, KS, [2]University of Michigan, an n Arbor, MI, [3]Fred Hutchinson Cancer Research Center, Seattle, WA.

Because conventional actin is critical for many cellular processes, it is generally highly conserved, but divergent actins do exist. Here, we investigate the interactions between Arp2/3, a branched actin nucleator, and actins with varying degrees of variance using the unicellular green alga *Chlamydomonas reinhardtii,* which expresses two actin genes: *IDA5*, a conventional actin that is 89% identical to rabbit skeletal muscle actin; and *NAP1,*a divergent actin with only about 65% sequence identity. Sequence alignments between IDA5 and NAP1 show that of the 30 actin residues that bind Arp2/3, over half are not conserved in NAP1. Based on these differences, we hypothesized that Arp2/3 would interact with IDA5 but not NAP1. To test this in *vivo*, we identified structures and phenotypes dependent on either IDA5 or NAP1 to use as readouts of interaction. We found IDA5 dependent puncta that may be analogous to actin patches or endocytic pits and flagellar assembly and maintenance were Arp2/3 dependent. This data supports the first half of our hypothesis that Arp2/3 can nucleate IDA5 filaments. Next, we tested whether Arp2/3 could interact with NAP1 by looking at NAP1-dependent structures and phenotypes. LatB-induced NAP1 perinuclear rings, NAP1-dependent flagellar assembly and maintenance under conditions free of IDA5 filaments, and NAP1-dependent restoration of gating proteins at the base of the flagella were inhibited by Arp2/3 perturbation. This data suggests that Arp2/3 can nucleate filaments of NAP1 disproving our hypothesis that Arp2/3 would not interact with NAP1. Overall, we

conclude that although sequence variance exists between the Arp2/3 binding regions of IDA5 and NAP1, chemical and genetic disruption of Arp2/3 affects organization and function of filaments made of either actin. This suggests potential interactions between IDA5 and NAP1 with Arp2/3 which we aim to biochemically characterize.

P958/B80

Photoreceptor Disc Membranes Are Formed through a Lamellipodium-like Mechanism.

W. Spencer; Duke University, Durham, NC.

The light-sensitive outer segment of the vertebrate photoreceptor is a highly modified primary cilium filled with disc-shaped membranes which provide a vast surface for efficient photon capture. The formation of each disc is initiated by a ciliary membrane evagination driven by an unknown molecular mechanism reportedly requiring actin polymerization. Since a distinct F-actin network resides precisely at the site of disc morphogenesis, we employed a unique proteomic approach to identify components of this network potentially driving disc morphogenesis. Most importantly, the only identified actin nucleator was the Arp2/3 complex, which induces the polymerization of branched actin networks. Conditional knockout of Arp2/3 from rod photoreceptors results in the complete loss of the F-actin network specifically at the site of disc morphogenesis, and completely halts the initiation of new disc formation. These data establish a new model of photoreceptor disc morphogenesis in which Arp2/3 initiates disc formation in a “lamellipodium-like” mechanism.

Deep Learning Reveals the Link between Filament Architecture and Subunit Conformation in Bent Actin.

M. J. Reynolds, R. Gong, S. Espinosa de los Reyes, G. M. Alushin; the Rockefeller University, New York, NY.

Migrating cells can be “steered” by mechanical cues in their local microenvironments on rapid timescales through direct mechanical regulation of the branched actin networks powering motility. The binding probability of the ARP2/3 complex, which nucleates daughter filament branches from the side of pre-existing mother filaments, was previously shown to be biased by mother filament curvature, suggesting a mechanism to couple network density to filament bending by compressive load. We pursued cryo-EM structural analysis of bent filaments, hypothesizing it could reveal structural states of the actin subunit which could be recognized by binding partners at the molecular scale. We found that standard single-particle classification methods to probe structural heterogeneity poorly captured bent states of actin, which occur infrequently under standard sample preparation conditions and differ too subtly from straight actin to be separated by maximum-likelihood based approaches. We thus developed a deep-learning based approach to identify bent actin segments: F-actin was curved in silico and synthetic projection images were generated. A denoising autoencoder was trained to learn a continuous manifold of actin bending from these images. The encoding portion of the network was then used to help train two other neural networks: one network performed semantic segmentation on entire micrographs, and another network measured filament curvature on a per-particle basis. These trained networks were used to pick actin segments with curvatures measured above a fixed threshold, which were then used to reconstruct a bent F-actin state to near-atomic resolution. This structure shows substantial rearrangements of the actin subunits in the bent region which could be recognized by

binding partners including ARP2/3. This study also represents, to our knowledge, the first high-resolution glimpse at a high-energy, mechanically-regulated structural state, providing insight into how mechanical forces are transduced into protein conformational regulation in atomistic detail.

P960/B82
Insights into Actin Polymerization and Nucleation Using a Coarse-grained Model.
B. G. Horan, **D. Vavylonis**; Lehigh University, Bethlehem, PA.

We studied actin filament polymerization and nucleation with molecular dynamics simulations and a previously established coarse-grained model having each residue represented by a single interaction site located at the C_α atom. We approximate each actin protein as a fully or partially rigid unit to identify the equilibrium structural ensemble of interprotein complexes. Monomers in the F-actin configuration bound to both barbed and pointed ends of a short F-actin filament at the anticipated locations for polymerization. Binding at both ends occurred with similar affinity. Contacts between residues of the incoming subunit and the short filament were consistent with expectation from models based on crystallography, X-ray diffraction and cryo-electron microscopy. Binding at the barbed and pointed end also occurred at tilted conformations and the barbed end tilt range was dependent on the flexibility of the D-loop. Additional barbed end bound states were seen when the incoming subunit was in the G form. Consistent with an activation barrier for pointed end polymerization, G-actin did not bind at an F-actin pointed end. In all cases, binding at the barbed end also occurred in a configuration similar to the antiparallel (lower) dimer. Individual monomers bound each other in a short-pitch helix complex in addition to other configurations, with several of them apparently non-productive for polymerization. Simulations with multiple monomers in the F-actin form reproduce filamentation as well as transient aggregates at the barbed end. We discuss the implications on the kinetic pathway of actin filament nucleation and polymerization and possibilities for future improvements of the coarse-grained model.

Regulation of Actin Dynamics 2

P961/B83
Regulators of Arp2/3 Nucleation Are Combinatorially Deployed to Build Complex 3D Actin Structures in *Vivo*.
Y. Xie, J. Blankenship; University of Denver, Denver, CO.

Despite extensive studies on the actin regulators that direct microfilament dynamics, how these regulators are combinatorially employed to generate complex three-dimensional structures in an intact organism is an unsolved question. Here, we present an in-depth characterization of actin cap dynamics and their regulation in vivo in the early Drosophila syncytium. Actin caps go through rapid phases of initiation, expansion, elongation and fragmentation in each syncytial cycle. We examine the role of 7 different Arp 2/3 regulators and find they provide distinct but cooperative functions in building actin cap morphologies. Specifically, while DPod1 is the major regulator of actin intensities in the apical cap, Cortactin is required for the continued growth of the cap as well as the maintenance of cap size. Coronin, on the other hand, functions in both cap size and intensity, and, intriguingly, is required for Cortactin localization to the cap periphery. Surprisingly, knocking down the function of Formin or Arp2/3 networks leads to faster FRAP recoveries, suggesting that these networks are in deep competition for a limited G-actin pool. We also measure the relative efficiencies of Arp2/3 recruitment by each regulator

in the embryo. Finally, proper structuring of the actin cap is essential for genomic stability and nuclei anchorage, with a loss of actin/intensity/levels/size correlating with nuclear fallout. Our results suggest how the coordination of multiple actin regulators can orchestrate organized and dynamic actin structures in an in vivo system.

P962/B84

Roles for CIN85, an SH3 Domain- and Proline-rich Motif-containing Adaptor Protein, in Actin Assembly at Sites of Clathrin-mediated Endocytosis in Human Stem Cells.

M. Jin, Y. Sun, D. Drubin; University of California, Berkeley, Berkeley, CA.

Clathrin-mediated endocytosis (CME) is highly conserved in eukaryotic cells and generally is augmented by a burst of actin assembly. In yeast cells, actin filament assembly plays an indispensable role in plasma membrane invagination and vesicle scission during this process. Proteins containing Src homology 3 (SH3) domains and proline-rich motifs (PRMs) are highly enriched among endocytic proteins. Interactions between these domains are important for precise special and temporal regulation of actin assembly at clathrin-coated pits (CCPs). SH3 domains of the endocytic adaptor protein Sla1 and the PRM of the coat protein Pan1 link actin assembly to endocytic sites by recruiting SH3- and PRM-containing proteins that play roles in the subsequent actin assembly step, including Las17, a WASP-related nucleation promoting factor (NPF). In mammalian cells, the functions and regulation of actin assembly during CME are less well understood. CME is a complex and highly regulated process, which involves the sequential recruitment of over 60 proteins to endocytic sites. Our lab studies CME in human induced pluripotent stem (iPS) cells using genome editing to express fluorescent protein fusions of endocytic proteins at endogenous levels, thus avoiding disruption of the physiological temporal and spatial organization of the process that can result from protein overexpression. In this study, to investigate actin assembly regulation during mammalian CME, we generated cell lines expressing Halotag labeled endogenous CIN85 (Sla1 homolog) using the CRISPR-Cas9 genome-editing. By applying total internal reflection fluorescence (TIRF) live-cell imaging, we quantitatively analyzed the dynamics of these proteins at CCPs. To our surprise, we observed distinctive behaviors of CIN85, which contains both SH3 domains and PRM, from its yeast homolog. To determine its functions in mammalian CME, we studied actin assembly and overall CME dynamics in the CIN85 knockdown or overexpressed cells and further analyzed the behaviors of various forms of SH3 or PRM mutants of CIN85. Our results provide important insights into roles for CIN85 in actin assembly at CCPs in human stem cells.

P963/B85

The Scaffold Protein RACK1 Modulates Cytoskeletal Rearrangement during Regulated Secretion.

E. G. Freitas, Filho[1], L. A. M. Jaca[1], W. D. Swaim[2], H. Ong[2], I. S. Ambudkar[2], **C. Oliver**[1], M. Jamur[1]; [1]FMRP-USP, Ribeirao Preto, BRAZIL, [2]NIH-NIDCR, Bethesda, MD.

RACK1 (receptor for activated protein C kinase 1) is crucial for cellular activities and acts as a signaling hub in immune cell responses. Mast cell (MC) activation via antigen results in secretory granule release and is accompanied by cytoskeletal reorganization. The involvement of RACK1 in this process is unknown. By immunostaining, RACK1 was distributed throughout the cytoplasm of RBL-2H3 MCs. In antigen-stimulated cells, RACK1 was primarily localized adjacent to the plasma membrane. In order to investigate the relationship of RACK1 to the cytoskeleton in MCs, RACK1 was knocked down using lentiviral particles encoding shRNAs. Non-stimulated ShControl MCs were fusiform with a continuous

cortical F-actin layer and organized vimentin filament bundles. However, ShRNA mediated RACK1 knockdown (KD) MCs were rounded and the cortical F-actin was fragmented. The intermediate filaments in the cortical region in the KD MCs were also discontinuous. After antigen-stimulation, cortical F-actin was dramatically reduced, and the vimentin filament bundles were disorganized with vimentin free spaces in RACK1 KD MCs. When live LifeAct-RFP transfected MCs were analyzed by TIRFM, this disorganization of the cortical F-actin following stimulation in RACK1 KD MCs was highlighted. The distribution of microtubules in RACK1 KD MCs appeared to be unchanged. The microtubules continued to follow the cell shape. Although, co-immunoprecipitation experiments demonstrated an antigen-stimulation dependent increase in RACK1 interaction with cytoskeletal constituent proteins, high resolution confocal microscopy showed that there was a gap between RACK1 and actin. This suggests that RACK1 and actin are coupled through a linker and do not directly interact. Furthermore, RACK1 depletion significantly increased basal and stimulus-induced degranulation. $CD63^+$ secretory granules were localized in F-actin and vimentin-free cortical regions in non-stimulated RACK1 KD MCs and following antigen-stimulation they were concentrated in the apical region. This localization most likely facilitates and accelerates their release in RACK1 KD MCs. In contrast, RACK1 depletion resulted in a decrease in the secretion of newly synthesized mediators but did not affect newly formed mediator release. These results show that RACK1 is a critical regulator of actin dynamics and intermediate filament organization and provide additional information for understanding the molecular mechanisms involved in secretory granule release.

P964/B86

Role of the Actin Severing Factors, ADF/cofilin and Gelsolin, in Regulating the Fast Amoeboid Or Leader Bleb-based Migration of Cancer Cells.

M. F. Ullo, J. S. Logue; Albany Medical College, Albany, NY.

The cortical actomyosin cytoskeleton lies directly underneath the plasma membrane of all cells. In cancer cells, a high level of cortical actomyosin contractility is correlated with invasiveness. Recently, it was discovered that cancer cells can undergo fast amoeboid or Leader Bleb-Based Migration (LBBM), which requires the formation of a large and stable bleb for migration. Contained within all leader blebs, is a fast cortical actomyosin flow driving the cell forward, however the fundamental mechanisms required to maintain contractility and actin flow in leader blebs is not understood. Here, we hypothesize that actin severing factors, such as the ADF/cofilin family and gelsolin, are essential to maintain both contractility and actin flow for LBBM. Using RNAi in melanoma A375-M2 cells and a flow cytometry-based method for measuring F-actin, we find that co-depleting ADF and cofilin and not gelsolin led to a large increase in the level of F-actin, suggesting that ADF and cofilin together regulate actin in these cells. Moreover, using barbed-end assays and high-resolution imaging, RNAi of ADF and cofilin increased the number of cortical, polymerization competent, barbed-ends. Therefore, severing by these proteins appears to promote cortical actin turnover in melanoma A375-M2 cells. Furthermore, actin severing has been shown to promote contractility through the regulation of actin architecture. In line with this concept, RNAi of ADF and cofilin significantly increased cell deformability, as determined by a gel sandwich approach. As LBBM is stimulated by cell confinement, we next used a PDMS slab-based approach, which uses micron-sized beads for the precise control of cell confinement, to evaluate the role of ADF/cofilin in regulating cortical actin dynamics in blebbing cells. Ratio imaging of EGFP-cofilin and mScarlet revealed cofilin to be enriched within leader blebs, whereas RNAi of ADF and cofilin reduced bleb sizes and the frequency of motile cells. Strikingly, many blebs failed to retract in the

absence of ADF and cofilin, these cells had exceptionally long necks separating blebs and the cell body. Therefore, actin severing by these proteins appears to be critical to the function of the contractile bleb neck. Collectively, our data identifies ADF and cofilin as cortical actin remodeling factors required for the amoeboid migration of metastatic cancer cells.

P965/B87

Mechanistic Contributions of Coronin 1b and Coronin 1c in Cell Migration.

Z. King, J. Bear; University of North Carolina- Chapel Hill, Chapel Hill, NC.

Cell migration plays an essential role in physiological events including morphogenesis, wound healing and immune responses. To facilitate cell migration, actin must undergo rapid cycles of assembly and disassembly in a highly-coordinated manner. Type I coronins, a conserved class of actin binding proteins, have been shown to regulate the process of cell migration by modulating the turnover of the branched actin network at the leading edge. Recent work suggests that Coronin 1C (Coro1C) mediates the formation of membrane protrusions during cell migration; while the structurally similar Coronin 1B (Coro1B) regulates the disassembly of branched actin networks within these protrusions. However, despite these results our understanding of the function of Coro1B and Coro1C to actin dynamics and specifically in directed cell migration remains incomplete. Therefore, the overall objective is to elucidate the mechanistic contributions of Coro1B and Coro1C in branch stability and de-branching during migration. *I hypothesize that Coro1B and Coro1C regulate branched actin dynamics by modulating the functions of cofilin and actomyosin contractility during directed cell migration. To* test this hypothesis, I have established a fibroblast cell line derived from Coro1B knockout (KO), Coro1CFL/FL mice that is rescued with a flox-able Coro1B-GFP expression construct. Upon Cre-mediated recombination, both exogenous Coro1B-GFP and endogenous Coro1C are deleted to create a matched-pair null cell line. To assess the functional role of Coro1B and Coro1C in haptotaxis, I utilized a microfabrication technique that generates substrate-bound gradients. In addition, we used live-cell imaging and acute pharmacological inhibition of branched actin to examine changes to cell morphology, cell behavior, and cytoskeletal structure and organization in the matched-pairs. In the absence of Coro1B and Coro1C, cells lack directionality, migrate more slowly and have altered protrusions dynamics as compared to WT counterparts. Furthermore, deletion of Coro1B and Coro1C increased actomyosin contractility as well as increased total cofilin levels while inactive cofilin levels remained the same. These data suggest that Coro1B and Coro1C are highly involved in regulating actin dynamics at the leading edge which is required for effective actin remodeling and organization as well as directed migration.

Effects of Hiv-1 Tat on Microglial Phagocytic Activity and Cytoskeletal Protein Cofilin.

N. Barnes, K. Blake, T. Swindell, J. King; Ursinus College, Collegeville, PA.

Neuroinflammation is a mechanism that occurs in response to injury or infection and often its effects can lead to neurodegeneration. The neuroinflammatory process is implicated in a number of neurodegenerative diseases including Alzheimer's Disease (AD), Parkinson's Disease (PD), and HIV associated neurocognitive disorders (HAND). A key component of neuroinflammation are microglia that function to balance the micro-environment of neurons through the phagocytosis of bacteria, viruses and any foreign substances. Key findings from our studies have shown that the HIV-1 tat protein used as an inflammatory mediator induces a significant increase in two chemokines that directly control cell

migration and phagocytic activity. It is important to note that actin cytoskeleton plays an essential role in the homeostasis and normal functioning of cells, including microglia. Specifically, the motility, phagocytic activity, morphology and immune response of microglia hinges on the remodeling of the cystoskeleton. Over activated microglia can lead to alterations in their cytoskeleton thereby effecting functional activity. Cofilin and Phospho-Cofilin (P-Cofilin) are regulatory proteins that assist in actin reorganization and cytoskeletal function. We used HIV-Tat protein as a model inflammatory mediator to observe how microglial cells respond to an inflammatory environment. Previous research has been inconclusive in addressing these specific changes, therefore we aim to understand the effect inflammatory mediators have on microglia phagocytic activity and cytoskeletal structure. Through a series of cell culture experiments utilizing phagocytosis assays, immunofluorescence and immunoblotting techniques we have shown that microglia phagocytic activity is consistently decreased when exposed to inflammatory mediators and that modulation occurs as cytoskeletal protein activation decreases. Overall, our studies indicate that neuroinflammation can modulate microglial cytoskeletal proteins and function that could play a role in indirect neurodegeneration.

Ecm29-dependent Localization of the Proteasome Regulates Actin Polymerization and Immune Synapse Formation in B Cells.

J. Ibañez-Vega[1], F. Del Valle-Batalla[1], J. Saez[1], A. Soza[2], M. I. Yuseff[1]; [1]Cell and molecular Biology, Pontificia Universidad Catolica De Chile, Santiago, CHILE, [2]Cell and molecular Biology, Universidad San Sebastian, Santiago, CHILE.

Recognition of surface-tethered antigens by the B cell receptor (BCR), leads to the formation of a specialized platform termed immune synapse (IS), where actin remodeling, signaling and membrane trafficking are focused. Concomitantly, BCR engagement triggers the recruitment of lysosomes to the IS by mobilizing the centrosome, a process which relies on the depletion of perinuclear actin. We previously described that the proteasome localizes at the centrosome and IS, and its activity is necessary for actin remodeling during IS formation. In this work we studied the cellular mechanisms involved in the localization of the proteasome and focused on Ecm29, previously shown to link the proteasome to motor proteins in neurons. We asked whether Ecm29 could mediate the localization of the proteasome to the centrosome and IS in B cells and evaluated whether silencing of Ecm29 could have an impact in actin remodeling within these sites. We first characterized proteasome dynamics at the IS in B cells activated with immobilized antigens, by Total Internal Reflection Fluorescence Microscopy (TIRFM). For this, we labeled microtubules or the actin cytoskeleton together with the proteasome, using a specific probe, which allowed us to track the proteasome in live cells, upon activation. We found that proteasome movements at the IS followed the microtubule network and its localization was coupled to local actin depletion. Additionally, our results show that Ecm29-silenced B cells display reduced proteasome mass and activity at the centrosome, which was more enriched at the synaptic membrane, compared to control cells. In agreement with these observations, actin dynamics at the IS of Ecm29-silenced B cells was increased, as measured by the Fluorescence Recovery After Photobleaching (FRAP) of Actin-GFP. Moreover, actin accumulation within isolated synaptic membranes was reduced and BCR signaling was enhanced in Ecm29-silenced cells. Thus, Ecm29 controls the localization of the proteasome to the IS, where it mediates local actin remodeling and B cell activation. Finally, we determined the effect of Ecm29 silencing on the centrosome pool of actin and found that the perinuclear actin clearance, triggered by BCR activation, was delayed. Consequently, lysosome and centrosome

recruitment to the IS were impaired in Ecm29 silenced B cells, which also displayed deficient antigen extraction and presentation. In conclusion, we show that Ecm29 regulates the localization of the proteasome in B cells, where it tunes actin dynamics at the IS and promotes the depletion of actin at the centrosome, controlling activation, antigen extraction and presentation in B cells.

P968/B90

Both Branched and Bundled Actin Are Required for B-cell Receptor-induced B-cell Response to Antigen.

A. Bhanja, A. Johnston, I. Rey, A. Upadhyaya, W. Song; University of Maryland, College Park, College Park, MD.

B-cells confer adaptive immunity through generating antibodies. Upon antigen recognition by the B-cell receptor (BCR), B-cells spread over the antigen-presenting surface, which promotes BCR aggregation into microclusters, amplifying signaling. Following spreading, the B-cell contracts, driving BCR microclusters to reorganize into a large central BCR cluster, which leads to signal attenuation. Inhibition of B-cell spreading or contraction through perturbing actin results in immune deficiency and autoantibody production in mouse models. However, how actin reorganization transitions B-cells from spreading to contraction remains unclear. Here we examined the role of branched and bundled actin, the two major types of actin structures, in this process. We utilized Arp2/3 and formin inhibitors to perturb the generation of branched and bundled actin. We analyzed their effects on lifeact-GFP expressing primary B-cells activated by antigen presented on planar lipid bilayers using live cell imaging by total internal reflection fluorescence (TIRF) microscopy. Perturbation of either branched or bundled actin before B-cell spreading reduced the overall level of F-actin accumulation at the B-cell contact zone. Particularly, perturbation of bundle actin disrupted the centripetal flow of actin. Concurrently, the rate of B-cell spreading was reduced and B-cell contraction was inhibited, which led to a decrease in BCR aggregation. Perturbation of branched actin after spreading inhibited B-cell contraction. Consequently, BCR clusters failed to move centripetally and grow in size. Our results suggest that both branched and bundled actin are required for not only B-cell spreading, but also B-cell contraction, which regulates BCR signaling by modulating the formation, growth and centripetal movement of BCR clusters.

P969/B91

Actin Dynamics and Organization at the T Cell Immune Synapse: the Role of the Signaling Protein Bcl10.

K. Wagh[1], B. A. Wheatley[1], M. K. Traver[2], I. Hussain[2], B. C. Schaefer[2], A. Upadhyaya[1]; [1]University of Maryland, College Park, MD, [2]Uniformed Services University, Bethesda, MD.

T cells form an essential part of the adaptive immune system. Stimulation of the T cell receptor (TCR) leads to rapid remodeling of the actin cytoskeleton. Defects in actin dynamics and organization lead to impaired immune response. Here, we use total internal reflection fluorescence (TIRF) microscopy to monitor actin dynamics at the immune synapse of primary murine effector T cells. Quantification of these dynamics using spatiotemporal image correlation spectroscopy (STICS) reveals two distinct temporal phases, showing differences in speeds and directionality. Interestingly, our results indicate that cells lacking Bcl10 - a protein involved in NF-κB signaling - display faster actin flows, more dynamic lamellipodia and smaller actin rings, resulting in altered T cell function.

P970/B92

Abelson Tyrosine Kinases Link Cbl E3 Ubiquitin Ligase to Regulate WAVE Regulatory Complex.

P. Jiang, J. Faulkner, H. K. Hudgins,, D. FARRIS, T. Smalligan, R. Walker, T. Naguib, **Z. Dai, 79119**; Texas Tech University Health Sci. Ctr, Amarillo, TX.

The family of Abl-interactor (Abi) proteins is a downstream target of Abelson (Abl) tyrosine kinases and a component of WAVE regulatory complex (WRC). As a subunit of WRC, Abi proteins interact with diverse membrane proteins and intracellular signaling molecules and link them to the actin cytoskeleton remodeling. The ability to interact with the regulatory machinery of actin assembly as well as membrane proteins places Abi1 at a central position in the network that controls endocytosis and/or intracellular trafficking of membrane receptors. However, the mechanism by which Abi proteins regulates these cellular processes remains largely unknown. We have previously shown that Abi2 is rapidly degraded in Bcr-Abl-positive leukemic cells through an ubiquitin-dependent proteolysis pathway. In this study we present the evidence that Bcr-Abl-induced Abi2 degradation is mediated by Cbl E3 ubiquitin ligases. Double knockout of c-Cbl and Cbl B in Bcr-Abl-transformed leukemic cells completely abolishes Bcr-Abl-induced degradation of Abi2. We have identified a Cbl-PKB binding motif in Abi2 and we show here that the tyrosine 213 (Y213) in this motif is essential for Cbl-mediated degradation. A mutation of Y213 to phenylalanine in Abi2 is sufficient to abrogate the Bcr-Abl-induced degradation of Abi2. Together, these studies uncover a novel mechanism by which the WRC is regulated in leukemic cells. Given that both Cbl and WRC have been shown to regulate membrane receptors, these studies may shed light on the mechanism that controls membrane receptor endocytosis and trafficking.

P971/B93

Analysis of the Proteome of the Immunological Synapse in NK Cells.

A. M. Meyer[1], G. Jacquemet[2,3], M. T. Lam[1], J. Ivaska[2], A. F. Carisey[1,4], J. S. Orange[1]; [1]Department of Pediatrics, Columbia University Medical Center, New York, NY, [2]Turku Bioscience Centre, University of Turku and Åbo Akademi University, Turku, FINLAND, [3]Faculty of Science and Engineering, Cell Biology, University of Turku and Åbo Akademi University, Turku, FINLAND, [4]WTS Center for Human Immunobiology, Baylor College of Medicine, Texas Children's Hospital, Houston, TX.

NK cells are innate immune cells that provide protection against virally compromised or transformed cells. Direct killing occurs through the release of lytic granules onto the target cell at the immunological synapse (IS). The IS is a unique structure formed at the site of contact between the immune cell and the target cell and is characterized by a dense actin mesh on the effector cell side. The formation of dynamic hypodense regions of actin in this mesh allows for lytic granules to reach the plasma membrane, resulting in the release of the granule's contents within the IS space. While many key components regulating the dynamics of the IS have been identified, its complete composition remains unknown and our understanding of this structure remains therefore limited to the list of known targets with available antibodies. To address this, we sought to create an innovative experimental approach to identify the molecular components mobilized on the NK cell side of the IS during cytotoxic activity that would allow the identification of new components. We have developed a method to extract and purify the portion of the NK cell cortex engaged in the IS. Ligand-coated beads replaced typical target cells and were incubated with a human NK cell line (NK-92), allowing the IS to form. Using a combination of cross-linkers, detergent and sonication, we then separated and purified the cellular cortex at the IS from the bulk of the NK cell. To demonstrate that our technique works, we screened by Western blot for a series

of known markers for the IS and other various cellular compartments to testify to the specificity and efficacy of our purification approach. In parallel, we observed by immunofluorescence that F-actin and myosin IIa are maintained as a patch on the beads following sonication of the whole cell. The footprint left by the effector cell onto the bead suggests that the architecture of the IS is preserved by our extraction protocol, increasing the probability of purifying intact cortices. In a subsequent large-scale assay, we have analyzed by mass spectrometry the proteome ("immune synapsome") present at the IS and compared the activated and tethered-only NK cell conditions. 515 proteins were unique to the cortex of activated NK cells and 256 additional ones were enriched compared to those in the tethered-only cortex condition. Among the proteins enriched, we confirmed the identification of expected IS-localized proteins such as CD3ζ, ZAP70, granzymes, perforin, and several downstream adaptors of the activation receptor in the activated NK cell cortex sample. This result validates our method and provides confidence to further investigate other IS-enriched proteins, with the ultimate goal of uncovering novel key regulators of NK cell cytotoxic function.

P972/B94

Novel Actin Ring Structure in *Clamydomonas in* Vegetative *Clamydomonas*Cells Plays Potential Role in Nuclear Integrity.

A. Salberg, B. M. Bigge, E. Craig, P. Avasthi; University of Kansas Medical Center, Kansas City, KS.

The unicellular, green alga *Chlamydomonas reinhardtii* is an excellent model organism to study the cytoskeletal actin network because of its two actin genes, *IDA5* and *NAP1*. IDA5 is a conventional actin that is about 90% identical to mammalian actin, whereas the divergent actin NAP1 has only about 65% sequence identity to mammalian actin. Using a phalloidin staining protocol, we are able to visualize the complex branched actin network. Upon treatment with Latrunculin B, a drug that depolymerizes IDA5, NAP1 is upregulated and a novel ring-like structure made of filamentous actin forms around the nucleus in about 60% of wild-type cells. Interestingly, the same treatment in gametes results in significantly less rings. These rings can also be seen in *ida5* null mutants, but not in *nap1* null mutants, suggesting NAP1 is necessary and sufficient for ring formation. Quantification of these perinuclear actin rings shows that ring area and perimeter scale with cell volume and surface area. The function of these rings remains unknown, but we have observed possible DNA leakage from the nucleus during the time of early ring formation leading us to hypothesize that these ring structures play a critical role in nuclear integrity.

P973/B95

Unveiling the Role of Actin Regulation on Kras-induced Autophagy Using *Caenorhabditis Elegans* as an in *Vivo* Model.

A. Mendes[1], F. Chan[1], I. Loureiro[1], A. Preto[2], A. Carvalho[1]; [1]Health Innovation and Investigation Institute, Porto, PORTUGAL, [2]Centre of Molecular and Environmental Biology, Braga, PORTUGAL.

KRAS is a small GTPase protein that is found mutated in 30-50% of sporadic colorectal cancer (CRC). Cancer-related mutations lead to activated KRAS and have been shown to upregulate autophagy. Moreover, it was shown that KRAS activating mutations lead to an increase in the levels of activated Rho and Rac, two key regulators of actin dynamics. We are interested in understanding whether different actin regulators are involved in RAS-induced autophagy. The RAS signalling pathway has been primarily dissected in the *C. elegans* vulva. LET-60 (RAS homologue in *C. elegans*) is required for vulva development, which involves tightly controlled cell proliferation and differentiation. Expression of the

activating mutant LET-60(G13E) induces ectopic vulva cell divisions, migrations and fusions resulting in a multivulva phenotype, indicative of an excess of proliferative signaling. As vulva development is thoroughly understood and fluorescent tools are available to directly monitor it by microscopy, *C. elegans* vulva development is a unique model to explore the mechanisms underlying the interplay between RAS, actin dynamics and autophagy in the carcinogenic process. We are using depletion of LET-60, autophagy machinery and actin regulators by RNAi, generation of let-60 activating mutants by CRISPR/Cas9 technology, and live imaging-based approaches to assess vulva development and autophagy. We confirmed that animals in which LET-60(G13E) is the only source of LET-60 do present more than one vulva. Moreover, by expressing LGG-1::GFP (equivalent to LC3) in these animals we were able to prove that an increase of autophagy is also observed in these animals. Our analysis indicates that specific actin regulators are involved in Ras-induced autophagy, as depletion of LET-60 or several actin regulators leads to decreased levels of autophagy in the vulva of let-60(G13E) animals. Further studies will be necessary to dissect how the LET-60 pathway regulates actin dynamics to drive autophagy.

P974/B96

Enhancing Sensitivity of Glioblastomas to Ionizing Radiation by Actin and Tubulin Cytoskeleton Disruption.

G. D. Cardella, Y. T. Magalhães, F. L. Forti; Department of Biochemistry, Institute of Chemistry, University of São Paulo, Sao Paulo, BRAZIL.

Glioblastomas (GBM) are a common primary brain tumor in adults of high malignancy characterized for increased cellular proliferation and resistance to chemo and radiotherapy. The cytoskeleton of GBM is closely related to its high capacity of invasiveness and migration, but little is known about the role of cytoskeleton in DNA damage response (DDR) and repair pathways, or its possible involvement in therapies resistance. The main objective of this study is to evaluate whether the response of glioblastoma cell lines to ionizing radiation (IR) is altered or enhanced as actin cytoskeleton or microtubules are somehow perturbed. It also aims to verify if cytoskeleton disruption affects the DNA damage response pathway and thereafter DNA repair, and whether this mechanism is p53-dependent or not. The GBM cell lines U87-MG (p53 wild type) and T98G (p53 mutated) were used as experimental models. The actin cytoskeleton was destabilized with Cytochalasin D (Cyto D), and the microtubules with Vincristine, and then cells were exposed to gamma radiation through a Cobalt-60 irradiator. Cell proliferation curves showed different behaviors between these two cell lines. T98G was more sensitive to IR than U87-MG, but the combined treatment Cyto D + IR lead to an expressive reduction in proliferation only in U87-MG cells. Clonogenic assays confirmed an additive effect of Cyto D and IR, decreasing the survival of T98G cells, while for U87-MG the effect was synergistic, with a higher increase in the cell's sensitivity to IR. On the other hand, microtubules destabilization provoked the same response in both cell lines. Vincristine treatment enhanced significantly the sensitivity to IR with synergic effects, as evidenced by an expressive decrease of cellular proliferation and survival in both cell lines. Immunofluorescence assays showed that γH2AX foci formation after IR is strongly inhibited in U87-MG under previous Cyto D treatment, but this combined treatment only slightly reduced the signaling in T98G. Vincristine + IR association changed the kinetics of H2AX phosphorylation and also provoked an inhibition in this signaling in both cells, but especially in T98G. These results indicate that Cyto D enhanced significantly the sensitivity of U87-MG therefore suggesting a dependency on p53 activity. Otherwise, the effect of microtubules disruption by Vincristine in the response to IR was similar for both

cells, seemingly independent of p53 activity. Both cytoskeleton components seem to be essential for DDR and DNA repair pathways, however through the regulation of different mechanisms.

P975/B97

Absent Actin Filament Regulation Reinforces Pathologic Acetylcholine Receptor Clustering.

R. Jühlen[1], V. Martinelli[1], J. Breckpot[2], B. Fahrenkrog[1]; [1]Université Libre De Bruxelles, Gosselies, BELGIUM, [2]Catholic University Leuven, Leuven, BELGIUM.

Background: NUP88 is a protein of the nuclear pore complex, the main transportation hub in the cell for exchange between the cytoplasm and the nucleus. We showed earlier that biallelic mutations in *NUP88* lead to a rare condition, termed fetal akinesia deformation sequence, that is characterized by reduced fetal movement (fetal akinesia). Known genetic causes for fetal akinesia are mutations in genes linked to signaling at the neuromuscular junction (NMJ), such as *RAPSN* or *MUSK*. Objective: We sought to identify cellular mechanism(s) in the pathogenesis of fetal akinesia disorders. Herein, we established two specific aims: first, characterizing the overall interplay of the cytoskeleton in fetal akinesia and second, disclosing the function of NUP88 in muscle cell development in health and in NUP88-related fetal akinesia. Results: Firstly, by using micropatterning and bioinformatic tools, we extensively analyzed cytoskeletal components of fibroblasts from fetal akinesia patients. We found that these cells suffer from abnormal contractile actin-myosin modules and enhanced focal adhesion maturation due to increased activation of RhoGTPase. Over-representation of actin microfilaments also perturbed the microtubular and intermediate filament network in these cells. Secondly, by using murine myoblasts, we could show that loss of Nup88 impairs muscle cell differentiation and furthermore, altered acetylcholine receptor (AChR) clustering in *vitro* at the plasma membrane in murine myotubes and in *vivo* in skeletal muscle of zebrafish. The mechanism of AChR patterning involves podosomes, conical actin-enriched structures at the plasma membrane. Consecutively, podosomal structure and number were increased in Nup88-mutant myotubes and in fetal akinesia fibroblasts. Conclusion: Our results establish a consequential link between dysregulation of the actin cytoskeleton, muscle cell maturation, and AChR patterning at NMJs. Intact NMJs are critical for proper skeletal muscle contraction and especially for fetal movement. Thus, fetal akinesia disorders are the result of pathologic actin microfilament regulation involving proteins responsible for signaling at NMJs and most interestingly, the nuclear pore complex protein NUP88.

P976/B98

Physiological Concentrations of Hydrogen Peroxide and Glutamate, Induce Tunneling Nanotube Formation in Hela and Cad Cells.

J. Ajanel, Z. Xiong, A. Pham, K. Gousset; California State Univeristy, Fresno, Fresno, CA.

Discovered in 2004 tunneling nanotubes (TNTs) are bridge like structures that allow cell-to-cell communication. Initially described as long, actin-based, non-adherent to the substratum, transient nano-structures, their main function is the intercellular transport of cellular components, electrical signals and pathogens. Thus, TNTs have been implicated in viral propagation, neurodegenerative diseases, and cancer. Most research has focused on examining the molecules within cells that aid in TNT formation and function, but little has been documented on the role that exogenous molecules have on the formation of TNTs. Past research has determined that hydrogen peroxide (H_2O_2)—coincidentally secreted by cancer cells—induces TNTs in various cell lines; however, the amount of H_2O_2 used was

above normal physiological concentrations. The aim of this study was to establish if TNT formation can be induced using physiological H_2O_2 concentrations, as well as determine if TNT formation can be induced exogenously using H_2O_2. In addition, we also investigated, glutamate, another important signaling molecule released by cancer cells and an inducer of actin based filopodia in astrocytes, as a possible tunneling nanotube inducer. The data obtained through the use of fluorescence microcopy suggests that physiological concentration of H_2O_2 and glutamate are able to increase the formation of TNTs in both HeLa cells and the neuronal CAD cell line. Moreover, preliminary data obtained with the use of a microscope capillary single cell sorting system suggests that high concentrations of H_2O_2 can induce the formation as well as the elongation of possible preliminary TNT structures in distances ranging from 20-65 µm. Altogether, these results provide useful insights regarding TNT formation pathways in cells as well as the exogenous molecules involved in the formation of TNTs.

P977/B99

CD13 Is a Critical Regulator of Cell-cell Communication Via Tunneling Nanotubes.

E. Meredith; University of Connecticut Health Center, Farmington, CT.

CD13 is a Critical Regulator of Cell-Cell Communication via Tunneling Nanotubes Emily Meredith, Mallika Ghosh and Linda H. Shapiro Center for Vascular Biology, University of Connecticut Health Center, Farmington, Connecticut Cell-cell communication is essential for proper growth, function and survival of organisms. Tunneling Nanotubes (TNTs) are open ended actin based cellular protrusions detached from the substratum that connect two or more distant cells and facilitate cell-cell communication by transporting cargoes ranging from cytoplasmic proteins to intact organelles. However, little is known about the molecular mechanisms that induce and maintain TNT formation, control the direction of their growth or regulate cargo transfer under physiologic or pathologic conditions. Recently, we have discovered that adhesion molecule, CD13, is a physiologic regulator of TNT formation in a variety of endothelial and myeloid cells. Indeed, cells stressed by low serum conditions led to robust TNT formation in the wild type human Kaposi sarcoma endothelial cell line (KS) which was clearly absent in KS-$CD13^{KO}$ CRISPR lines lacking CD13. Moreover, treatment of WT KS cells with a CD13 activating antibody induced TNT formation in a CD13-dependent manner. Interestingly, CD13 and actin are highly abundant at the base as well as along the length of the TNTs, potentially indicating a role for CD13-mediated membrane and protein organization at the site of TNT initiation. Homotypic coculture of WT and $CD13^{KO}$ cells indicated that CD13 expression is necessary for membrane and organelle transfer via functional TNTs. Mechanistically, treatment with peptides designed to interfere with CD13's cytoplasmic signaling domain diminished TNT formation in a dose dependent manner, suggesting that CD13-dependent signal transduction mediates TNT formation. Future investigation will focus on the identification of fundamental mechanisms and molecules involved in transfer of organelles through TNTs in a CD13 dependent manner.

P978/B100

The Desmosomal Cadherin Desmoglein-2 Controls Rap1 GTPase-mediated Cell Spreading Independent of Cell-cell Adhesion.

W. T. Shelton[1], D. E. Conway[2], A. D. Dubash[1]; [1]Furman University, Greenville, SC, [2]Virginia Commonwealth University, Richmond, VA.

The desmosome is a cell-cell adhesion complex which facilitates the mechanical stability of tissues and cell-cell communication. Desmosome function depends upon a tripartite organizational structure wherein transmembrane cadherins (Desmoglein and Desmocollin) link adjacent cellsin the extracellular space, armadillo proteins (Plakophilin and Plakoglobin) stabilize the intracellular plaque, and the cytolinker Desmoplakin (DP) connects the plaque to the intermediate filament network. In addition to their central role in maintaining cell-cell junction integrity, desmosomal cadherins also coordinate biological processes such as proliferation, apoptosis, differentiation and cell migration. In our study, we sought to investigate the signaling mechanisms involved in control of actin architecture via desmosomal cadherins, using A431 cells lacking either Desmoglein-2 or Desmocollin-2, generated via CRISPR-mediated knock-out (Dsg2 KO and Dsc2 KO, kindly provided by Dr. Daniel Conway, VCU). Wildtype, Dsg2 KO and Dsc2 KO A431 cells were subjected to single cell spreading assays on different extracellular matrix proteins. Compared to control cells, Dsg2 KO cells displayed a significant increase in spreading area on both fibronectin and collagen. Interestingly, knockout of Dsc2 caused the opposite effect, leading to a significant reduction in spreading area. As these experiments were performed in singly spreading cells, these experiments have identified a novel cell-autonomous, cell-cell adhesion independent role for desmosomal cadherins in regulation of cell spreading. Spreading changes in Dsg2 KO cells were dependent on Rap1 GTPase, as siRNA-mediated knockdown of Rap1 in Dsg2 KO cells rescued the increase in spreading area. Dsg2 KO cells also demonstrated a decrease in expression of Paxillin, suggesting that the enhanced spreading phenotype may be due to alterations in cell-matrix adhesion. Not surprisingly, loss of Dsg2 results in a significant increase in the Triton-X solubility of other desmosomal components such as Plakophilin-2, Plakophilin-3, Plakoglobin, and Desmoplakin. Knockdown of Desmoplakin was able to rescue the enhanced spreading seen in Dsg2 KO cells alone, thereby implicating Desmoplakin-dependent signaling in control of cell spreading via Dsg2. Future experiments will investigate the upstream signaling mechanisms via which Dsg2 and Desmoplakin regulate Rap1 activity and signaling. These data have identified a novel cell-cell adhesion independent role for Desmoglein-2 in mediating cell spreading via Rap1, which provides significant insight into the signaling mechanisms via which desmosomal cadherins control cell-matrix attachment and cytoskeletal architecture.

Actin-membrane interactions

In Vivo Knockdown of the IP3R1 Calcium Channel Disrupts Er-tbc Membrane Contacts and Alters the Actin Cytoskeleton in Rat Sertoli Cells.

A. Adams, A. Vogl; University of British Columbia, Vancouver, BC, CANADA.

During spermatogenesis, late stage spermatids are temporarily attached to the apex of Sertoli cells in the seminiferous epithelium by large anchoring junctions. These large junction complexes are termed ‘ectoplasmic specializations’ (ESs) and are proposed to be disassembled by clathrin based endocytic structures only found in mammalian Sertoli cells, called ‘tubulobulbar complexes’ (TBCs). TBCs have a dendritic actin network encircling their tubular portions that extend from the plasma membrane to the ‘bulb’ where the actin is replaced by a cisternae of ectoplasmic reticulum (ER) that forms a membrane contact site (MCS) with the TBC. Previously, we’ve localized the IP3R calcium channel to the TBC bulb-ER contacts as well as other calcium exchange machinery to various parts of the ER in the apical process of Sertoli cells. The movement of calcium between membranes at MCSs is now a well-established function

of MCSs, and allows for substantial alteration to target organelles such as in mediating the fusion and acidification of endosomes. Changes in local calcium levels can also affect the polymerization of actin networks in cells generally. We've proposed that the presence of IP3R1 at TBC-ER contacts may indicate that calcium exchange is a function of these contacts and that this exchange could facilitate the maturation and fusion of TBC bulbs as they develop into putative endosomes or alter local actin networks. If calcium exchange from the ER is responsible for regulating the maturation of TBC bulbs in the apical process or altering actin networks, then knocking down the IP3R1 should alter TBC bulb morphology and distribution, disturb the ER-TBC contacts, and change the actin networks in Sertoli cells. To test this, we injected the testes of Sprague Dawley rats with siRNAs against IP3R1 (ITPR1) and collected tissues at 2 days post injection and processed the tissues for either western blot, immunofluorescence, or electron microscopy. Tissues injected with siRNA against the gene associated with IP3R1 (ITPR1) showed significant morphological alterations to the actin networks including a loss of TBC actin and the acquired presence of ectopic para-crystalline actin bundles in Sertoli cell stalks. There was also a change in the abundance and distribution of a known TBC-ER MCS specific marker, ORP9. Together, these findings are consistent with the hypothesis that calcium exchange at TBC-ER contacts is involved in regulating actin dynamics at TBCs and in maintaining the structure of TBC bulbs.

P980/B102

Identifying Components of the Molecular Clutch That Regulates Apical Constriction.

M. M. Slabodnick, S. C. Tintori, A. Chen, T. D. Cupp, B. Goldstein; University of North Carolina, Chapel Hill, Chapel Hill, NC.

Apical constriction is mechanism commonly used to change a cell's shape and initiate morphogenesis in a broad range of animal systems, including in vertebrate neural tube formation. Apical constriction occurs as a result of actomyosin contractions at the apical surface, which shrink the exterior face of a cell, or cells, bending or internalizing a cell or tissue. In the model system *C. elegans*, gastrulation begins with two endodermal precursor cells that utilize apical constriction to internalize at the 26-28 cell stage. Surprisingly, data suggests that a temporally regulated link is required for the actively contracting apical actomyosin networks to pull the apical cell-cell junctions inward, triggering apical constriction. We refer to this mechanism as the clutch. We used single-cell RNA-seq data to identify genes of interest and this approach has identified a candidate that functions at least in part in this clutch mechanism - *zyx-1*/zyxin. Zyxin is part of a family of LIM domain-containing proteins and has known functions in other systems consistent with a clutch-type mechanism. *C. elegans* embryos lacking zyxin display gastrulation defects and have defective coupling during apical constriction. Using a similar RNA-seq approach, we have identified other LIM domain-containing genes that are specifically expressed in other internalizing cells. LIM domain-containing proteins, including zyxin, are broadly conserved, and these results could apply to mechanisms that regulate apical constriction in other systems.

P981/B103

Investigating the Role of a Conserved Amphipathic Helix in Curvature Sensing by the Septin Cytoskeleton.

K. Cannon, B. Woods, A. Gladfelter; University of North Carolina at Chapel Hill, Chapel Hill, NC.

Cell shape is often described in terms of membrane curvature. Septins are filament forming, GTP-binding proteins that assemble on positive, micrometer-scale curvatures from yeast through humans. At

these sites, septins function in several cellular processes including cytokinesis, migration, and autophagy. However, the mechanism for curvature sensing by septins is not fully understood. Recently, we identified an amphipathic helix (AH) at the very C-terminus of the budding yeast septin Cdc12. This AH domain is highly conserved and is both necessary and sufficient for septins to sense membrane curvature. However, it is currently unclear how the AH domain enables septins to preferentially adsorb onto micrometer-scale membrane curvatures. An interesting feature of the septin complex is its symmetry across its long axis, with neighboring AH domains spaced ~24 nm apart. We wondered if we could change septin curvature preference by changing the space between AH domains within the septin complex. Wild-type septin complexes (AH spacing ~24 nm) preferentially assemble onto a membrane curvature of 2 μm^{-1}. In contrast, changing the spacing between AH domains from ~24 nm to ~16 nm, we observed preferential binding of septins onto a curvature of 4 μm^{-1}. Interestingly, by moving the AH domains 32 nm apart, we observed no difference in curvature preference compared to wild-type (preferred curvature = 2 μm^{-1}). These data suggest that the space between AH domains is an important factor in promoting septin assembly onto specific membrane curvatures.

Single-molecule Strategy Uncovers the Turnover of Actin and Coat Proteins during Clathrin-mediated Endocytosis.

M. Lacy, B. David, **J. Berro**; Yale University, West Haven, CT.

Actin dynamics generate forces to deform the membrane and overcome the cell's high turgor pressure during clathrin-mediated endocytosis in yeast, but precise molecular details are still unresolved. Our previous models predicted that actin filaments of the endocytic meshwork continually polymerize and disassemble, turning over multiple times during an endocytic event, similar to other actin systems. We applied single-molecule speckle tracking in live fission yeast to directly measure molecular turnover within endocytic sites for the first time. In contrast with the overall ~20-sec lifetimes of actin and actin-associated proteins in endocytic patches, we detected median single-molecule residence times around 1 to 2 sec, and similarly high turnover rates of membrane-associated proteins in CME. Furthermore, we find heterogeneous behaviors in many proteins' motions. These results indicate that the formation of endocytic vesicles is a highly dynamic process, and that endocytic proteins turn over up to 5 times during the formation of an endocytic vesicle. These new data forces us to revise quantitative models of force production by the actin machinery during endocytosis.

Mechanistic Insights into Actin-based Force Generation during Clathrin-mediated Endocytosis Via *in Situ* Cryo-Electron Tomography.

D. Serwas[1], M. Akamatsu[1], K. M. Davies[2], D. G. Drubin[1]; [1]UC Berkeley, Berkeley, CA, [2]Lawrence Berkeley National Laboratory, Berkeley, CA.

Networks of interconnected actin filaments act in essential cellular processes, for example by providing force generated through polymerization. One of these processes is clathrin-mediated endocytosis (CME), a major pathway for down-regulation of signaling receptors and uptake of extracellular material, that involves a series of plasma membrane remodeling steps resulting in the formation of clathrin-coated vesicles (CCVs) containing cargo. Structural aspects of CME have been extensively studied by transmission electron microscopy of platinum replicas, and of thin sections of plastic embedded cells.

However, both of these sample preparation methods have been shown to alter actin cytoskeleton organization. As a result, precise structural information on actin organization in CME, which is key to understanding actin's mode of function in this process, is lacking. Here, we made use of recent technological advances in cryo-electron tomography (cryo-ET) to discover the 3-dimensional actin cytoskeleton organization in mammalian CME at near-native state conditions. Combined with mathematical modeling, this analysis promises to reveal how actin functions in CME. We found growth conditions for SK-MEL-2 cells that allow cryo-ET of intact cells. Strikingly, individual actin filaments, actin branches, CME sites and CCVs can clearly be identified in our tomography data. The actin cytoskeleton associated with CME sites and CCVs consists of branched as well as unbranched filaments. Filaments at CME sites are not exclusively localized around the neck of membrane invaginations as was seen before by platinum replica EM, but rather form more complex 3-dimensional arrangements. We determined filament polarity based on branch point geometry and found an accumulation of plus-ends at positions that would allow for force production by polymerization to support plasma membrane deformation and CCV transport. Moreover, branched filaments do not arise from a common single filament, contradicting the theory that a single mother filament gives rise to the entire CME-associated network. Surprisingly, we also found varying amounts of very long, heavily bent actin filaments at CME sites. Based on mathematical modeling, these filaments are predicted to store elastic energy, which augments force generation by actin polymerization to support membrane deformation and thus represents a previously unrecognized mode of actin-based force production in CME. Taken together, our results reveal the complex actin filament organization at endocytic sites in unprecedented detail. We are in the process of in-depth quantitative analysis of our data, which will, in combination with mathematical modeling, ultimately result in a detailed understanding of actin function in CME.

Force Patterning at the Immune Synapse.

A. Kumari[1], J. Pineau[1], P. J. Saèz[1], M. Maurin[1], D. Lankar[1], M. San Roman[1], K. Hennig[2], V. F. Boura[3], R. Voituriez[4], M. C. I. Karlsson[3], M. Balland[2], A. Lennon-Duménil[1], **P. Pierobon**[1]; [1]Institut Curie, Paris, FRANCE, [2]Université Joseph Fourier (Grenoble 1), Grenoble, FRANCE, [3]Karolinska Institutet, Stockholm, SWEDEN, [4]Université Pierre et Marie Curie and Laboratoire Jean Perrin, Paris, FRANCE.

p { margin-bottom: 0.25cm; line-height: 115%; }a:link { } p { margin-bottom: 0.25cm; line-height: 115%; }a:link { } a crucial phase of immune response is antigen acquisition by B cells in the lymph node. This occurs through endocytosis of native antigen presented on the surface of opposing cells, via a specific cell-cell contact, the immunological synapse. We investigate the forces developed by B cell at the immunological synapse during antigen extraction. We found that two main types of force, a centripetal peripheral one and a central one perpendicular to the synapse, are essential for antigen extraction. The centripetal peripheral component is Myosin II dependent while the central forces are produced by actin-rich protrusions and surprisingly correlate with the antigen extraction spots. Both global energy and antigen extraction are strongly reduced by Myosin II inhibition and are increased, by lysosomal calcium release. The interplay between global and local forces dictated by the organization of the actomyosin cytoskeleton therefore controls endocytosis at the immune synapse.

P985/B107

Identification of a Novel B Cell Actomyosin Network That Promotes Antigen Contraction during Immune Synapse Formation.

J. C. Wang, X. Wu, J. A. Hammer; National Institutes of Health, Bethesda, MD.

B cells are a critical branch of the immune system and drive antibody-based protection. The strength of an antibody response is determined by the ability of B cells to extract and internalize membrane-bound antigens from antigen-presenting cells (APCs). Antigen uptake requires the formation of an immune synapse (IS) where B cell receptor-bound antigens are moved centripetally into a central cluster before being extracted from the APC and internalized. The force provided by the actin motor myosin 2A (M2A) powers antigen extraction. B cells that lack M2A activate aberrantly and mount weak antibody responses. However, the organization of the actomyosin network, its role in IS formation, and the mechanism by which M2A powers antigen extraction in B cells are unknown. Here we test the hypothesis that the actomyosin network drives the events of IS formation that promote B cell activation and antigen uptake. We first define the dynamic organization of actin and M2A at the IS using the super-resolution imaging modalities TIRF/SIM, 3D-SIM and Airyscan. On functionalized glass and planar lipid bilayers, the A20 B cell line forms concentric arcs in the medial portion of the IS. These arcs are rich in M2A based on immunostaining, and on imaging cells in which endogenous M2A was tagged with GFP using CRISPR. 3D-SIM imaging of APCs with primary splenic B cells isolated from M2A-GFP knock-in mice shows that M2A polarizes towards the IS. B cell IS studies are often performed using antigen stimulation only. In *vivo*, B cell integrins provide adhesion to APCs and, via an unknown mechanism, allow for IS formation and antigen uptake with weakly-stimulating antigens. Surprisingly, we found that actomyosin arc formation in primary B cells requires both antigen and integrin costimulation, conditions that reflect physiological B cell activation. These contractile actomyosin arcs are especially prominent in primary B cells such that the actomyosin arcs are the major actin structure at the IS. The contractile nature of the actomyosin arcs that dominate at the primary B cell IS may explain why integrin costimulation boosts B cell responses to weakly-stimulating antigens. Notably, integrin costimulation on bilayers produces actin arcs that sweep peripheral antigen clusters centripetally and is required for contracting low amounts of antigen to form the IS. Moreover, M2A inhibition abrogates the organization of actin arcs and prevents antigen centralization. Therefore, we have identified in primary B cells a novel actomyosin network, which comprises the major actin structure at the IS and promotes robust antigen centralization during IS formation. Current efforts are directed at defining the mechanism by which the actomyosin network drives antigen extraction from APCs using live-cell volumetric imaging.

P986/B108

Structural and Mechanistic an alysis of Two Distinct Endocytoc Pathways for B Cell Receptors in B Lymphocytes.

A. Roberts, T. M. Davenport, A. M. Dickey, R. Ahn, K. A. Sockacki, J. W. Taraska; NIH, Bethesda, MD.

B lymphocytes play a critical role in adaptive immunity. Upon antigen binding, B cell receptors (BCR) cluster on the plasma membrane and are internalized by endocytosis. B cells capture diverse antigens in various contexts and concentrations. However, it is unclear whether the mechanism of BCR endocytosis changes in response to these factors. Here, we studied the concentration dependence of soluble anti-human IgM Fab'2-induced BCR clustering and internalization in the human IgM+ DG-75 B cell line using correlative super resolution fluorescence and electron microscopy. First, by directly visualizing

nanoscale structures associated with BCR clusters we provide evidence that BCR cluster size increases with Fab'2 concentration. Next, we directly show that the mechanism of internalization switches in response to BCR cluster size. Specifically, at low concentrations of Fab'2, B cells internalize small BCR clusters by classical clathrin-mediated endocytosis. At high Fab'2 concentrations when cluster size increases beyond the size of a single clathrin coated pit, B cells retrieve clathrin-capped BCR clusters using large invaginations of the plasma membrane that may require actin for internatlization. We propose that in B cells the mechanism of endocytosis switches to accommodate large plasma membrane receptor clusters induced when cells encounter high concentrations of antigen.

Self-organization and Load Adaptation by the Mammalian Endocytic Actin Network: Integrating Modeling with Experiment.

M. Akamatsu[1], R. Vasan[2], D. Serwas[1], M. Ferrin[1], P. Rangamani[2], D. G. Drubin[1]; [1]UC Berkeley, Berkeley, CA, [2]UC San Diego, La Jolla, CA.

Force generation due to actin assembly is a fundamental aspect of membrane sculpting for many essential processes. We hypothesized that the spatial restriction of actin filament nucleators to the base of the pit and actin/membrane linkages in the clathrin coat might dictate how endocytic actin networks organize, produce force, and adapt to elevated membrane tension. Here, we use a multiscale computational model constrained by experimental measurements to show that a minimal branched actin network is sufficient to internalize endocytic pits against physiological membrane tension. A parameter sweep identified the number of Arp2/3 complexes as particularly important for robust internalization, which prompted the development of a molecule-counting method in live mammalian cells. From engineered GFP-tagged multimeric proteins of defined copy number, we constructed an intracellular calibration curve relating fluorescence of endogenously GFP-tagged proteins to numbers of molecules in live cells. A peak of ~200 molecules of Arp2/3 complex assemble at endocytic sites marked by the clathrin adaptor AP2-RFP in human induced pluripotent stem cells. Our simulations also revealed that actin networks self-organize in a radial branched array with barbed filament ends oriented to grow toward the base of the pit, and that the distribution of linker proteins around the endocytic coat is critical for this organization. Surprisingly, our model predicted that long actin filaments bend from their attachment sites in the coat to the base of the pit and store elastic energy that can be harnessed to drive endocytosis. This prediction was validated using cryo-electron tomography on cells, which revealed the presence of bent actin filaments along the endocytic site. Furthermore, we predict that under elevated membrane tension, the self-organized actin network directs more growing filaments toward the base of the pit, increasing actin nucleation and bending for increased force production. Thus, our study reveals that spatially constrained actin filament assembly utilizes an adaptive mechanism that enables endocytosis under varying physical constraints. We anticipate that the principles of self-organization and load-adaptation uncovered in this study will apply to other cellular membrane-deforming processes driven by the cytoskeleton.

P988/B110

Intravital Subcellular and Single Molecule Imaging Reveal Multiple Actin Filament Populations Collaborate in the Remodelling of the Secretory Granule Membrane.

M. Heydecker[1], A. Masedunskas[1], S. Ebrahim[2], M. Appaduray[1], A. Shitara[2], N. Bryce[1], R. Weigert[2], P. Gunning[1], E. Hardeman[1]; [1]School of Medical Sciences, University of New South Wales, NSW 2052, Sydney, AUSTRALIA, [2]Laboratory of Cellular and Molecular Biology, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, MD.

The actin cytoskeleton contributes to many cell functions involving the remodelling of membranes. This is achieved both via interaction of actin filaments with myosin motors and through the force generated by branched actin networks. One of these processes is exocytosis of large secretory granules in the salivary gland of rodents. We used intravital subcellular microscopy (ISMic) to identify the types of actin filaments that are required for the granule integration into the apical membrane and intravital single molecule microscopy (iSiMM) to study the molecular behaviour and nanostructures at the basolateral membrane. We find at least two types of actin filaments are associated with exocytosis at the apical membrane. Actin filaments containing tropomyosin Tpm3.1 are used to build a scaffold around the granule upon initial fusion. Myosin II motors are subsequently recruited to the scaffold independently from F-actin. An Arp2/3 nucleated branched actin filament network emanates from the scaffold and drives rapid remodelling of the granule membrane. Inhibition of Arp2/3 nucleation eliminates the generation of the branched network. Subsequent contraction of the actin filament scaffold displays much slower kinetics to achieve identical remodelling of the granule membrane. This emphasizes the collaboration of multiple actin filament populations in the process of membrane remodelling during regulated granule exocytosis. At the basolateral membrane iSiMM was used to reveal single molecule dynamics of Tpm3.1 and myosin II motors. Molecular recruitment and nanostructures were analysed before and during exocytosis. A decrease in the diffusion coefficient of Tpm3.1 after stimulation indicate that remodelling at both the basolateral and apical membranes take place during exocytosis.

P989/B111

The Role of Non-muscle Myosin Motors in Actively Organizing Molecules at the Plasma Membrane.

P. Sil[1], T. S. van Zanten[1], S. Saha[2], S. Mayor[1,3]; [1]National Centre for Biological Sciences, Bangalore, INDIA, [2]Cardiovascular Research Institute and Department of Biochemistry and Biophysics, University of California, San Francisco, CA, [3]Institute of Stem Cell Science and Regenerative Medicine, Bangalore, INDIA.

The plasma membrane of living cells is an active composite of a bilayer of lipids and proteins tightly coupled to an actin-based cytoskeleton. This configuration supports the nano and meso-scale organization of GPI-anchored proteins (GPI-AP) and Trans-membrane Actin binding proteins (TmABD). Theoretical and experimental work from our laboratory over the past decade[1-3] has argued for a central role for myosin motor activity in driving actin filaments into contractile aster-like configurations juxtaposed to the plasma membrane, which in turn can spatially pattern membrane molecules. However in non-muscle cells, greater than fifteen sub-types of myosins perform specialized functions and differ in terms of mechanical properties, localization and collective behavior. While it is known that the activity of various classes of non-muscle myosin motors impart contractility to the cytoskeleton, their precise role in the organization of membrane components is poorly understood. We employed genetic and pharmacological perturbation approaches to down-regulate the functions of different classes of non-

muscle myosins in mammalian cells. Using live cell FRET-based microscopy to obtain nano-scale information about the distribution of membrane molecules, we identify that distinct non-muscle myosin classes I and II are selectively required for the nanoscale organization of the different classes of membrane molecules, lipid-anchored (GPI-AP) and trans-membrane proteins with actin binding domains (TmABD). Additionally we observe that the lipid anchored GPI-AP and trans-membrane TmABD are organized into segregated domains at both nano (<10nm) and meso-scale (100nm-1μm) at the membrane. Our findings suggest that by independent regulation via the different non-muscle myosins, cells actively organize the lateral heterogeneity of the plasma membrane across multiple length scales. Membrane Binding of Actin Bundles Inside Giant Liposomes Promotes Condensation into Single Ring Structures.

T. Litschel, C. Kelley, N. Mizuno, P. Schwille; Max Planck Institute of Biochemistry, Munich, GERMANY.

In cells, actin filaments are often organized into cross-linked, branched, or bundled networks. These different architectures appear in structures such as filopodia, stress fibers, the cell cortex, and contractile actomyosin rings; each has unique physical properties and fulfills different roles in important cellular processes. Bottom-up reconstruction of these fundamental eukaryotic features, and their stabilizing, as well as transformative functions on the cell membrane, will not only help us understand physiological processes, but is also an important stepping stone towards the engineering of artificial cells. In recent years, in *vitro* reconstitution of actin systems on synthetic vesicles and supported lipid bilayers has attracted great interest from physical biologists. However, encapsulation of actin inside cell-sized vesicles remains technically challenging. Here, we have adopted recent advances in vesicle encapsulation methods in order to study bundled actin filaments in giant unilamellar vesicles. We were thus able to compare actin organization mediated by different actin cross-linking proteins in a confined compartment, and directly visualize the effect of linking actin structures to a phospholipid bilayer. By changing a few key parameters, the assembly of actin bundles can be differentiated to resemble various types of actin networks in living cells in both structure and function. Importantly, we find membrane binding to be crucial for the robust condensation into single actin rings in vesicles. Once formed, the physical characteristics of the different actin network topologies can be directly observed. For example, cortices from bundled actin can act as a mechanically supportive scaffold that determines vesicle shape. With the application of force via myosin motors, ring-like actin bundles contract and can constrict the vesicle membrane inwards, a behavior that has not been reconstructed in *vitro* thus far. These observations confirm not only the suitability of this system for reconstituting processes such as cell division or migration, but also indicate the key role that membrane connections likely play in determining actin architecture and function in cells.

Sub-organellar Actin Dynamics Revealed by Organelle-targeted Actin Chromobodies.

C. R. Schiavon[1], T. Zhang[1], B. Zhao[2], J. Feng[3], L. R. An drade[1], M. Wu[1], T. Sung[1], O. A. Quintero[3], Y. Dayn[1], R. Grosse[2], **U. Manor**[1]; [1]Salk Institute for Biological Studies, La Jolla, CA, [2]University of Freiburg, Freiburg, GERMANY, [3]University of Richmond, Richmond, VA.

The actin cytoskeleton has long been known to regulate organelle dynamics. However, the small and transient actin structures regulating organelle dynamics are difficult to detect with fluorescence or electron microscopy. Live cell fluorescence imaging of organelle-associated actin is particularly hindered by the huge amounts of “background” signal caused by an unfortunate combination of (i) the ubiquity of actin throughout the cytoplasm, (ii) the relatively large and stable actin structures in the cell cortex of adherent cells, and (iii) the resolution limit optical microscopy. To circumvent this issue, we developed an approach using fluorescent protein-tagged actin nanobodies fused to organelle membrane targeting sequences. We validated the probes using pan-actin probes including phalloidin and cytoplasmic actin nanobodies. Fluorescence recovery after photobleaching measurements showed that these probes are highly diffuse on the organelle membrane unless bound to actin, which immobilizes them. Live cell imaging of these probes revealed previously undetected sub-organellar actin structures on mitochondria, the ER, and the nucleus. Simultaneous imaging of both ER- and mitochondria-associated revealed that actin first accumulates on mitochondria prior to the ER during mitochondrial fission events. Finally, we found ER-associated actin marks constriction or fission sites for all the organelles we tested, including mitochondria, endosomes, lysosomes, peroxisomes, and the Golgi. Overall, these results show that using organelle-targeted nanobody probes for studying organelle-cytoskeleton dynamics can reveal previously undetected structures in the cell with very high spatiotemporal resolution.

Mel-28-mediated Regulation of Microtubule Motors Affects Fertility in the Nematode *Caenorhabditis Elegans*.

G. Crosio, A. Fernandez; Fairfield University, Fairfield, CT.

Microtubule motors are multi-molecular machines that ferry cargoes from one location to the other within a cell. We have been studying MEL-28, a conserved and essential protein important for chromosome segregation and the post-mitotic rebuilding of the nuclear pore. Previous work showed that MEL-28 and the minus-end directed microtubule motor dynein work in parallel to support fertility in *C. elegans*. Simultaneous disruption of *mel-28 and dhc-1* (which encodes the large subunit of dynein) causes low brood size and disorganization of the oogenic germline. Our main goal has been to understand why *dhc-1;mel-28* double mutants have reduced fertility. Using markers that identify oocyte stage, we have observed that *dhc-1;mel-28* double mutants have oocyte maturity defects. To find cellular components that regulate MEL-28 and dynein-related cellular processes, we did a candidate RNAi screen searching for genes that when disrupted rescue the brood size of *dhc-1;mel-28* double mutants. We found that disrupting *klc-2,*which encodes the light chain of the plus-end directed microtubule motor kinesin, drastically improves the brood size of *dhc-1;mel-28* double mutants. This suggests that MEL-28 and dynein work together to promote a cellular process that is opposed by KLC-2-

mediated kinesin activity. We are currently using RNAi to test known cargoes regulated by KLC-2 in order to determine if these are implicated in the rescue of *dhc-1;mel-28* fertility defects. All of the genes we are studying are conserved and essential in all animals. What we learn by studying genetic networks regulating fertility in *C. elegans* could be valuable for understanding regulation of intracellular trafficking in other animals, including humans.

P993/B116

A Means to an End: How a Non-Motile Kinesin Finds the Cilia Tip.

N. Mani[1], S. Jiang[1], E. M. Wilson-Kubalek[2], P. Ku[1], R. A. Milligan[2], R. Subramanian[1]; [1]Harvard Medical School / Massachusetts General Hospital, Boston, MA, [2]The Scripps Research Institute, La Jolla, CA.

The correct localization of Hedgehog effectors to the tips of primary cilia is critical for proper signal transduction. The conserved non-motile kinesin Kif7 defines a “cilium-tip compartment” by localizing to the distal ends of axonemal microtubules. How Kif7 recognizes microtubule ends remains unknown. We find that Kif7 preferentially binds GTP-tubulin at microtubule ends over GDP-tubulin in the mature microtubule lattice, and ATP hydrolysis by Kif7 enhances this discrimination. Cryo-electron microscopy structures suggest that a rotated microtubule footprint and conformational changes in the ATP-binding pocket underlie Kif7’s atypical microtubule-binding properties. Finally, Kif7 not only recognizes but also stabilizes a GTP-form of tubulin to promote its own microtubule-end localization. Thus, unlike the characteristic microtubule-regulated ATPase activity of kinesins, Kif7 modulates the tubulin mechanochemical cycle. We propose that the ubiquitous kinesin fold has been repurposed in Kif7 to facilitate organization of a spatially restricted platform for localization of Hedgehog effectors at the cilium tip.

P994/B117

Does Giraffe Kinesin Move Faster Than Mouse?

T. Kambara[1], Y. Okada[1,2]; [1]RIKEN BDR, Osaka, JAPAN, [2]U. Of Tokyo, Grad. Sch. Of Sci., Tokyo, JAPAN.

Axonal transport has been demonstrated to be essential for various neuronal functions including neurite formation and extension, synaptic functions and survival. Many neurodegenerative diseases are known to be caused by the mutations in the genes related to this transport system. For example, various point mutations in the motor domain of KIF5A, a vertebrate specific neuronal isoform of kinesin-1, is known to be causative for an autosomal dominant form (SCG10) of hereditary spastic paraplegia (HSP), which mainly affects the distal part of the long motor tracts in the spinal cord. Most of the HSP mutations partially impairs the motor activity of KIF5A. Its velocity is reduced by 25-75% of the wild type. Considering that the mutated proteins are expressed at the similar amount to the wild type proteins, the transport would be only slightly slower in the heterozygous patients’ neurons. That would explain why neurons with longest axons are affected. If fast velocity is important for the survival of neurons with long axons, large animals with longer axons than human would require faster kinesin. Here, we addressed a simple question. Does kinesin of giraffe move faster than that of small animals such as mice? We have identified kinesin genes in the draft genome sequence of giraffe, and expressed recombinant giraffe KIF5A (GcKIF5A) protein. The motility of GcKIF5A was compared with mouse KIF5A (MmKIF5A) both in vitro and in cellulo. GcKIF5A moved about 25 % faster than MmKIF5A on purified neuronal microtubules in vitro and in axon, but similar velocity with MmKIF5A in dendrites and non-neuronal cells. Furthermore, transport of vesicles by GcKIF5A moved about 25 % faster than by

MmKIF5A in mouse hippocampus neurons. Interestingly, specific amino acid substitutions found in the motor domain of GcKIF5a were conserved only on burmese python KIF5a (PbKIF5a) among 150 species analyzed, and PbKIF5a moved significantly faster than MmKIF5a on purified neuronal microtubules in vitro. These results suggest that KIF5a of large animals with longer axons might have adapted for the longer axonal transport.

P995/B118

Cargo Diffusion Shortens Single-kinesin Runs.

J. Wilson, A. Zaragoza, D. Quint, A. Gopinathan, J. Xu; University of California, merced, Merced, CA.

Molecular motors such as kinesin-1 drive active, long-range transport of cargos along microtubules in cells. Thermal diffusion of the cargo can impose a randomly directed, fluctuating mechanical load on the motor carrying the cargo. Recent experiments highlighted a strong asymmetry in the sensitivity of single-kinesin run length to load direction, raising the intriguing possibility that cargo diffusion may non-trivially influence motor run length. To test this possibility, here we employed Monte Carlo-based simulations to evaluate the transport of cargo by a single kinesin. Our simulations included physiologically relevant viscous drag on the cargo and interrogated a large parameter space of cytoplasmic viscosities, cargo sizes, and motor velocities that captures their respective ranges in living cells. We found that cargo diffusion significantly shortens single-kinesin runs. This diffusion-based shortening is countered by viscous drag, leading to an unexpected, non-monotonic variation in run length as viscous drag increases. To our knowledge, this is the first identification of a significant effect of cargo diffusion on motor-based transport. Our study highlights the importance of cargo diffusion and load-detachment kinetics on single-motor functions under physiologically relevant conditions.

P996/B119

Kinesin-based Transport Is Controlled by Cholesterol in the Cargo Membrane.

Q. Li[1], J. Wilson[1], K. Tseng[2], W. Qiu[2], S. King[3], M. Vershinin[4], **J. Xu**[1]; [1]University of California, merced, Merced, CA, [2]Oregon State University, Corvallis, OR, [3]University of Central Florida, Orlando, FL, [4]University of Utah, Salt lake city, UT.

Motor protein-based transport in cells underlies all eukaryotic cell function and survival; dysfunctions in this transport are implicated in many diseases, including neurodegeneration. While the properties of motor proteins have been extensively studied both in vivo and in vitro, many important questions remain, including how the properties of the cargo itself impact motor function. In cells, cargos are often membrane-bound; the composition of the cargo membrane has long been hypothesized to impact motor protein-based transport. However, quantitative investigation of this hypothesis is limited; most cargos in current in vitro assays lack a physiological membrane. To address this technical challenge, here we combined advances in membrane biophysics with established single-molecule optical-trapping experiments to characterize the transport of membrane-enclosed cargos in vitro. Our study focused on the major microtubule-based motor kinesin-1 and employed the microtubule-associated protein tau to mimic the crowded surface of the cytoskeletal tracks in cells. In contrast to the traditional, membrane-free approach, we found that coupling motors via a biomimetic membrane significantly enhanced the transport of cargos along tau-decorated microtubules. This effect diminished when we added cholesterol to our model membrane. Stochastic simulations indicated that the observed membrane effects reflect a change in the number of motors available to drive cargo transport. To our knowledge,

our study uncovers the first direct link between cargo-membrane composition and kinesin function. The experimental approach employed here is generally applicable as a controlled experimental platform for interrogating the control of motor proteins in a context directly relevant to in vivo scenarios.

P997/B120

Dexamethasone Accelerates Muscle Regeneration by Modulating Kinesin-1-mediated Focal Adhesion Signals.

J. Lin, **J. Kuo**; National Yang-Ming University, Taipei, TAIWAN.

Skeletal muscle differentiation requires the fusion of mononucleated myoblast to form multinucleated muscle fibers. The glucocorticoid dexamethasone (Dex) is therapeutically applied to muscular dystrophy by inhibiting inflammation, slowing muscle degeneration and stabilizing muscle strength; nevertheless, how Dex promotes myogenesis remains unclear. Here we show that Dex directly accelerates kinesin-1 motor activity, which is required for the expression of muscle myosin heavy chain 1/2, the process of myoblast fusion and the formation of polarized myotube. Upon differentiation, kinesin-1 mediates the recruitment of integrin β1 onto microtubules for its delivery into focal adhesions. Integrin β1-mediated focal adhesion signals guide myoblast fusion in polarized morphology. By imposing geometric constrains via micropatterns, we have proved that cell adhesion is able to rescue the defects caused by kinesin-1 inhibition in the process of myogenesis. In adult and aged mice, we found that Dex significantly promotes muscle regeneration after injury through kinesin-1. These discoveries provide a mechanism of Dex in promoting myogenesis and lead us towards an efficient approach to improve the capacity for skeletal muscle regeneration with age.

P998/B121

Glycogen Synthase Kinase 3beta and Presenilin Mediated Regulatory Mechanisms of the Kinesin-1 Motor during Long Distance Axonal Transport.

R. BANERJEE[1], T. Day[2], M. C. Yu[2], S. Gunawardena[2]; [1]Biological Sciences, UNIVERSITY AT BUFFALO, SUNY, Buffalo, NY, [2]UNIVERSITY AT BUFFALO, SUNY, Buffalo, NY.

Long distance transport of essential components within axons is required for neuronal function and viability, and transport defects have been implicated as an early event in many neurodegenerative diseases including Alzheimer's disease (AD). Axonal transport is aided by kinesin-1 (anterograde) and dynein (retrograde) motor proteins on microtubules (MTs). One possible mechanism by which transport defects could occur is by improper regulation of these motors. Previously, we found that excess Glycogen synthase kinase 3β (GSK3β) cause transport defects by increasing the binding of motors to cargo. Presenilin (PS), a protein implicated in AD, also influences motor function. We identified that functional PS and the catalytic loop region of PS is essential for the rescue of GSK3β-mediated transport defects. Further, active GSK3β associated with and phosphorylated kinesin-1. Together, our observations propose a scaffolding mechanism for PS where the loop region sequesters GSK3β away from motors for proper regulation of motor function. To further identify the sites on kinesin-1 that GSK3β phosphorylates, we mutated three putative serine residues to generate phospho-defective and phospho-mimicking forms of kinesin-1 and found that only one of these sites is phosphorylated by GSK3β. Interestingly, only the phospho-mimicking kinesin-1 mutation abolished both kinesin-1 binding to MTs and MT motility, while the phospho-defective kinesin-1 mutation did not influence MT binding, but it impaired MT motility. Therefore, our findings identify the functional significance of PS-GSK3β-

mediated regulatory events on kinesin-1 motors, and isolate the mechanistic details of how GSK3β-mediated phosphorylation controls kinesin-1 activity during long distance axonal transport.

The Spatiotemporal Construction of the Axon Initial Segment Via KIF3/KAP3/TRIM46 Transport Under MARK2 Signaling.

S. Ichinose, T. Ogawa, X. Jiang, N. Hirokawa; Dept of Cell Biol and an atomy, Grad School of Med, the University of Tokyo, Tokyo, JAPAN.

The axon initial segment (AIS) is a fundamental compartment serving as a molecular barrier to achieve axon-dendrite differentiation. Distribution of specific proteins within the early stage of neuronal development has been proposed to be critical for AIS construction. However, it remains unknown how these proteins are specifically targeted to the proximal axon within the limited time period. Here, we reveal spatiotemporal regulation driven by the microtubule (MT)-based motor KIF3A/B/KAP3 that transports TRIM46 under the specific MARK2 phosphorylation cascade. In the proximal part of the future axon under low MARK2 activity, the KIF3/KAP3 motor recognizes TRIM46 as cargo and transports it to the future AIS. In contrast, in the somatodendritic area under high MARK2 activity, KAP3 phosphorylated at serine 60 by MARK2 cannot bind with TRIM46 and transport. This spatiotemporal regulation between KIF3/KAP3 and TRIM46 under specific MARK2 activity underlies the specific transport for axon differentiation.

Direct Competition between Molecular Motors Defines Posterior Determination in *Drosophila* Oocytes.

W. Lu[1], M. Lakonishok[1], A. Rich[2], M. Glotzer[2], V. I. Gelfand[1]; [1]Northwestern University Feinberg Sch Med, Chicago, IL, [2]University of Chicago, Chicago, IL.

The posterior pole of the *Drosophila* embryo is defined by an accumulation of *oskar (osk*) mRNA in the oocyte. Defects in *osk* mRNA localization prevent germ cell formation and abdomen specification. It is known that two major motor proteins, kinesin-1 and myosin-V, are essential for *osk* mRNA posterior localization. In this study, we used Staufen, an RNA-binding protein that colocalizes with *osk* mRNA, to visualize posterior determination in the oocyte. We find that the posterior localization of Staufen depends on three activities of kinesin-1: directed transport of Staufen particles toward the posterior pole, sliding microtubules to drive cytoplasmic streaming, and inhibition of Staufen particle accumulation at sites other than the posterior pole. Posterior localization of Staufen is defined by competition between kinesin-1 that removes Staufen from the cortex and myosin-V that anchors it. The outcome of this competition is determined by cortical microtubule density: it is won by myosin-V at the posterior pole where the microtubule density is low but not at the other parts of the oocyte cortex. In agreement with this model, local depolymerization of cortical microtubules in the lateral cortex using optogenetics causes ectopic accumulation of Staufen. Thus, direct competition between two motors defines the initial localization of posterior determinants in the *Drosophila* oocyte.

P1001/B124

Kif3b Transports Nr2a Complex and Supports Neuronal Plasticity and Functional Synapse Formation.

M. Morikawa[1], A. Alsabban[1,2], Y. Tanaka[1], Y. Takei[1], N. Hirokawa[1]; [1]The University of Tokyo, Tokyo, JAPAN, [2]King Abdulaziz University, Jeddah, SAUDI ARABIA.

Dysfunction of KIF3B, a member of the kinesin superfamily proteins (KIFs), causes schizophrenia (SCZ)-like phenotypes in *vivo* and in *vitro*. Here, we show that KIF3B supports the transport of vesicles simultaneously containing *N*-methyl-D-aspartate receptor (NMDAR) subunit 2A (NR2A), but not NR2B, and the adenomatous polyposis coli (APC) complex. *Kif3b*$^{+/-}$ neurons exhibited a reduction of synaptic levels of both NR2A and NR2B due to the impaired transport of NR2A and increased degradation of NR2B. The transport of NMDARs is crucial for neuronal plasticity and functional synapse formation. Indeed, electrophysiological recordings revealed that the reduction in the surface NMDAR expression of *Kif3b*$^{+/-}$ neurons altered their synaptic plasticity, which is a common basis of SCZ. A mutation of KIF3B was specifically identified in human SCZ patients and the SCZ-specific mutation-carrying KIF3B, but not wild-type KIF3B, failed to reverse the *Kif3b*$^{+/-}$ phenotypes in *vitro*. Therefore, we propose that SCZ-like phenotypes in KIF3B deficiency is caused by the defects in the transport and function of the NR2A/APC complex.

Allosteric Effects of Mutations in the Kif1a Motor Domain Associated with Neurodevelopmental Disorders.

B. G. Budaitis[1], S. Jariwala[2], L. Rao[3], D. Sept[4,2], K. J. Verhey[5,1], A. Gennerich[3]; [1]Cellular and Molecular Biology Program, University of Michigan, an n Arbor, MI, [2]Department of Computational Medicine and Bioinformatics, University of Michigan, an n Arbor, MI, [3]Department of an atomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, [4]Department of Biomedical Engineering, University of Michigan, an n Arbor, MI, [5]Department of Cell and Developmental Biology, University of Michigan, an n Arbor, MI.

The functional output of the microtubule (MT) cytoskeleton depends on a family of molecular motor proteins called kinesins. For transport kinesins, the catalytic motor domain converts the chemical energy of ATP hydrolysis into the mechanical outputs of force generation and directed “stepping” along MT tracks. KIF1A, a member of the kinesin-3 family, is a fast, super processive motor that is critical for the transport of presynaptic vesicles in neurons. Mutations in the KIF1A motor domain have been linked to neurodevelopmental disorders, however we have a limited understanding of how these mutations impact the functional output of the motor domain. Here, we used an interdisciplinary approach to determine the functional impact of two KIF1A mutations located at or near positions involved in kinesin force generation: V8M in beta-1 and Y89D in alpha-1/beta-3. Molecular dynamics (MD) simulations predict that Y89D impairs neck linker docking but not cover-neck bundle formation, suggesting that this mutation decreases force generation of the motor. Both mutations are predicted to have allosteric effects on (1) ATP binding/hydrolysis, and (2) association with the MT track. We tested these predications using single-molecule motility and optical-trapping assays. We find that the mutant motors are slower, less processive, and have a higher frequency of nonproductive, diffusive events along the MT. These motility properties are only modestly rescued when a mutant motor domain is paired with a wild-type motor domain in a heterodimeric motor. Furthermore, Y89D dramatically impairs the motor’s ability to generate force and remain attached to the MT track when under load. Our results highlight

how single residue changes in the motor domain can have allosteric effects that alter the functional output of the motor. This work provides insight into the structural elements critical for kinesin-3 motility, and advances our understanding of how mutations in the kinesin motor domain can manifest in disease.

P1003/B126

Using Protein Interaction Networks to Understand Kinesin-based Hereditary Spastic Paraplegia.

A. Mello, A. Dixon, M. Hayes, T. Huckaba; Xavier University of Louisiana, New Orleans, LA.

Hereditary Spastic Paraplegia (HSP) is a progressive neurodegenerative disease that causes spasticity and weakness in the lower limbs due to denervation of neurons in the corticospinal tract. To date, HSP has been shown to be caused by a variety of mutations in 74 separate human genes (SPGs), as well as another 13 distinct genetic loci. While subsets of the SPGs share gene ontology groupings or participate in broad cellular processes, there is no clear biological pathway that is common among the separate genes that could tie them to a single cellular disease mechanism. The bulk of the existing HSP research has focused on individual SPGs and the altered function of proteins that result from HSP-causing mutations. While this has shed light on the functional deficits associated with mutation in each gene, it has not led to insight in the shared cellular process that is abrogated in the context of HSP. We have taken a different approach by attempting to identify potential interactions between the protein products of SPGs to link them to a common cellular function. To do this, we began with a bioinformatics approach to glean data from existing protein-protein interaction databases. We downloaded the BioGRID database in TAB 2.0 format and built an undirected graph in PERL. We identified SPGs as vertices in the graph, then performed a breadth first search to identify direct interactions (vertices that were neighbors) or indirect interactions (vertices that were neighbors of neighbors). While there were a number of single interactions between SPGs, three larger nodes were identified, the largest of which was centered on the neuronally enriched conventional kinesin, KIF5A. This node contained KIF5A (SPG10), two kinesin light chains (KLC2/SPG68 and KLC4/SPG), and three additional SPGs (SPG20, SPG13, and SPG74). When we expanded the analysis to indirect interactions between SPGs, the KIF5A-containing node expanded to include 13 additional SPGs that indirectly interact with KIF5A. In recognition that this approach is only as complete as the starting data set, we attempted to develop a more complete set of KIF5A-interacting proteins. We first performed a 2-hybrid screen using the cargo binding domain of KIF5A as bait, and screening a human brain cDNA library. This identified 90 distinct genes whose protein products could interact with KIF5A. We are in the process of carrying out a secondary screen using the proximity biotinylation assay to distill the data such that we can follow up on the overlapping data sets from each screen.

P1004/B127

Cargo-mediated Activation of KIF1C Transport.

N. Siddiqui[1], A. J. Zwetsloot[1], A. Bachmann[1], D. Roth[1], H. Hussain[1], A. Toleikis[1], J. Brandt[1], I. Kaverina[2], R. A. Cross[1], **A. Straube**[1]; [1]Centre for Mechanochemical Cell Biology, University of Warwick, UNITED KINGDOM, [2]Vanderbilt University, Nashville, TN.

The kinesin-3 KIF1C is a fast organelle transporter implicated in the transport of dense core vesicles in neurons and the delivery of integrins to cell adhesions. Mutations in KIF1C result in hereditary spastic paraplegia (HSP) and cerebellar dysfunction. Here we show that the activity of KIF1C is controlled by its

own stalk domain, which competes with the microtubule binding interface of the motor domain. These autoinhibitory, intermolecular interactions are released when the cargo adapter HOOK3 or the protein tyrosine phosphatase PTPN21 bind to the stalk domain. Both activators increase the landing rate of the motor and remain bound to KIF1C during transport. The FERM domain of PTPN21 stimulates dense core vesicle transport in primary hippocampal neurons and rescues integrin trafficking in KIF1C-depleted cells, while HOOK3 mediates the formation of a bidirectional transport complex of KIF1C and dynein/dynactin. In vitro, full length human KIF1C is a highly processive, plus-end directed motor with a stall force of 5.5 pN. Removing the stalk domain results in a hyperactive motor with a 20-fold increased landing rate and 5-fold increased speed that is, however, unable to functionally replace KIF1C in cells. On the other hand, mutations in the KIF1C motor domain found in HSP patients, result in slower and weaker motors that are still processive, but cannot generate forces of more than 2 pN. Our findings reveal a mechanism to control the activity of the major neuronal transporter KIF1C and a molecular understanding of the altered mechanical properties of the motor resulting from human disease mutations.

P1005/B128

Analysis of the Immotile Kinesin-4 Motor Kif7 and Its Role in Hedgehog Signaling.

Y. Yue, M. Engelke, L. Blasius, **K. Verhey**; University of Michigan Medical School, an n Arbor, MI.

Hedgehog signaling plays critical roles during development and tissue homeostasis. The kinesin-4 motor KIF7 is a conserved regulator of Hedgehog signaling and mutations in KIF7 are linked to human ciliopathies. In response to Hedgehog pathway activation, KIF7 localizes to the tip of the primary cilium in mammalian cells and facilitates the localization of Hedgehog effectors to the same location. However, unlike conventional kinesins, KIF7 is immotile and its ability to interact with microtubules is not regulated by ATP binding or hydrolysis. How the microtubule binding of KIF7 is regulated and relates to its functions in Hedgehog signaling are unclear. We demonstrate that KIF7 is regulated by autoinhibition as full-length KIF7 does not bind to microtubules whereas truncated motors bind statically to all microtubules in cells, including along the ciliary axoneme. Thus, unlike the behavior of purified motors in *in vitro* assays, truncated versions of KIF7 do not bind selectively to or track the plus ends of microtubules in cells. Using an inhibitable version of the heterotrimeric kinesin-2 motor KIF3A/KIF3B/KAP, we demonstrate that kinesin-2-driven intraflagellar transport (IFT) is required for localization of KIF7 to the cilium tip in response to Hedgehog stimulation. To understand how the unique microtubule-binding features of KIF7 are adapted for its role in Hedgehog signaling, we generated KIF7 variants with altered microtubule interaction phenotypes (no microtubule binding, increased microtubule binding, or microtubule-based motility) and examined their localization and functional output in KIF7-/- MEF cells. We demonstrate that KIF7 motors that lack microtubule binding activity behave similar to wild-type motors in their ability to a) localize to the cilium tip and b) facilitate accumulation of the Gli2 and Gli3 transcription factors at the cilium tip in response to Hedgehog pathway activation. In contrast, KIF7 motors capable of microtubule-based motility can a) localize to the cilium tip and b) drive the localization of Gli2 and Gli3 to the cilium tip even in the absence of Hedgehog pathway activation. Together this work suggests that autoinhibition and the immotile behavior of KIF7 are important for preventing the localization of Hedgehog effectors to the primary cilium in absence of Hedgehog signaling.

P1006/B129

Motor-specific Regulation by Maps - Tau and Map7 Differentially Regulate Kinesin and Dynein Motors to Direct Transport of Intracellular Cargoes.

A. R. Chaudhary[1], L. Balabanian[1], H. Lu[2], K. M. Trybus[2], A. G. Hendricks[1]; [1]McGill University, Montreal, QC, CANADA, [2]University of Vermont, Burlington, VT.

Cargoes are shuttled to different locations in the cell along microtubules by plus-end directed kinesin and minus-end directed dynein motors. While many cargoes are transported by similar sets of kinesin and dynein motors, they exhibit different transport characteristics and are localized differently in the cell. Emerging evidence suggests that microtubule associated proteins (MAPs) regulate kinesin and dynein to target intracellular transport. Two neuronal MAPs, tau and MAP7, control the motility of organelles by regulating the forces exerted by kinesin and dynein teams. We isolated endogenous cargoes driven by teams of kinesin-1, kinesin-2, and dynein motors and reconstituted their motility in vitro. On tau-decorated microtubules, we observe more minus-end directed motility, while cargoes moving along MAP7 decorated microtubules demonstrate more plus-ended motility. Furthermore, the specific set of motor proteins associated with a cargo determine how its transport will be affected by MAPs. Early endosomes are enriched for kinesin-1, while kinesin-2 is the dominant plus-end directed motor on late endosomes. Previous studies have shown that tau inhibits kinesin-1 more strongly than kinesin-2 or dynein. Accordingly, we observe that early endosomes are more sensitive to tau expression in COS-7 cells. Collectively, our results indicate that MAPs can differentially regulate the load-dependent binding and unbinding rates of specific motor proteins to enable cargo trafficking to precise locations in the cell.

Mitochondria-adaptor TRAK Enables Kinesin-1 Driven Transport in Crowded Environments.

V. Henrichs[1,2], Z. Nahácka[1], J. Rohlena[1], C. Bařinka[1], J. Neužil[1], S. Diez[3,4], M. Braun[1], Z. Lánský[1]; [1]Institute of Biotechnology of the Czech Academy of Sciences, BIOCEV, Vestec u Prahy, CZECH REPUBLIC, [2]Faculty of Science, Charles University in Prague, Prague, CZECH REPUBLIC, [3]B CUBE - Center of Molecular Bioengineering, Technische Universität Dresden, Dresden, GERMANY, [4]Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, GERMANY.

Intracellular trafficking of organelles driven by kinesin-1 stepping along microtubules underpins essential processes, such as neuronal activity. Numerous experiments in the absence of other proteins show that during a single microtubule attachment kinesin-1 performs hundreds of steps resulting in micron-long runs along the microtubule. The presence of other microtubule-associated proteins, however, decreases drastically the lengths of kinesin-1 runs. How can kinesin-1 act as an efficient transporter in the crowded cellular environment thus remains largely unclear. Here, we in *vitro* show that the interaction of TRAK (Milton), an adaptor protein essential for mitochondrial trafficking, activates kinesin-1 and enables kinesin-1-based transport in crowded environments. The binding of TRAK to kinesin-1 i) increased the probability of kinesin-1 passing through cohesive envelopes of tau molecules formed on the microtubule surface, ii) facilitated kinesin-1 navigation around obstacles on microtubules and iii) increased the run length of kinesin-1 in cell lysate. Moreover, TRAK enabled kinesin-1-based long-distance transport of isolated mitochondria along microtubules in vitro. We explain this enhanced transport activity of kinesin-1 by an observed interaction of TRAK with microtubules, which provides an additional foothold for the stepping of the TRAK-kinesin-1 complex. We show that anchoring of kinesin-1 to the microtubule

by an adaptor protein can turn kinesin-1 into an efficient long-range transporter in crowded environments.

P1008/B131

Kinesin-associated Protein KAP3 Is a Neuronal Vesicle Adaptor for KIF3AB and KIF3AC.

A. Garbouchian, S. P. Gilbert, M. Bentley; Rensselaer Polytechnic Institute, Troy, NY.

Cells require precise localization of proteins for proper health and function. This is especially evident in neurons, where elongated processes contain distinct protein populations which must be transported long distances from the soma to their appropriate locations. Proteins are packaged into vesicles that are transported by molecular motors such as kinesins or dynein. These motors typically use adaptor proteins to facilitate binding to their vesicles. The Kinesin-2 family members KIF3AB and KIF3AC uniquely differ from conventional kinesins in that they are heterodimers instead of homodimers. KIF3AB is the major anterograde transporter for IFT particles, using KAP3 as an adaptor protein. Much less is known about KIF3AC. Both kinesins are expressed in neurons, but their neuronal functions are unknown. Here we show that KAP3 is a neuronal vesicle adaptor for both KIF3AB and KIF3AC. In cultured hippocampal neurons, KIF3AB and KIF3AC each bind organelles that have similar distributions. They are localized to soma and dendrites and excluded from axons.The identity of these organelles is not known. To determine whether KIF3AB and KIF3AC reside on the same organelles, we co-expressed fluorescently tagged KIF3B or KIF3C in cultured hippocampal neurons, each along with unlabeled KIF3A to ensure dimerization. We found substantial overlap between KIF3B and KIF3C, indicating that KIF3AB and KIF3AC can bind the same organelle. Additional two-color experiments found that KAP3 co-labeled vesicles with KIF3B and KIF3C. This result supports the hypothesis that KAP3 acts as the adaptor for both KIF3AB and KIF3AC. To test this directly, we utilized the well-characterized FRB-FKBP heterodimerization system to artificially target KAP3 to peroxisomes in cultured hippocampal neurons. Fluorescently labeled KIF3B and KIF3C do not normally localize to peroxisomes. Targeting of KAP3 to peroxisomes caused the recruitment of KIF3B and KIF3C to these organelles, while it did not recruit the Kinesin-1 family member KIF5C. This shows that KAP3 binds to Kinesin-2s KIF3AB and KIF3AC in neurons and supports the hypothesis that it acts as a neuronal vesicle adaptor for both heterodimeric kinesins. Together, these results show for the first time that KAP3 is a neuronal vesicle adaptor for KIF3AC and show that KAP3 interacts with KIF3AB.

P1009/B132

ARL8 Dependent Autoinhibition of SKIP Regulates Its Association with Kinesin-1.

T. Keren-Kaplan, J. S. Bonifacino; NIH/NICHD, Bethesda, MD.

Intracellular transport and positioning of organelles rely on coupling to motor proteins that move bidirectionally along microtubule tracks. Coupling of organelles to motors is mediated by specific adaptor proteins. The correct spatio-temporal functions of the motors are crucial to maintain cellular processes. Indeed, malfunctions in this machinery are the cause of numerous pathologies including amyotrophic-lateral-sclerosis and hereditary-spastic-paraplegia. Here, we focused on lysosomes, which are highly dynamic organelles. Recent evidence indicates that the precise positioning of lysosomes in the cell is important for autophagy, nutrient signaling and plasma membrane repair. The outward movement of lysosomes is regulated by a lysosome-associated complex named BORC that initiates a chain of interactions involving the small GTPase ARL8, the adaptor protein SKIP, and kinesin-1. We used

bioinformatics, biochemical and cell biology tools to identify elements that regulate lysosome positioning, focusing on the adaptor protein SKIP. We found that dimerization of SKIP is required for its function. Most importantly, we discovered that SKIP is inhibited by an intra-molecular interaction between its N- and C-terminal parts. This inhibition is relieved by interaction with ARL8, indicating that ARL8 promotes conformational activation of SKIP for coupling of lysosomes to kinesin-1. More generally, these findings uncover a novel regulatory mechanism in which an organelle adaptor changes from an autoinhibited to an active conformation upon interaction with regulators on the organellar membrane.

P1010/B133

Ramp (Reversible Association with Motor Proteins): a Novel Method to Control the Positioning of Organelles within the Cell.

C. M. Guardia[1], R. De Pace[1], A. Sen[2], M. Jarnik[1], D. A. Kolin[1], A. Kunwar[2], J. S. Bonifacino[1]; [1]National Institutes of Health, Bethesda, MD, [2]Indian Institute of Technology Bombay, Powai, INDIA.

Recent advances in live-cell imaging have revealed that the spatial organization of cytoplasmic organelles is highly dynamic. These organelles move back and forth between the center and the periphery of the cell along microtubule tracks. Organelle positioning and movement are critical for maintenance of cellular homeostasis, but the connection of these properties to organelle function remains unclear. This limitation is due to the lack of strategies to manipulate organelle movement and positioning. Therefore, we developed a new method named RAMP (for Reversible Association with Motor Proteins) to control the positioning of different organelles in the cytoplasm. RAMP consists of co-expressing in cells (i) an organellar protein fused to the streptavidin-binding peptide (SBP), and (ii) a microtubule motor fused to streptavidin. Binding of SBP to streptavidin forces the coupling of the organelle to the microtubule motor. The use of plus- or minus-end directed kinesin motors causes accumulation of organelles in the peripheral or perinuclear cytoplasm respectively. Addition of biotin disrupts the SBP-streptavidin interaction, allowing the return of the organelle to its normal steady-state distribution. Using this method, we could manipulate the positioning of various organelles in non-polarized cells: lysosomes, mitochondria, peroxisomes, and ER-resident proteins. This method has been also applied in hippocampal neurons in culture. In these polarized cells, RAMP can be used to accumulate cargo in the perinuclear area and study its trafficking into the dendrites and axon, but also to force the entry of cargo into the axon and study its retrograde transport back to the soma. When applying RAMP to mitochondria, we found that they became rounder and smaller when accumulated at the cell periphery. In contrast, accumulation of mitochondria at the cell center had no effect on their shape. These observations open the possibility of using RAMP to study the mechanisms involved in fission-fusion of mitochondria and their relationship with the pulling forces of motor molecules. We also used RAMP to manipulate the distribution of the ER by using an engineered ER-resident protein. The redistribution of the ER was partial and did not lead to complete disruption of the ER network. The residual structures could be resistant to redistribution because they are tightly tethered to the nucleus, the plasma membrane, or cytoskeletal structures. ER exit sites (ERES) also underwent redistribution after RAMP demonstrating that ER-associated structures can also be manipulated with this tool. In conclusion, RAMP is a new tool for manipulating organelle positioning, which, because of its distinct features, ease of use, and versatility may find broad application in the study of organelle biology.

Development of Chemical Probes That Target the Mitotic Kinesin Kif15.

A. L. Solon[1], M. Dumas[2], R. Ohi[1]; [1]University of Michigan, an n Arbor, MI, [2]Vanderbilt University, Nashville, TN.

Many anti-proliferative drugs used to treat cancer have off-target effects on non-dividing cells. To circumvent this shortcoming, drugs are now being developed to target proteins with roles specific to dividing cells. Promising targets include mitotic kinesins such as Eg5, which drives formation of the mitotic spindle; however, while effective in *vitro*, Eg5 inhibitors have failed clinical trials. One explanation for this discrepancy is that a second kinesin, Kif15, suppresses the cytotoxic effect of Eg5 inhibitors in *vivo* by driving bipolar spindle assembly independent of Eg5 activity. This led to the hypothesis that targeting both Eg5 and Kif15 is an effective strategy for undermining spindle assembly in dividing cells. A novel small molecule Kif15 inhibitor was identified by the Ohi lab during a screen of the GlaxoSmithKline library of Published Kinase Inhibitors. This compound, GW406108X, potently inhibits Kif15 and can effectively disrupt bipolar spindle assembly in Eg5-inhibitor-resistant cells, but has off-target effects due to its anti-kinase activity. To improve our chances of identifying a successful Kif15 inhibitor, I screened the MB 24K Maybridge library of small molecules at University of Michigan's Center for Chemical Genomics using an ATPase assay that correlates ATPase activity with luminescence. Primary screening and secondary hit follow-up of the MB 24K Maybridge library was completed, and the pool of compounds was narrowed down from 24,000 library compounds to 4 potential Kif15 inhibitors. Preliminary experiments suggest these compounds have minimal off-target affects and can block bipolar spindle assembly. I will present an update of my screen, strategies I used to confirm compounds that scored positively, and assays I employed to evaluate and prioritize hits. In conclusion, we have identified four potential Kif15 inhibitor scaffolds that potently and specifically block Kif15 activity both in *vitro* and in cells.

P1012/B135

Biochemical Characterization of the KIF1A Chemomechanical Cycle.

T. M. Zaniewski, W. O. Hancock; the Pennsylvania State University, University Park, PA.

Kinesin-3 is the fastest and most processive neuronal transport kinesin, yet important mechanistic features, such as the cause for binding of the tethered head and the identity of the rate-limiting step(s), are poorly understood. Superprocessivity requires a high probability that the motor will step rather than detach, so understanding the biochemical initiation of the forward step is paramount. We proposed three potential triggers for binding of the tethered-head to the next tubulin: 1) no trigger, 2) ATP-binding trigger, or 3) ATP-hydrolysis trigger. A trigger-less step would minimize the one-head-bound state (1HB), and an ATP binding trigger would maintain the motor in a tightly bound state, making each an attractive explanation for superprocessivity. In contrast, a hydrolysis trigger, which has been recently established for kinesin-1, involves a post-hydrolysis weakly-bound state susceptible to detachment, a feature that hinders superprocessivity. To test these models, we used stopped-flow fluorescence spectroscopy, steady-state kinetics, and single-molecule motility assays to characterize the chemomechanical cycle of the kinesin-3, KIF1A. The KIF1A on-rate, k_{on}^{Mt}, is 17.3 $\mu M^{-1}s^{-1}$, 20-fold faster than kinesin-1. The k_{cat} from solution ATPase assays is 278 s^{-1}, in agreement with the fast motility. KIF1A releases one ADP when combined with nucleotide-free microtubules, ruling out the no-trigger model. When this 1HB complex was combined with ATPγS, the tethered-head ADP release rate was 16.9 s^{-1}

whereas ATP triggered half-site release was 162 s^{-1}. This result indicates ATP hydrolysis occurs before tethered head binding and undermines the ATP-binding trigger model. The similarity of the half-site release rate to the k_{cat} suggests the rate-limiting step is before or during the release of ADP. We conclude that KIF1A exercises the same general stepping framework as other neuronal transport families but differs in the kinetics of specific transitions within the chemomechanical cycle.

P1013/B136

In Vitro Reconstitution of Kinesin-driven Vesicle Transport.

R. Jiang, Q. Feng, Y. Kang, W. O. Hancock; Pennsylvania State University, University Park, PA.

Intracellular vesicle cargos are transported along microtubules by kinesin and dynein motors, towards the cell periphery and cell center, respectively. Individual motors generally have run lengths of several μm, whereas organelles need to travel tens of μm to reach their destinations. Therefore, vesicle cargos usually have multiple copies of motors such that when one or more motors detach from the microtubule, other motors can continue transport. We previously used a 2D lipid bilayer system to measure the microtubule binding kinetics of membrane-bound kinesin-1 motors, from which we predicted long-range transport of 100 nm diameter vesicles required 35 kinesin-1 motors. Our predicted motor number was higher than what was measured on purified neuronal vesicles, thus we aimed to reconstitute kinesin-driven vesicle transport and characterize vesicle motility behaviors in the present study. GFP-labeled kinesin-1 was linked to POPC liposomes through a DNA linker. As the mixing ratio of kinesin-1 and vesicle increased, the vesicle landing density in AMPPNP increased linearly and then reached a plateau. The average vesicle travel distance in ATP increased continuously with the mixing ratio, indicating that multi-motor transport was achieved. Vesicle transport velocity was insensitive to motor number. This system enables reconstitution of vesicle motility with controlled motor densities and can be extended to study bidirectional transport by kinesins and dyneins.

P1014/B137

Tracking Down the Fast and Superprocessive Kif1a with Gold Scattering Microscopy.

A. Gicking; Pennsylvania State University, State College, PA.

The kinesin-3 family member KIF1A is a neuronal kinesin that performs long-distance anterograde vesicle transport in axons and dendrites. Single molecule studies observe KIF1A velocities > 1 μm/s and average run lengths > 5 μm, making KIF1A one of the fastest and most processive members of the kinesin superfamily; however, the mechanistic basis of these high speeds and long run lengths is unknown. One prevailing model for superprocessivity holds that the positively-charged “K-loop” in the KIF1A motor domain diffusively tethers the motor to the negatively-charged microtubule, which prevents complete dissociation of the motor and effectively links together short runs. However, this model does not account for how KIF1A reaches such high speeds, or what role the K-loop plays in the ATP-driven stepping mechanism. To address these questions, we labeled the C-terminus of a truncated KIF1A dimer with a 30-nm gold nanoparticle and used interferometric scattering microscopy (iSCAT) to observe the KIF1A stepping cycle at sub-millisecond time scales and nanometer-level precision. Our preliminary data reveal that KIF1A motility is characterized by periods of directed stepping interspersed by periods where the motor is statically bound to the microtubule, rather than diffusively tethered, as predicted by the K-loop model. An alternate explanation for superprocessivity, that could also account for the stepping speed, is that during each step the K-loop ensures the tethered head binds to the

microtubule hundreds of times faster than the bound head detaches from the microtubule. Our ongoing investigations employ a KIF1A construct with a nanoparticle-functionalized motor domain to characterize the nature of these paused states, and the duration of the one-head bound state in the chemomechanical cycle.

P1015/B138

Modulation of Kif18b Function through Regulatory Interactions of Its Tail.

M. Hazelbaker[1], S. Shrestha[1], A. Prasannajith[1,2], S. C. Ems-McClung[1], C. E. Walczak[1]; [1]Medical Sciences, Indiana School of Medicine - Bloomington, Bloomington, IN, [2]Khorana Scholars Program, New Delhi, INDIA.

Tight regulation of microtubule dynamics and organization is necessary for proper spindle assembly and chromosome segregation. One important mitotic regulator is the Kinesin-8 motor Kif18B, which localizes to the plus-ends of astral microtubules and regulates their length and number during prometaphase. Using yeast two-hybrid and in *vitro* pull-down assays, we previously showed that Kif18B can interact with the plus-tip tracking protein EB1, as well as with the nuclear transport receptor importin alpha. Here, we want to understand how the binding of Kif18B to EB1 and importin alpha affects its function in mitotic spindle assembly. We developed in *vitro* FRET biosensors to examine the interactions of Kif18B with EB1 and importin alpha and to map their binding sites. Using these biosensors, we found that the tail of Kif18B interacts independently with either EB1 or importin alpha/beta and that binding of EB1 to Kif18B can be competitively inhibited by importin alpha/beta. The tail of Kif18B also binds to microtubules, and its binding to microtubules is inhibited by importin alpha/beta, but not by EB1. Using site-directed mutagenesis, we identified two EB1 Binding Domains (EBBD) and two Nuclear Localization Signals (NLS) in the tail of human Kif18B. Mutation of both EBBD sites was required to abolish interaction with EB1, but these mutations had no effect on microtubule binding. Similarly, mutation of both NLS sites was required to abolish intermolecular FRET between the tail of KIF18B and importin alpha. Mutation of the NLS sites also reduced the affinity of the tail for microtubules, suggesting that importin alpha binding is used to modulate the interaction of Kif18B with microtubules. To examine how the interaction of Kif18B with each of these modulators affects microtubule dynamics in mitosis, we are using lentiviral transgene delivery to express eGFP tagged Kif18B wild type and mutant constructs in cells in which the endogenous Kif18B has been knocked down. We have created a series of single and double mutant constructs for both NLS and EBBD binding sites that also have silent mutations that allow the siRNA to selectively knockdown the endogenous Kif18B, while not silencing the expressed transgenes. By examining the mitotic spindle morphology as well as measuring the size and density of the astral microtubule array, these studies will reveal how differential interactions of Kif18B with its binding partners modulate Kif18B activity in mitosis.

P1016/B139

Endogenous Kif25 Associates with Centrosomes to Oppose Centrosome Separation during S and G2 Phases of the Cell Cycle.

M. Wagenbach, J. Vicente, J. Decarreau, **L. Wordeman, 98195**; University of Washington, Seattle, WA.

Kif25 is a minus-end directed bipolar tetrameric kinesin which is expressed at low levels in cultured human cells. Depletion of endogenous Kif25 protein with siRNA elicited premature centrosome separation in S and G2 cells. Premature centrosome separation also led to stochastic mis-positioning of

the nucleus which destabilized spindle positioning when cells entered mitosis. Previously, we have shown by RT-PCR that Kif25 mRNA is transcribed in HeLa cells. We have prepared polyclonal antibodies against both the motor and the N-terminus of Kif25. Using an ATP-free microtubule pelleting assay to enrich for kinesins we have identified full-length Kif25 as a protein that co-purifies with microtubules in an ATP-dependent manner from both HeLa and Hct116 human cell lines. Affinity purified antibodies raised against expressed Kif25 motor cross-reacted with a 64kD protein consistent with the predicted size of full-length Kif25. Addition of ATP to the microtubule pellet releases Kif25 into the supernatant consistent with its identity as an ATP-dependent motor. Mass spec analysis indicates that Kif25 interacts with CEP170, a centrosomal protein that has also been shown to target kinesin-13 family members to the centrosome. We have prepared a Neon-green (NG)-FKBP-Kif25 transgenic CRISPR human cell line which enables us to visualize Kif25 expressed at endogenous levels. Endogenous NG-FKBP-Kif25 colocalized with pericentrin and with centrosomal satellites. The localization is dynamic in live cells. Depletion of protein with siRNA directed against Kif25 eliminated the endogenous NG-FKBP-Kif25 fluorescence. The addition of the FKBP moiety to the first intron of Kif25 allowed us to relocalize the protein from centrosomes to FRB-BFP anchored in the plasma membrane by the addition of Rapamycin. Relocation of exogenous Kif25 to the membrane led to premature centrosome separation in S and G2 cells, similar to what we have seen using siRNA depletion of Kif25. Kif25 protein is expressed at low levels in all tissues and, as a result, is often overlooked in screens. This is why detection of Kif25 full-length protein requires enrichment on microtubules in the absence of ATP. Some studies have reported higher median Kif25 expression in brain, adipose, testis and kidney tissue than in other tissues (GTEx an alysis Release V8). We investigated Kif25 expression in human NTera-2 cells which differentiate along a neural pathway when serum is withdrawn. Interestingly, we observed more centrosomes with associated Kif25 label in differentiating neurons as compared to undifferentiated cells in serum suggesting that Kif25 facilitates centrosome cohesion during neuronal differentiation as well as during S and G2 in other cultured human cell lines.

Mutations in the Chromokinesin KIF22 Disrupt Mitotic Chromosome Segregation and Cause Skeletal Dysplasia.

A. F. Thompson[1], P. R. Blackburn[2], M. Wagenbach[3], L. Wordeman[3], J. B. Lian[1], E. W. Klee[2], J. Stumpff[1]; [1]University of Vermont, Burlington, VT, [2]Mayo Clinic, Rochester, MN, [3]University of Washington, Seattle, WA.

The chromokinesin KIF22 (Kid) generates polar ejection forces and contributes to anaphase chromosome compaction in mitotic cells. The structure of this protein includes a conserved kinesin motor domain, a second microtubule binding domain in the tail, a coiled-coil domain, and a C-terminal DNA binding domain. Mutations in *KIF22* dominantly cause spondyloepimetaphyseal dysplasia with joint laxity- leptodactylic type (SEMDJL2), a skeletal developmental disorder. Published exome sequence analyses of SEMDJL2 patient samples have identified mutations in proline 148 and arginine 149 of the motor domain α2 helix as causative of disease pathology. Additionally, we report that two new skeletal dysplasia patients have point mutations in the coiled-coil rather than motor domain of KIF22. To assess the effect of SEMDJL2 patient-derived mutations on the mitotic function of KIF22, we have built stable cell lines that inducibly express KIF22-GFP with SEMDJL2 causative mutations R149Q (motor domain) and V475G (coiled-coil domain). Expression of KIF22-GFP R149Q or V475G does not disrupt polar ejection force generation, and expression of either mutant motor rescues polar ejection force

generation in cells depleted of endogenous KIF22. We observe anaphase chromosome segregation defects and disrupted nuclear morphology following mitosis in cells expressing KIF22-GFP R149Q or V475G. These results suggest that SEMDJL2-causative mutations impair the anaphase, but not prometaphase, function of KIF22. We are currently investigating the mechanisms by which the effects of motor and coiled-coil domain mutations are specific to phases of mitosis, and why SEMDJL2 mutations result in a patient pathology specific to the skeletal system.

Schizophrenia-like Phenotypes in Mice with Molecular Motorkif3bgenedeficiency.

A. ALSABBAN[1,2,3], M. Morikawa[3], Y. Takei[3,4], Y. Tanaka[5], N. Hirokawa[5,6]; [1]Department of Biology, Faculty of Science, King Abdulaziz University, Jeddah, SAUDI ARABIA, [2]Princess Al-Jawhara Center of Excellence in Research of Hereditary Disorders (PACER.HD), Department of Genetic Medicine, Faculty of Medicine, King Abdulaziz University, Jeddah, SAUDI ARABIA, [3]Department of Cell Biology and an atomy, Graduate School of Medicine, University of Tokyo, Tokyo, JAPAN, [4]Department of an atomy and Neuroscience, Faculty of Medicine, University of Tsukuba, 1-1-1 Tennodai, Tsukuba, Ibaraki 305-8575, Tokyo, JAPAN, [5]Department of Cell Biology and an atomy, Graduate School of Medicine, University of Tokyo, Tokyo, japan, Tokyo, JAPAN, [6]Center of Excellence in Genome Medicine Research, King Abdulaziz University, Jeddah 21589, Saudi Arabia., Jeddah, SAUDI ARABIA.

Schizophrenia (SCZ) is one of the most common neurodevelopmental disorders and is tightly linked to a variety of genetic factors. KIF3B is a member of the KIFs and forms a heterotrimeric complex (KIF3 complex) with KIF3A and kinesin superfamily-associated protein 3 (KAP3). Here we carried out a series of behavioral analyses and found that KIF3B dysfunction causes SCZ-like phenotypes. In the prepulse inhibition test (PPI), the extent of inhibition with the prepulse in Kif3b+/- mice was significantly smaller than that in Kif3b+/+ mice. Kif3b+/- mice exhibited a lower level of anxiety and social interest, whereas they exhibited a higher level of exploratory behavior and repetitive behavior such as jumping and rotating activity, and they spent more time grooming, suggesting locomotion hyperactivity. Kif3b+/- mice also had impaired spatial memory formation and learning flexibility, which is similar with other mouse models of SCZ. The histological features of Kif3b+/- mouse brain also mimicked SCZ features, which underlie behavioral defects of Kif3b+/- mice in PPI, the social interest, and learning flexibility. Therefore, we propose that KIF3B dysfunction causes SCZ-like phenotypes.

Microtubule Dynamics and its Regulation 2

The Elongator Complex Controls Symmetry Breaking of the Central Spindle and Thereby Polarized Trafficking of Cell Fate Determinants during Asymmetric Cell Division.

E. Derivery[1], V. J. Planelles-Herrero[1], C. Seum[2], M. Gonzalez Gaitan[2]; [1]MRC Laboratory of Molecular Biology, Cambridge, UNITED KINGDOM, [2]University of Geneva, Geneva, SWITZERLAND.

Asymmetric cell division gives rise to two daughter cells, which inherit different determinants, thereby acquiring different fates. The polarized sorting of signalling endosomes from an asymmetric central spindle has recently emerged as an important feature of asymmetric cell division in Drosophila Sensory Organ Precursors (SOP). However, how symmetry breaking of the central spindle occurs in vivo remains poorly understood. Here, we have identified a new player in this pathway, namely the Elongator

complex. Elongator is a 6-subunits multiprotein complex that has been involved in the regulation of transcription and translation through histone acetylation and tRNA methylation, respectively. We found that, in SOPs, Elongator localizes to the central spindle, and that deletion of the catalytical subunit Elp3 abolishes central spindle asymmetry and, accordingly, Sara endosome asymmetric segregation. As Sara endosomes contain the cell fate determinants Notch and Delta, this induces cell fate phenotypes in the adult fly. We further investigated the molecular mechanism by which Elongator breaks the symmetry of the central spindle. Mammalian Elongator has previously been proposed to acetylate microtubules, thereby potentially controlling their dynamics. However, we found that purified Drosophila Elongator does not acetylate tubulin in vitro and that Elp3 mutants can be rescued with an acetylase-dead version of Elp3 in vivo. Rather, we found that Elongator binds to dynamic microtubules and lowers the frequency of microtubule catastrophe in in vitro reconstituted single molecule assays. This data suggests that Elongator asymmetrically stabilizes microtubules on one side of the central spindle, thereby generating central spindle asymmetry. We demonstrate this by modifying the Elongator activity gradient through asymmetric targeting of Elongator to the anterior cortex, which accordingly perturbs Sara endosome asymmetric segregation. Altogether, this data suggests that Elongator constitutes a novel link between polarity cues at the cell cortex and symmetry breaking of the microtubule cytoskeleton in the cytosol.

Investigating the Role of Lateral Interactions in Microtubule Dynamics.

G. Li, J. Moore; University of Colorado an schutz Medical Campus, Aurora, CO.

Microtubule dynamics are driven by tubulin subunits making longitudinal and lateral contacts with neighboring subunits in the microtubule polymer. While recent structural data suggests that polymerization involves structural changes at the longitudinal interface, we know less about the role lateral interactions play. **We hypothesize that the lateral interface determines how tubulin forms the cylindrical microtubule lattice and plays an important role in microtubule dynamics**. To test this hypothesis, we investigate how changes across the lateral interface affect microtubule polymerization and depolymerization, focusing on the M-loop of β-tubulin and its interaction with H1-S2 of the neighboring β-tubulin subunit. Based on previous EM studies, the lateral interactions are highly sensitive to temperature decrease. We first measured that effect of temperature on microtubule polymerization, depolymerization, and length. We found all parameters scale with temperature, with the depolymerization rate being more affected by changes in temperature than polymerization. To test the prediction that lateral interfaces determine the microtubule's response to temperature, we generated mutations in the yeast β-tubulin gene, *TUB2*, to mimic amino acid substitutions found in the H1-S2 and M loops of an tarctic species that exhibit cold stable microtubules. We find that an S278G mutation in the M loop increases microtubule dynamics and lowers the temperature dependence of microtubule dynamics by decreasing the activation energy for both polymerization and depolymerization. In contrast, a S56D mutation in the H1-S2 loop affects polymerization and depolymerization differently. We predict that the S56D substitution creates an additional charged-charged interaction across the lateral interface. To assess the relative contributions of lateral and longitudinal interactions during microtubule polymerization, we used combinations of the β-tubulin lateral loop substitutions with mutations known to disrupt the longitudinal interface. We propose a model for microtubule polymerization in which the longitudinal interface governs the on/off rate of a tubulin dimer at the protofilament level, and the lateral interface dictates how quickly protofilaments interact to create a

cylindrical lattice. This work extends our knowledge of how the less well understood lateral interface contributes to microtubule dynamics.

P1021/B145

Synthetic Effects of H^+, Na^+ and Illumination on Microtubule Dynamics in Light Responsive *Chlamydomonas*.

O. M. Potter, P. Yang, 53233-2214; Marquette University, Milwaukee, WI.

The versatile microtubule system plays crucial roles in cells. Some cellular processes harness its signature dynamic instability, whereas others rely on stabilized microtubules. Its various properties are controlled by numerous proteins. A recent study using fluorescent plus end binding EB1-NeonGreen (NG) as a reporter shows that microtubules in flagellated green alga, *Chlamydomonas*, are highly sensitive to H^+, Na^+ and the illumination exciting NG. Light opens cation-permeant channelrhodopsins and modulates flagellar motility. To dissect individual effects, we investigated a β-tubulin mutant, *tub-2, which* was refractory to H^+-triggered rapid microtubule resorption, allowing revelations of the other changes. In *tub-2*, H^+ had imperfect biphasic effects. Both low and high H^+ decreased EB-NG plus end-binding comets, increased lattice binding and decelerated microtubule dynamics, albeit with distinct kinetics. In contrast, medium H^+ drastically increased comets numbers and piggyback incidences, at the expense of comet sizes and lattice binding. Low Na^+ had a similar effect as low H^+. However, when present together, their influences became muted. Notably, NG-exciting illumination accentuate ion-elicited changes. These results demonstrate how acidification, salination and the activity of channels and transporters could jointly shape this crucial cytoskeletal system and thus diverse organisms.

Deciphering Tip Dynamics of *Drosophila Melanogaster* Class IV Neurons.

S. Shree; Yale University, New Haven, CT.

Dendrites are fine processes that form branched arbors. These arbors serve as the neuron's antenna, receiving input and integrating signals from thousands of other neurons. Despite their central role in information processing by the brain, little is known about the molecular and cellular processes by which dendrites form and grow. My current research interest leads me to study the complex morphology of dendrites in Drosophila Class IV dendritic arborization cells, which is a good model cell for studying dendrite morphology. These cells grow in a highly dynamic manner. Their arbors reach diameters of about 500 µm after five days and contain up to 1000 branches. Yet, the individual dendritic tips, whose diameters are only 250 nm, grow and shrink at rates of a few microns per minute, which is roughly 100 times faster than the long-term growth of the neuron. Thus, the overall growth of the branched dendritic network in these cells results from a delicate balance between the formation of new tips, their growth, and their retraction. Currently, in the lab in collaboration with theoretician, we have developed a live cell imaging system, together with automated image analysis, to record and track the dendritic tips of Class IV cells. We observed that the dendritic tips stochastically switch between phases of growth (G), shrinkage (S) and pause (P) and can be fitted into a three-state model. The stochastic growth of dendritic tip is highly reminiscent of dynamic instability of microtubules.Microtubule, Microtubule-associated motors and other proteins (MAPs) play major roles in establishing and maintaining dendritic morphology. As a starting point for a systematic investigation of the role of motors and MAPs, I have used CRISPR to knock out the motor protein dynein specifically in Class IV cells using the established

technique. The key question is how this attenuated phenotype depends on the microscopic dynamics of the tips. By including the tip dynamic parameters measured in dynein mutants into the models, we hope to test whether this can account for the morphological phenotype, this approach will bridge the microscopic behavior of dendrite to the overall morphology of the cells which are necessary for linking genotype to phenotype.

Alterations in Kif2c/mcak from Tumor Samples Increase Chromosome Instability.

L. Wordeman, J. Vicente, M. Wagenbach; University of Washington School of Medicine, Seattle, WA.

Recent years have seen the documentation of somatic mutations in human cancer in comprehensive databases such as the Catalogue of Somatic Mutations in Cancer (COSMIC). One limitation inherent in these databases is that, for many proteins, the effect of the recorded mutation on protein activity is unknown. The microtubule (MT) depolymerizing kinesis Kif2C/MCAK is often reported to be over expressed in certain cancers. The cellular effects of alterations in Kif2C/MCAK activity in cancer cells is an important question because increased Kif2C/MCAK activity has been reported to rescue chromosome instability (CIN), while decreased activity will increase CIN. Evaluation of the COSMIC database for alterations in Kif2C/MCAK activity reveal two principal, non-overlapping categories of Kif2C genetic changes: Point mutations and amplifications of the wild-type gene. We prepared Kif2C/MCAK constructs that identical to motor domain point mutation hotspots identified in the COSMIC database. We found that the majority of point mutations identified in the COSMIC database lead to impaired Kif2C/MCAK microtubule depolymerizing activity in cells. In contrast, we hypothesized that amplifications of Kif2C/MCAK would, presumably, increase cellular Kif2C/MCAK activity. We tested this hypothesis by quantifying the effect of point mutations and changes in Kif2C/MCAK levels on CIN by assaying lagging chromosomes during telophase. We prepared CRISPR modified transgenic cell lines that allowed us to rapidly remove endogenous GFP-FKBP-Kif2C/MCAK from the cytoplasm in Rapamycin. Relocalization of Kif2C/MCAK from microtubules and centromeres using this method led to an increase in CIN as quantified by lagging chromosomes. Cytoplasmic GFP-Kif2C/MCAK rescued this phenotype and restored proper chromosome segregation to cells in Rapamycin. In contrast, Kif2C/MCAK possessing mutations from hotspots identified in the COSMIC database exhibited high levels of CIN which became higher still, in combination with endogenous Kif2C/MCAK relocalization. Thus, while additional cytoplasmic GFP-Kif2C/MCAK could rescue CIN in cells with relocalized endogenous GFP-Kif2C/MCAK, we found that control cells expressing GFP alone were not tolerant of further increased Kif2C/MCAK activity. These data support the conclusion that both Kif2C/MCAK amplification and point mutations are likely to increase CIN in tumors in which they are identified.

P1024/B148

Clasp2 Mediates Interactions between Microtubules and Bundled Actin Filaments.

N. C. Rodgers, E. J. Lawrence, M. Zanic; Vanderbilt University, Nashville, TN.

Coordination between the microtubule and actin cytoskeletons is essential for cell motility, neuronal growth cone guidance, and wound healing. In a cellular context, this coordination is controlled by crosslinking proteins, and when disrupted can lead to disease. While studies in cells have identified important crosslinking proteins, the molecular mechanisms underlying the interactions between microtubules and actin filaments remain unclear. Members of the CLASP (Cytoplasmic Linker Associated

Protein) family of proteins have been implicated in cytoskeletal crosstalk. However, the specific dynamic interactions between microtubules and actin mediated by CLASPs remain less understood. Here, we use purified proteins to demonstrate direct interactions of CLASP2α with actin and microtubules, visualized using total internal reflection fluorescence microscopy (TIRFM). Our results demonstrate that CLASP2α directly interacts with actin in *vitro*, preferentially colocalizing with bundled F-actin, and is able to increase coalignment of microtubules along F-actin bundles. Furthermore, we characterized interactions between dynamic microtubules and bundled F-actin over a range of CLASP2α concentrations, and found that CLASP2α increases events of dynamic microtubule zippering along bundled F-actin. Our in *vitro* reconstitution approaches will elucidate the direct biochemical mechanisms underlying microtubule-actin coordination by CLASP2, essential for a range of cellular processes.

P1025/B149

Microtubule Minus-end Stability Is Dictated by the Tubulin Off-rate.

C. Strothman[1], V. Farmer[1], G. Arpag[1], N. Rodgers[1], M. Podolski[1], S. Norris[1], R. Ohi[2], M. Zanic[1]; [1]Vanderbilt University, Nashville, TN, [2]University of Michigan, an n Arbor, MI.

Dynamic organization of microtubule minus ends is vital for the formation and maintenance of acentrosomal microtubule arrays. In vitro, both microtubule ends switch between phases of assembly and disassembly, a behavior called dynamic instability. Although minus ends grow slower, their lifetimes are similar to those of plus ends. The mechanisms underlying these distinct dynamics remain unknown. Here, we use an in vitro reconstitution approach to investigate minus-end dynamics. We find that minus-end lifetimes are not defined by the mean size of the protective GTP-tubulin cap. Rather, we conclude that the distinct tubulin off-rate is the primary determinant of the difference between plus- and minus-end dynamics. Further, our results show that the minus-end-directed kinesin-14 HSET/KIFC1 suppresses tubulin off-rate to specifically suppress minus-end catastrophe. HSET maintains its protective minus-end activity even when challenged by a known microtubule depolymerase, kinesin-13 MCAK. Our results provide novel insight into the mechanisms of minus-end dynamics, essential for our understanding of microtubule minus-end regulation in cells.

P1026/B150

Interplay between Microtubules and Integrin-mediated Adhesion in an giogenesis.

A. J. Farrugia[1], N. B. M. Rafiq[1], A. Mercurio[2], G. Adriani[2], A. D. Bershadsky[1,3]; [1]Mechanobiology Institute, National University of Singapore, Singapore, SINGAPORE, [2]Singapore Immunology Network, Agency for Science, Technology and Research, Singapore, SINGAPORE, [3]Department of Molecular Cell Biology, Weizmann Institute of Science, Rehovot 76100, ISRAEL.

Angiogenesis is the formation of new blood vessels from pre-existing vasculature and is essential during many physiological and pathological processes including wound healing and cancer. To initiate angiogenesis, cytokines from external sources activate endothelial cells (ECs) leading to increased extracellular matrix (ECM) degradation, cell migration, sprouting, and eventually reorganizing to form a tubular network of vessels. Changes in cell adhesion and shape, orchestrated by the cytoskeleton, are integral to the various steps of angiogenesis. Microtubules (MT) are major regulators of cell shape and are able to negatively regulate focal adhesion (FA) growth. This is evident after complete disruption of MT following nocodazole treatment which results in an increased number of myosin II-filaments and larger FA size. The interplay between MT and FA in the different stages of angiogenesis is not fully

understood. FA are associated with MT tips via proteins of KANK family, linking the FA protein talin with a complex of proteins trapping the MT ends. We have previously shown that depletion of KANK proteins led to an increase in FA size, similar to nocodazole treatment. Additionally, KANK proteins control the release/sequestration of GEF-H1, which sequentially affects Rho-Rho kinase (ROCK) signaling and actomyosin contractility. Here we demonstrate that in ECs (HUVEC), KANK1 localizes around FA complexes in close proximity to MT. RNAi knockdown of KANK1 induces the release of GEF-H1 from MT, resulting in elevated Rho-ROCK signaling and in turn an increase in myosin II-filaments and FA size, similar to treatment with nocodazole however without apparent disruption of MT. To study angiogenesis, we employed an *in-vitro* 3D microfluidic device that recapitulates the process of vascular sprouting. Additionally, we characterized the reorganization stage of angiogenesis by plating HUVECs onto an ECM support where the cells form capillary(tube)-like structures. In both systems we show that treatment of HUVEC with either nocodazole or siRNA depletion of KANK1 was sufficient to inhibit angiogenic sprouting or promote the disruption of tubular networks. We observe that co-knockdown of GEF-H1 or addition of ROCK inhibitor Y27632 was able to rescue the effects of KANK1 depletion, resulting in the restoration of vascular sprouts and capillary-like networks. Our research supports a unique role for KANK as a molecular tool to regulate MT/FA interactions, alter cellular contractility and inhibit angiogenesis, suggesting it may also possess a therapeutic potential.

P1027/B151

Dynein-mediated Nuclear Translocation of Yes-associated Protein through Microtubule Acetylation Controls Fibroblast Activation.

E. You, P. Ko, J. Jeong, S. Keum, S. Rhee; Chung-Ang University, Seoul, KOREA, REPUBLIC OF.

Myofibroblasts are the major cell type that are responsible for increase the mechanical stiffness in fibrotic tissues. It has well documented that the TGF-β/Smad axis is required for myofibroblast differentiation under the rigid substrate condition. However, the mechanism driving myofibroblast differentiation in soft substrates remains unknown. In this research, we demonstrated that interaction of yes-associated protein (YAP) and acetylated microtubule via dynein, a microtubule motor protein drives nuclear localization of YAP in soft matrix, which in turn increased TGF-β1 induced transcriptional activity of Smad for myofibroblast differentiation. Pharmacological and genetical disruption of dynein impaired the nuclear translocation of YAP and decreased the TGF-β1 induced Smad activity even though phosphorylation and nuclear localization of Smad occurred normally in α-tubulin acetyltransferase (α-TAT1) knockout cell. Moreover, microtubule acetylation prominently appeared in the fibroblast-like cells nearby the blood vessel in the fibrotic liver induced by CCl_4 administration which were conversely decreased by TGF-β receptor inhibitor. As a result, quantitative inhibition of microtubule acetylation may be suggested as a new target for overcome the fibrotic diseases.

P1028/B152

Prc1 Is Required for Recruiting Eb1 to the Central Spindle Where Both Proteins Become Immobilized as the Midzone Compacts during Late Mitosis.

J. Asthana, N. I. Cade, W. M. Lim, T. Surrey; the Francis Crick Institute, London, UNITED KINGDOM.

At the onset of anaphase, antiparallel microtubules and associated proteins form a bundled structure known as the central spindle. How the dynamic properties of the central spindle develop as the cell transitions from metaphase to telophase is still poorly understood. To quantitatively characterize the

morphology and the dynamics of the central spindle in a native context, CRISPR/CAS9 endogenous gene editing was used in htert-RPE1 cells to fluorescently tag PRC1, a marker of antiparallel microtubule overlaps in the central spindle; and EB1, a marker for microtubule dynamics. FRAP analysis of mGFP-PRC1 in the central spindle shows that initially in metaphase the binding/unbinding turnover of PRC1 is fast, and then slows down in anaphase until PRC1 is essentially irreversibly bound to the midbody in telophase. In cells expressing both mGFP-EB1 and mCherry-PRC1 from their endogenous promotor EB1 tracks growing microtubule plus-ends, but surprisingly also colocalizes with PRC1 to the central spindle. Similar to PRC1, the turnover of mGFP-EB1 strongly decreases over time as the central spindle compacts and more PRC1 and EB1 accumulate there. These measurements demonstrate that the central spindle becomes 'solid' as it compacts. Central spindle localization of EB1 depends on the presence of PRC1, as shown by knock-down experiments. It also requires the ability of the C-terminal part of EB1 to interact with its binding partners, as shown by lentiviral expression of C-terminally mGFP-tagged EB1 that is known to disrupt the interaction with its partners. Taken together, these results reveal an unexpected link between PRC1 and EB1 during mitosis, although they have been thought until now to recruit their binding partners strictly to different localizations in human cells. Moreover, the turnover of both proteins indicate that the central spindle 'solidifies' as it ages, which may be an important part of its function.

P1029/B153

Microtubule Dynamics an alysis of Human Dermal Fibroblasts Using Hydrolyzed Eggshell Membrane-bound Acrylamide Gel Reflecting in Vivo Conditions.

Y. ATOMI[1], M. Shimizu[1], S. Horinouchi[1], T. Akaishi[1], E. Ohto-Fujita[1], K. Yoshimiura[2], Y. Hasebe[3]; [1]Tokyo University of Agric. & Tech., Tokyo, JAPAN, [2]Jichi Medical University, Shimotsuke-shi, JAPAN, [3]Almado Inc., Tokyo, JAPAN.

Cells change differentiation, proliferation, and metabolism in response to the environment. Hard plastic petri dishes that are routinely used in laboratories have unusual hardness that is incomparable to living organisms, and therefore change the properties of cells. In human fibroblasts, cells that have been passaged 30 times or more are used as senescent cell models, but detailed molecular mechanism is yet to be analyzed. We focus on cytoskeletal dynamics that control cell adhesion, especially microtubule dynamics. Based on previous studies, it has been shown that alphaB-crystallin, which functions as a tubulin / microtubule chaperone, controls cell shape and adhesion (PLoS One, 2016) and simultaneously found that microtubule dynamics are altered by knockdown and overexpression of alphaB-crystallin. On the other hand, cell culture systems that mimic the environment of living bodies have been actively constructed, and 2D and 3D collagen gels, laminin 511, decellularized ECM have been reported. We have developed and reported a cell culture system using chicken eggshell membrane, a unique natural ECM material. That is, the gene expression of human fibroblasts on hydrolyzed eggshell membranes conjugated to MPC polymer (Cell & Tissue Research, 2011) is surprisingly identical to the gene expression pattern when hydrolyzed eggshell membranes are applied to mouse skin (Cell & Tissue Research, 2019). This indicates that the hydrolyzed eggshell provides an ECM environment that reflects in vivo. However, since MPC polymers are expensive and difficult to obtain, we considered the use of versatile acrylamide gels. Transparent, microscopically observable thin gels with various amounts of hydrolyzed eggshell membranes were prepared using acrylamide, N, N'-methylenebis (acrylamide), and Acrylic acid N-hydroxysuccinimide ester. Human dermal fibroblasts were seeded on the gel and cultured for 24 hours. Thereafter, cells were fixed using formalin and the shape of the cells was observed by

immunostaining. In addition, RNA was extracted from the cells on the gel, and gene expression analysis was performed by RT-PCR. As a result, the expression patterns of type III collagen, Decorin, and MMP2 that are characteristic of eggshell membranes were confirmed, and it was found that they not only replace expensive MPC polymers but also agree with the results in mouse skin. This indicates that eggshell membrane conjugate acrylamide gel can be used as a cell culture system reflecting in vivo. In order to evaluate the health of fibroblasts, we investigated the relationship between spatiotemporal distribution of Vinculin controlled by alphaB-crystallin and microtubule dynamics using the developed eggshell membrane acrylamide gel system.

Overexpression of α-tubulin Acetyltransferase 1 (αTAT1) Promotes Microtubule Hyperacetylation and Impairs Multiple Hepatic Polarized Protein Trafficking Steps.

R. Adhikari, 20064, J. L. Groebner, A. M. Richard, P. L. Tuma; the Catholic University of America, Washington DC, DC.

Alcoholic liver disease presents with a well-described clinical progression ranging from steatosis to fibrosis and ultimately cirrhosis. However, the mechanisms that promote alcohol-induced liver injury are far from established. The liver sustains the most damage from chronic alcohol consumption as it serves as the body's metabolic center. In this capacity, it converts alcohol into highly reactive metabolites that readily form adducts with proteins, lipids and DNA thereby disrupting liver homeostasis. It has also become apparent that chronic ethanol exposure induces post-translation protein modifications - most notably, lysine acetylation. Previously, we determined that microtubules are more acetylated in alcohol-treated hepatocytes, liver slices and in livers from ethanol-fed rats. We further correlated microtubule acetylation with many known defects in alcohol-induced protein trafficking including basolateral secretion, basolateral-to-apical transcytosis, STAT nuclear translocation and clathrin-mediated endocytosis. To determine whether microtubule acetylation itself can explain the alcohol-induced defects in protein trafficking, we overexpressed αTAT1 in polarized, hepatic WIF-B cells to promote tubulin acetylation in the absence of alcohol. Expression of αTAT1 led to a dose-dependent increase in tubulin acetylation up to 10-fold over control. In overexpressing cells with an equivalent increase in tubulin acetylation as seen in ethanol-treated cells (3 fold), we measured defects in secretion and transcytosis to similar levels as observed in ethanol-treated cells (50% of control). We further observed that the punctate basolateral distributions of markers of clathrin-mediated endocytosis (recycling receptors and AP2), were significantly increased in overexpressing cells suggesting that the dynamin-mediated fission of invaginated clathrin-coated pits was similarly impaired as we documented for ethanol-treated cells. Somewhat surprisingly, STAT5 nuclear translocation was not impaired in αTAT1 expressing cells which may point to differences in the mechanism regulating this process. We conclude that microtubule hyperacetylation is the underlying feature of a subset of alcohol-induced defects in protein sorting and further suggest that agents already in clinical trials that modulate cellular acetylation may provide a novel therapeutic for chronic alcoholics.

Measurement and Modeling of Microtubule Tip Dynamics.

J. Cleary; Pennsylvania State University, University Park, PA.

The ability of microtubules to undergo dynamic instability is a fundamental process in all cells and a target of antimitotic drugs. Traditionally, microtubule growth and shrinkage phases in vitro have been assessed through kymograph analysis, which provides limited insight into the precise dynamics at growing tips. Here, we used interference reflection microscopy (IRM) to image dynamic microtubules at 10 frames/s over 10s of minutes, and used a half-gaussian function to track the precise position of the growing plus- and minus-end positions. To study polymerization dynamics occurring during phases of growth and shrinkage, time-dependent fluctuations of tip position were fit to an equation for drift plus diffusion. We found that the plus-tip diffusivity and velocity both increase with increasing tubulin concentration. To understand tubulin on-and off-kinetics, we measured tip diffusivity, growth rate, shrinkage rate, and microtubule lifetimes, and incorporated them into a biochemical model. Using our measured parameters for both the plus- and minus-ends, we were able to put constraints on the on-rate, the longitudinal bond energy, and the lateral bond energy parameters. Current work is focused on comparing the growth of microtubules in GTP versus the non-hydrolyzable analog GMPCPP. Collectively, our measurements will be utilized to understand the impact of hydrolysis on reversible tubulin binding at the plus- and minus-ends.

Electron Cryo-tomography and Brownian Dynamics Modeling Elucidate the Mechanism of Microtubule Polymerization.

J. McIntosh[1], E. O'Toole[1], C. Page[1], G. P. Morgan[1], E. V. Ulyanov[2], D. S. Vinogradov[3], E. Szczesna[4], A. Roll-Mecak[4], F. Ataullakhanov[2], N. Gudimchuk[2]; [1]University of Colorado, Boulder, CO, [2]Lomonosov Moscow State University, Moscow, RUSSIAN FEDERATION, [3]Russian Academy of Sciences, Moscow, RUSSIAN FEDERATION, [4]NINDS, Bethesda, MD.

Recent studies from our labs have shown that the ends of both growing and shortening microtubules (MTs) terminate in bent protofilaments (PFs), suggesting that MTs polymerize by the addition of bent GTP-tubulin to the tips of curving PFs (McIntosh et al., J. Cell Biol., *217*:2691(2018)). Here we develop a Brownian dynamics model for MT growth by examining a range of values for all key parameters that are not specified by observation. We then use the model to make predictions about MT assembly under a range of conditions. The model predicts that the shapes of growing MT tips should be insensitive to growth rate. We have tested this prediction by varying the soluble tubulin concentration over 4X, by adding two concentrations of a TOG polymerase that increases MT growth rate, and by slowing MT growth with low concentrations of Taxol or Epothilone. All results conform to model predictions. The model predicts that the structures of adjacent PFs should not correlate, compared with randomly chosen PFs from a MT tip, and this prediction too is valid. The model predicts that the irregularity of multiple PFs at each MT tip, or raggedness, should not vary with the rates of MT growth or shortening. This prediction is approximately true, but experimental results show greater tip raggedness than model MTs with only two exceptions: shortening MTs and those growing in GMPCPP. We surmise that the rates of individual PF elongation vary for reasons not included in the current model. One possible explanation is the heterogeneity of brain tubulin, so we examined the tips of MTs elongating with a human tubulin, purified from an embryonic kidney cell line, which is composed predominantly of one

isoform of α-tubulin and two of β, and which harbors no detectable posttranslational modifications. This tubulin also produced ragged MT ends. Ragged ends in model MTs can be obtained when the tubulin addition rate constant is lower than we have commonly used, making it as low as that recently measured for yeast tubulin. This may explain why our current model is less successful in accounting for raggedness than other features of MT growth.

A Kink in Brain Development: Altering Tubulin's Conformational Transitions Disrupts Neuronal Migration.

K. J. Hoff[1], J. E. Aiken[1,2], M. A. Gutierrez[2], S. J. Franco[2], J. K. Moore[1]; [1]Department of Cell and Developmental Biology, University of Colorado an schutz Medical Campus, Aurora, CO, [2]Department of Pediatrics, University of Colorado an schutz Medical Campus, Aurora, CO.

Neurons require distinct microtubule activity in order to migrate properly, and therefore it is crucial that microtubule dynamics are tightly regulated throughout the neuron. Lissencephaly is a neurodevelopment disease that results from the improper migration of neurons in the developing brain and has been linked to a variety of mutations in the *TUBA1A* gene. Despite the association between *TUBA1A* mutations and disrupted neuronal migration, we still do not understand how tubulin modifications impact greater neuronal cell biology. In its free state, the tubulin heterodimer is in a kinked conformation, but must subsequently straighten as it is assembled into microtubule polymer. This transition from a kinked-to-straight conformation is therefore a potential point of microtubule dynamics regulation. Located at the position where the tubulin heterodimer hinges between its kinked and straight conformations is an understudied region of α-tubulin, the H11' helix. Our preliminary computational modeling indicates that mutating a single residue in the α-tubulin H11' helix perturbs the kinked conformation of the tubulin heterodimer, indicating the importance of this helix in establishing a kinked state. Interestingly, two patients with lissencephaly have been identified to have missense mutations within the α-tubulin H11' helix. Both patients have mutations that alter the valine at residue 409 (V409) of *TUBA1A*, but the mutations and resulting phenotypes are distinct. One patient with a V409A substitution exhibits severe lissencephaly, whereas another with a V409I mutation exhibits a milder form of pachygyria. We find that the ectopic expression of either *TUBA1A*-V409A or -V409I dominantly disrupts neuronal migration in the developing mouse brain, reminiscent of the phenotype we observe in patients. To determine the underlying molecular mechanisms of the *TUBA1A*-V409A and -V409I mutants that disrupt neuronal migration, we modeled these mutants in budding yeast. We show that both mutants have increased rates of microtubule polymerization and depolymerization. However, microtubules composed of either of these two mutants have depleted localization of XMAP215/Stu2, which selectively binds kinked heterodimer, to the microtubule plus-end. Decreased localization may therefore indicate a loss of kinked tubulin that XMAP215/Stu2 can readily bind. Taken together, these data indicate that V409 mutants in α-tubulin disrupt the regulation of microtubule dynamics that is normally coordinated via XMAP215/Stu2. We propose that these effects are attributable to a disruption of the kinked tubulin conformation. Our work thus highlights a critical role for the proper regulation of tubulin conformation in migrating neurons.

P1034/B158

The Role of Kif19 in Cell Migration, Microtubule, and Focal Adhesion Dynamics.

S. Eisenberg, D. Sharp; Albert Einstein College of Medicine, Bronx, NY.

Focal adhesions are a critical component of cell migration and attachment. Dysregulation and decreased stability of focal adhesions have been linked with cancer invasiveness and metastasis. It is unclear how focal adhesion disassembly occurs, but there is a growing body of work indicating that microtubules, and specifically their high dynamicity at adhesions, are a key regulator. While studies have described several mechanisms for guiding microtubule growth towards focal adhesions and mediating adhesion disassembly, the regulation of microtubule depolymerization at focal adhesions remains unknown. We have identified a member of the kinesin-8 superfamily, Kif19, as a protein that regulates cell migration and may destabilize microtubules at focal adhesions. Kif19 has previously been shown to move along and depolymerize microtubules in vitro. Our preliminary studies have demonstrated that depletion of Kif19 results in a significant inhibition of cell motility and decreased microtubule catastrophe at focal adhesions. Thus, we propose that Kif19 is a positive regulator of cell migration that acts by localizing to focal adhesions and depolymerizing nearby microtubules. Here we show that Kif19 depletion results in a significant increase in focal adhesion area, as well as a significant change in cell shape to a more circular morphology with fewer actin protrusions. Additionally, Kif19 depletion results in an increased proportion of tyrosinated (i.e. dynamic) microtubules compared to total tubulin. Our data imply that Kif19 is important in regulating focal adhesion disassembly and microtubule dynamics and may be important for regulating cell morphology.

P1035/B159

Investigating the Effect of Novel Microtubule-Severing Enzyme Fidgetin-Like 2 on Rac1 and RhoA GTPase Activation at the Leading Edge.

K. Smart, L. Hodgson, D. Sharp; Albert Einstein College of Medicine, Bronx, NY.

Fidgetin-like 2 (FL2) is a recently characterized microtubule-severing enzyme, which reduces cell motility by severing dynamic microtubules at the leading edge of migrating cells. We hypothesize that FL2 KD leads to a shift in local RhoA and Rac1 activation kinetics, which may then influence downstream effectors in order to suppress cell migration. Both Rac1 and RhoA GTPases are involved in key cell motility pathways, and both can be regulated by microtubule dynamics. Therefore, we used FRET (Forster resonance energy transfer) imaging with either a Rac1 or RhoA biosensor to investigate changes in activation after FL2 KD. Our data show that RhoA activation kinetics are spatially polarized after FL2 depletion, while typical Rac1 activation kinetics are simply strengthened. These experiments begin to provide some insight into the mechanism by which FL2's local microtubule-severing activity may suppress cell motility.

Microtubule Nucleation and Organization

P1036/B160

Microtubule Nucleation in Mouse Bone Marrow-derived Mast Cells Regulated by Src Homology 2 Domain-containing Protein Tyrosine Phosphatase 1.

A. Klebanovych, V. Sládková, T. Sulimenko, V. Vosecká, M. Čapek, E. Dráberová, P. Dráber, V. Sulimenko; Institute of Molecular Genetics, Czech Academy of Sciences, Prague, CZECH REPUBLIC.

Microtubules (MT) play an important role in essential cellular events. Rapid and transient reorganization of MTs was observed upon antigen-induced activation of bone marrow-derived mast cells (BMMCs), key components of adaptive and innate immune responses. Propagation of signals from activated cell membranes results in the generation of protrusions containing MTs, degranulation, release of multiple inflammatory mediators. While MTs are known to be important for degranulation, the molecular mechanisms responsible for microtubule reorganization remain largely unknown. In BMMCs, MTs are nucleated from the centrosomes, where γ-tubulin complexes are essential for this process. We have recently found that Src homology 2 (SH2) domain-containing protein tyrosine phosphatase 1 (SHP-1; Ptpn6) form complexes with γ-tubulin complex proteins. Therefore, we aim to test the hypothesis that SHP-1 can influence MT nucleation by following MT regrowth in BMMCs. We have developed a user-friendly macro for rapid processing of MT regrowth raw images using Fiji software (Klebanovych et al, Cells 8, e345, 2019). When compared to wild type cells, MT regrowth experiments revealed large MT asters emanating from interphase centrosomes and centrosomal accumulation of γ-tubulin in cells lacking SHP-1. Moreover, the inhibition of the SHP-1 activity by inhibitors TPI-1 and NSC87877 augmented MT nucleation as well. Further experiments with antigen-activated cells showed that the deletion of SHP-1 stimulated both the generation of microtubule protrusions and the degranulation. Our data suggest that SHP-1 is a novel negative regulator of MT nucleation that affects γ-tubulin level in centrosomes of BMMCs.

P1037/B161

Protein Tyrosine Phosphatase SHP-1 Is a Regulator of Microtubule Organization in Activated Mast Cells.

V. Sulimenko, A. Klebanovych, V. Sládková, T. Sulimenko, V. Vosecká, Z. Rubíková, E. Dráberová, P. Dráber; Institute of Molecular Genetics, CAS, Prague, CZECH REPUBLIC.

Antigen-mediated activation of mast cells initiates signaling events leading to degranulation and release of inflammatory mediators. While rearrangement of cytoskeleton is essential for mast cells degranulation, molecular mechanisms that modulate microtubule reorganization during this process are not fully understood. Microtubule nucleation is mediated by γ-tubulin complexes. Rapid tyrosine phosphorylation of proteins interacting with γ-tubulin in activated mast cells has been described (Sulimenko et al., 2006). Here, we report on interaction of Src homology 2 (SH2) domain-containing protein tyrosine phosphatase 1 (SHP-1; *Ptpn6*) with γ-tubulin complex proteins and its regulatory role in microtubule organization in bone marrow-derived mast cells (BMMCs). Reciprocal immunoprecipitation experiments revealed complexes of SHP-1 with γ-tubulin, GCP proteins and protein tyrosine kinase Syk. Pull-down experiments with truncated forms of γ-tubulin and SHP-1 unveiled corresponding interaction domains. When compared to controls, activated SHP-1 depleted cells had higher level of tyrosine phosphorylation, enhanced degranulation, as well as increased expression of cytokines and

prostaglandins. Depletion of SHP-1 also resulted in stimulation of de novo microtubule nucleation and generation of protrusions containing microtubules. Our data suggest a novel SHP-1 dependent mechanism for the suppression of microtubule formation in later stages of mast cell activation.

P1038/B162

Molecular Mechanism and Kinetics of Microtubule Nucleation in the Cell.

A. Thawani[1], M. Moritz[2], D. Agard[2], H. A. Stone[1], J. W. Shaevitz[1], S. Petry[1]; [1]Princeton University, Princeton, NJ, [2]University of California San Francisco, San Francisco, CA.

A variety of cytoskeletal structures are formed by regulating where and when microtubules are nucleated. How microtubules are generated from αβ-tubulin dimers in the cell? This has been a major open question in understanding how the cytoskeleton is assembled ever since the discovery of tubulin in the 1960s. Even though the γ-tubulin ring complex (γ-TuRC) has been accepted as the universal microtubule nucleator of the cell for several decades, its mechanism as well as its regulation in cytosol still remains to be elucidated. Partly, this has been due to the inability to purify the 2.2 MDa γ-TuRC consisting of roughly 40 subunits in biochemical quantities, such that to date no live assay for MT nucleation by γ-TuRC has been reported. Here, we overcome this hurdle by using purifying γ-TuRC from Xenopus egg extract, with which we reconstitute γ-TuRC mediated MT nucleation in vitro. Most importantly, we establish a novel assay in which single γ-TuRC molecules are observed live at the single molecule level to study MT nucleation. We find that γ-TuRCs display a kinetic lag in microtubule nucleation and a critical size of 4-5 tubulin dimers are needed for successful nucleation event, thereby defining the actual 'nucleus'. We demonstrate that the lag in γ-TuRC nucleation is the result of weaker interactions between γ-tubulin and αβ-tubulin, compared to strong interations between αβ-tubulin dimers. This is the molecular basis of the nucleation barrier. The recently discovered co-nucleation factor XMAP215 accelerates γ-TuRC nucleation by decreasing the critical concentration of tubulin at which γ-TuRCs generate microtubules. Single molecule experiments with 3 fluorescently components -γ-TuRC, XMAP215 and tubulin- show that XMAP215 and γ-TuRC associate first followed by generation of a microtubule from the nucleation site. Strikingly, microtubule associated proteins that tune the microtubule catastrophe and rescue frequency, TPX2 and EB1, unexpectedly had no effect on microtubule nucleation by γ-TuRC. In summary, in this work we define the nucleation barrier for MT nucleation by γ-TuRC and reveal its molecular basis. Nucleation by γ-TuRC is driven by finely tuned interactions at the interface of γ-TuRC to the microtubule and turned by microtubule associated proteins.

P1039/B163

Identifying and Understanding the Role of Microtubule Associated Proteins in Differentiated Tissue.

M. Tran, J. Feldman; Stanford University, Stanford, CA.

Microtubules are intracellular polymers that are required for various essential processes ranging from cell division to maintaining cell structure. Underlying the ability of microtubules to contribute to these diverse functions is the cell's ability to control microtubule organization, nucleation, and dynamics, which in part is achieved by microtubule associating proteins (MAPs). MAPs can affect microtubules in numerous ways including by stabilizing or destabilizing individual polymers or by creating higher order arrays by crosslinking them together. While some MAPs have been characterized, the diversity of MAPs between cell types in *vivo* and how these differences affect microtubule dynamics and organization is

not well understood. We are using *C. elegans* as a model to identify novel MAPs required for essential functions in differentiated cells. Using a published protocol for MAP isolation (Aamodt et al. 1989), we have purified proteins from mixed-stage worm lysates that co-sediment with taxol-stabilized microtubules. Using mass spectrometry, we have identified 1378 potential MAPs, of which 655 have been annotated by other groups' depletion studies as being required for embryogenesis. We are using a bioinformatic approach to further refine this list in order to guide a candidate based RNAi screen for genes that are important for microtubule organization and dynamics. Our biochemical approach revealed that MAPH-1.1, 1.2, and 1.3, the *C. elegans* orthologs of MAP1 (Waaijers et al. 2016) are among the mostly highly enriched MAPs in our dataset. The MAP1 family has been primarily studied in neurons, but little is known about how it interacts with microtubules or its function in other tissues. Unlike other MAP1 family members, C. elegans MAPH-1.1 is known to be expressed in many more tissues including the hypodermis and the muscles (Waaijers et al. 2016). Depletion of MAPH-1 suggest an important role of the MAP1 family in development, but its role in patterning and organizing microtubules is unknown. We show a novel localization of MAPH-1.3 to the microtubules of the mitotic spindle. We also show that MAPH-1.1 directly binds the entire length of the microtubules in vitro and may play a role in promoting growth. Our data suggests that MAPH-1 may play a role in microtubule patterning and may provide insight into the role of MAP1 proteins in non-neuronal tissue.

P1040/B164

Conserved Mechanisms Driving Branched Cytoskeletal Network Growth in the Rhizarian Syncytial Amoebae *Filoreta Ramosa*.

S. L. Guest, S. C. Dawson; UC Davis, Davis, CA.

Multicellularity involving cell organization and differentiation generates emergent morphological complexity through the development of specialized cytoskeletal structures and cell types. Multicellularity has evolved at least five times across the eukaryotic supergroups, including members of the SAR (Stramenopiles/Alveolates/Rhizaria). Our recently isolated Rhizarian amoeba, *Filoreta ramosa*, exhibits "aggregative multicellularity". Individual amoebae fuse and form a complex multinucleate syncytium, organized and structured by the cytoskeletal network of branching and anastomosing pseudopodia. Through branching mechanisms reminiscent of neuronal growth cones and dendritic arborization, the network can grow to span several centimeters. Self-recognition enables the fusion of neighboring syncytial branches, forming a dynamic and self-repairing complex morphology. How and when have the cytoskeletal mechanisms enabling polarized growth cones and branching evolved in Eukarya? We are using our recently completed genome combined with super-resolution imaging and morphometric analyses to quantify cytoskeletal elements of complex network growth and development. We used antibodies raised specifically to *F. ramosa* ɣ-TURC components and EB1 to visualize non-centrosomal MT nucleation and polarity throughout the network. We also compared morphological perturbations in the network following treatment with cytoskeletal drugs affecting actin and MT dynamics. As in neuronal branches, the branched network is organized with longitudinal MT arrays and actin-rich pseudopodial protrusions initiate branch formation. Cytoskeletal drugs alter syncytial network development, underscoring the critical role of MT and actin dynamics and interactions in generating the complex branched morphology in Rhizaria and Metazoa. We predict that the mechanisms governing the intricate cytoskeletal networks in *F. ramosa* are emergent properties of simple branch and anastomosis patterns involving conserved cytoskeletal proteins. Thus, the extensions and branching mechanisms

typified by neuronal growth cones are conserved in Rhizaria and pre-date the divergence of major eukaryotic lineages.

P1041/B165

Direct Observation of Branching MT Nucleation in Living an imal Cells.

V. Verma, T. J. Maresca; University of Massachusetts, Amherst, MA.

Centrosome-mediated microtubule (MT) nucleation has been well-characterized; however, numerous non-centrosomal MT nucleation mechanisms exist. The branching MT nucleation pathway envisages that the γ-tubulin ring complex (γ-TuRC) is recruited to MTs by the augmin complex to initiate nucleation of new MTs. While the pathway is well-conserved at a molecular and functional level, branching MT nucleation by core constituents has never been directly observed in animal cells. Here, multi-color TIRF microscopy was applied to visualize and quantitatively define the entire process of branching MT nucleation in dividing *Drosophila* cells during anaphase. The steps of a stereotypical branching nucleation event entailed augmin binding to a "mother" MT, recruitment of γ-TuRC after 15s, followed by nucleation 16s later of a "daughter" MT at a 36° branch angle. Daughters typically remained attached throughout their ~40s lifetime unless the mother depolymerized past the branch point. Assembly of branched MT arrays, which did not require D-TPX2 (*Drosophila* TPX2), enhanced localized RhoA activation during cytokinesis.

P1042/B166

Pcm Proteins Have Various Requirement during Development, between Cell Division and Ciliogenesis in C. Elegans.

J. Magescas, S. Eskinazi, J. L. Feldman; Stanford University, Stanford, CA.

The centrosome acts as a microtubule organizing center (MTOC) during mitosis, forming radial arrays essential to separate cellular components between daughter cells. Microtubules are organized at the centrosome by pericentriolar material (PCM) complexes. The fate of the centrosome following mitosis varies by cell type and developmental context. In differentiated cells, the centrosome is inactivated as an MTOC, losing its PCM and associated microtubules, and MTOC function is reassigned to other cellular sites. In contrast, in some types of ciliated cells the centrioles at the heart of the centrosome are repurposed as basal bodies to template the assembly of cilia and maintain some microtubule nucleation activity (Kunimoto et al. 2011, Clare et al. 2017, Roque et al. 2018). The exit from the cell cycle is thus not enough to explain the inactivation of the centrosome upon differentiation, and mechanisms controlling centrosomal MTOC function remains largely uncharacterized in differentiated cells. We are using *C. elegans* as a model to characterize MTOC recruitment and regulation at the centrosome in differentiated cells. Surprisingly, we have found that PCM proteins are differentially localized and have differential requirement in MTOC function depending on cell type and location. First, we found that PCM proteins in mitotic cells separate into overlapping spheres surrounding the centrioles with known binding partners such as the two main scaffolding protein SPD-2/CEP192 and SPD-5 separating into an inner and an outer sphere, respectively (Magescas et al 2019). Second, we found that although both SPD-2 and SPD-5 are essential for the first mitotic division in *C. elegans*, using tissue specific degradation we found that SPD-2 is dispensible for later divisions such as of the embryonic intestinal cells. Third, we found that SPD-5 and the microtubule nucleating complex γ-TuRC but not SPD-2 localize to the base of cilia. This result is particularly surprising given that basal bodies in *C. elegans*are degraded upon

ciliogenesis and suggests that these centriole-less remnants of the PCM might be required for ciliogenesis and/or MTOC function. Indeed, SPD-5 depletion in ciliated neurons resulted in aberrant ciliogenesis. Based on our data we propose that the PCM is composed of distinct SPD-5 based subcomplexes that can be differently regulated to impart MTOC function.

Aurora a Site Specific TACC3 Phosphorylation Regulates Astral Microtubule Assembly by Stabilizing γ-Tubulin Ring Complex.

R. RAJEEV[1], P. Singh[2,1], A. Asmita[3,1], U. An and[1], T. K. Manna[1]; [1]Indian Institute of Science Ed/Res (IISER) - IISER TVM, Kerala, Thiruvananthapuram, INDIA, [2]Centre for Cellular and Molecular Biology (CCMB), Hyderabad, INDIA, [3]Stony Brook University, New York, NY.

Astral microtubules emanating from the mitotic centrosomes play pivotal roles in defining cell division axis and tissue morphogenesis. Previous studies have demonstrated that human transforming acidic coiled-coil 3 (TACC3), the most conserved TACC family protein, regulates formation of astral microtubules at centrosomes in vertebrate cells by affecting γ-tubulin ring complex (γ-TuRC) assembly. However, the molecular mechanisms underlying such function were not completely understood. Here, we show that Aurora a site-specific phosphorylation in TACC3 regulates formation of astral microtubules by stabilizing γ-TuRC assembly in human cells. Mutation of the most conserved Aurora a targeting site, Ser 558 to alanine (S558A) in TACC3 results in robust loss of astral microtubules and disrupts localization of the γ-tubulin ring complex (γ-TuRC) proteins at the spindle poles. Under similar condition, phospho-mimicking S558D mutation retains astral microtubules and the γ-TuRC proteins in a manner similar to control cells expressed with wild type TACC3. Time-lapse imaging reveals that S558A mutation leads to defects in positioning of the spindle-poles and thereby causes delay in metaphase to anaphase transition. Biochemical results determine that the Ser 558- phosphorylated TACC3 interacts with the γ-TuRC proteins and further, S558A mutation impairs the interaction. We further reveal that the mutation affects the assembly of γ-TuRC from the small complex components. The results demonstrate that TACC3 phosphorylation stabilizes γ- tubulin ring complex assembly and thereby regulates formation of centrosomal asters. They also implicate a potential role of TACC3 phosphorylation in the functional integrity of centrosomes/spindle poles.

P1044/B168

Theory of Crosslinker-mediated Mitotic Spindle Assembly.

A. R. Lamson[1], C. J. Edelmaier[1,2], M. A. Glaser[1], M. D. Betterton[1]; [1]University of Colorado Boulder, Boulder, CO, [2]University of Colorado an schutz Medical Campus, Aurora, CO.

Cells grow, move, and respond to outside stimuli by large-scale cytoskeletal reorganization. A prototypical example of cytoskeletal remodeling is mitotic spindle assembly, during which microtubules nucleate, undergo dynamic instability, bundle, and organize into a bipolar spindle. Key mechanisms of this process include regulated filament polymerization, crosslinking, and motor-protein activity. Remarkably, using passive crosslinkers, fission yeast can assemble a bipolar spindle in the absence of motor proteins. We develop a torque-balance model that describes this reorganization due to dynamic microtubule bundles, spindle-pole bodies, the nuclear envelope, and passive crosslinkers to predict spindle-assembly dynamics. We compare these results to those obtained with kinetic Monte Carlo-Brownian dynamics simulations, which include crosslinker-binding kinetics and other stochastic effects.

Our results show that rapid crosslinker reorganization to microtubule overlaps facilitates crosslinker-driven spindle assembly, a testable prediction for future experiments. Combining these two modeling techniques, we illustrate a general method for studying cytoskeletal network reorganization.

P1045/B169

Investigation of Nucleation Independent Functions of the γ-TuRC.

A. Berman, M. Wieczorek, T. M. Kapoor; the Rockefeller University, New York, NY.

Microtubules play essential roles in various cellular activities, including intracellular transport, cell motility, and cell division. For microtubules to carry out these functions, their formation and organization must be tightly regulated. This regulation is imparted by the multimolecular γ-tubulin ring complex (γ-TuRC), which according to current models nucleates microtubules and remains bound to microtubule minus ends after polymer formation as a “cap” and anchor point, contributing to the stabilization of functional microtubule arrays. However, it has been difficult to dissect how the γ-TuRC functions in each of these different activities, especially in cell-based contexts. To differentiate between γ-TuRC nucleating and non-nucleating functions, we developed a γ-tubulin knockdown (KD) and a KD/addback human cell line which expresses mutant γ-tubulin that is GTP-binding deficient and has been shown in yeast to be compromised in its nucleation activity. We found that the interphase microtubule array was minimally affected by γ-tubulin KD or mutant expression. In contrast, >75% of mitotic cells in both the KD and KD/mutant-addback conditions formed monopolar spindles, and the mitotic index was increased ~4-fold. Surprisingly, microtubule number did not seem to decrease in these cell lines. Further investigation of these cell lines using advanced microscopy techniques coupled with in vitro systems will allow us to determine a separation of function between γ-TuRC nucleating and nucleation independent activities.

P1046/B170

Testis-specific Gamma-tubulin Complex Protein Paralogs with a Specialized Function in *Drosophila* Spermiogenesis.

E. M. Wight, J. V. Chen, C. Zheng, T. L. Megraw; Florida State University, Tallahassee, FL.

The γ-Tubulin Ring Complex, or γ-TuRC, is a highly conserved microtubule (MT) nucleation complex comprised of γ-tubulin and γ-Tubulin Complex Proteins (GCPs). GCP2-GCP3 heterodimer interactions are facilitated by the grip1 motif and each GCP binds to γ-tubulin through a grip2 motif. This tetrameric γ-tubulin small complex (γ-TuSC) oligomerizes to form the γ-TuRC, consisting of seven γ-TuSC subcomplexes. The γ-TuRC is organized into a lockwasher-shaped ring, such that 13 γ-tubulin molecules are positioned apically to anchor/nucleate microtubule (MT) assembly by binding to the α-tubulin subunit of αβ-tubulin dimers and initiating the assembly of 13 protofilaments into a MT. γ-TuRCs temporally and spatially mediate MT nucleation via interactions with regulators and site-specific anchors. For example, at centrosomes, the major MT organizing centers in animal cells, γ-TuRCs are the chief microtubule nucleators and are required for proper cell division. As a result, GCP2 and GCP3 are essential in *Drosophila melanogaster*. In general, γ-TuRCs are highly conserved throughout eukaryotes and no heterogeneity in the GCP core complex has been described. Here we describe paralogs of GCP2 and GCP3 that appear to be expressed exclusively in the testes of *Drosophila*. We have named these proteins GCP2t and GCP3t (“t” for testis). Our objective is to determine if GCPt paralogs have a diverged function from the canonical γ-TuRC. Our results suggest that GCPt paralogs have a specialized function

that is required for spermiogenesis. The 'conventional' GCP2 and GCP3 proteins are also expressed in testis, and mutations in those genes disrupt cell division. In contrast, mutations in the *GCP2t* and *GCP3t* do not impact cell division, but impair spermiogenesis, resulting in spermatozoa that are immotile and fail to enter the seminal vesicle. Remarkably, GCP2t is absent from centrosomes in spermatocytes where GCP2, GCP3, and γ-tubulin play a key role in meiosis. Moreover, ectopically-expressed GCP2t failed to localize at centrosomes, suggesting that it does not form a complex with conventional GCP3. In addition, GCP2t fails to localize to the mitochondrial MTOC of post-meiotic spermatids, previously described by our lab, that activates γ-TuRC nucleation via the CM1 domain of CnnT, a testis-specific splice variant of centrosomin. Rather, GCP2t co-localizes with γ-tubulin at a unique and poorly understood MTOC called the centriolar adjunct in post-meiotic spermatids. Mutants in *gcp2t* and *gcp3t* block γ-tubulin localization to the centriolar adjunct. From our current data, we hypothesize that these GCP paralogs form a testis-specific γ-TuRC at the centriolar adjunct with a noncanonical function that is essential for sperm maturation.

The Mitotic Motor Kifc1 Is Crucial for the Organization of the Microtubule Cage Around the Nucleus during Neuronal Migration.

H. Muralidharan, **S. Guha**, K. Madugula, X. Sun, K. Toyooka, P. W. Baas; Drexel University, Philadelphia, PA.

During neuronal migration, most but not all microtubules are attached to the centrosome. Dynein-based forces tug on the centrosome-attached microtubules that extend into the leading process to drag the centrosome along with the nucleus as the neuron itself moves. Crucial to this process is the organization of a portion of the microtubules into a cage around the nucleus, which enables the nucleus to rotate as it is dragged along. Here we investigated a potential role in neuronal migration of KIFC1, a molecular motor that we recently showed has important functions in the axon to organize microtubules and thereby regulate axonal growth and retraction. KIFC1 belongs to the kinesin-14 sub-family of kinesins, which are the only kinesins that move toward minus ends of microtubules rather than plus ends. Unlike most miotic kinesins, KIFC1 is strongly expressed throughout the life of the neuron. Here we report studies on cultured rat cerebellar migratory neurons either depleted of KIFC1 with siRNA or treated with AZ82, a drug that inhibits KIFC1. The results indicate that when KIFC1 is depleted or inhibited, the migration of the soma is impaired, with the nucleus failing to rotate and translocate forward as it normally does. Pulldown experiments indicate that KIFC1 interacts with proteins in the nuclear membrane. The behavior of GFP-tagged EB3 (which fluorescently marks the plus ends of microtubules) in the soma indicates that when KIFC1 is inhibited or depleted, microtubules no longer form a proper cage around the nucleus. In *vivo* studies in mice show that KIFC1 depletion by shRNA results in neurons with morphological defects, as well as delayed migration to the cortical plate. We, therefore, propose that KIFC1 is involved in nucleokinesis in migratory neurons by tethering microtubules to the nucleus in a manner crucial for the structure of a microtubule cage that allows for nuclear rotation. Together with our previous observations on KIFC1's role in the axon, we conclude that KIFC1 takes on distinct duties at different stages of the life of the neuron.

P1048/B172

A Role for the Apical PAR Complex in Reorganizing Microtubules in Dividing Intestinal Cells.

M. Sallee, J. Feldman; Stanford University, Stanford, CA.

Dividing and differentiating cells require different arrangements of microtubules to function. Mitotic cells establish centrosomes as microtubule organizing centers (MTOCs), producing radial microtubule arrays that are critical for chromosome segregation. In contrast, polarized epithelial cells form parallel arrays of microtubules emanating from a non-centrosomal MTOC, the apical membrane, that promote cell polarity and intracellular transport. During development and tissue homeostasis, some polarized epithelial cells divide, presenting an important but poorly understood obstacle: microtubules must temporarily cycle between the apical surface and the centrosomes. The developing *C. elegans* intestine provides an excellent in *vivo* epithelial model to study how this microtubule reorganization is achieved. After the 16-cell embryonic intestine polarizes and establishes an apical MTOC, exactly four "E16*" cells divide again. The E16* divisions involve a rapid change in microtubule organization from apical to centrosomal as cells enter mitosis, and back to apical upon mitotic exit. Using fluorescent markers, genetic screens, and tissue-specific protein depletion with live imaging, we are testing the hypothesis that apical polarity proteins control microtubule reorganization during the E16* divisions. During mitosis, we observe that, like microtubules, MTOC-associated proteins also leave the apical membrane as the centrosome becomes the MTOC. However, the apical PAR polarity proteins remain at the apical membrane during the E16* divisions, suggesting that they may act as a memory mark and help direct the return of microtubules and MTOC proteins after division. Consistent with this model, we have found that intestine-specific depletion of the apical polarity proteins PAR-6 and PKC-3 disrupts apical MTOC reformation following the E16* division. A pilot forward genetic suppressor screen has isolated a suppressor of the MTOC defects caused by PAR-6 depletion. These experiments reveal a role for PAR proteins in returning MTOC function to the apical membrane following mitosis, a critical step in epithelial cell divisions across organisms.

Biochemical Reconstitution of Branching Microtubule Nucleation.

R. Alfaro-Aco, A. Thawani, S. Petry; Princeton University, Princeton, NJ.

The microtubule cytoskeleton supports cell function by giving cells their shape, organizing their interior and segregating chromosomes. Microtubules are nucleated from specific locations at precise times in the cell cycle, and several of these microtubule nucleation pathways converge to form a particular architecture in the cell. Although many microtubule nucleation pathways have been identified, it remains poorly understood which factors comprise them and how they shape the microtubule cytoskeleton. Here, using purified proteins we biochemically reconstitute branching microtubule nucleation, a nucleation pathway where microtubules originate from pre-existing microtubules, which is essential for spindle assembly and chromosome segregation in many cell types and species. We found that besides the microtubule nucleator gamma-tubulin ring complex (γ-TuRC), the two branching effectors augmin and TPX2 are required to efficiently nucleate new microtubules from pre-existing ones. TPX2 has a key role in this process, as its binding sites along the microtubule generate regularly-spaced patches that serve as the sites of microtubule nucleation by recruiting augmin and γ-TuRC. We found that the preferred branching angle was less than 90 degrees, and the absence of TPX2 resulted in shallower branch angles. Our results demonstrate how the microtubule nucleator γ-TuRC is brought to

its site of nucleation to cause branching microtubule nucleation, a process critical for spindle assembly and axon architecture. We anticipate our results to help explain how other microtubule nucleation pathways give rise to a cell's microtubule cytoskeleton. Furthermore, our work serves as a stepping stone to reconstitute complete microtubule structures such as the mitotic spindle and to engineer specific microtubule architectures in health and disease.

P1050/B174

***In Vivo* Proximity Labeling of PTRN-1/Patronin with TurboID Reveals Novel Components of Non-centrosomal MTOCs in Epithelial Cells.**

A. D. Sanchez[1], T. Branon[2], A. Y. Ting[1], J. L. Feldman[1]; [1]Stanford University, Stanford, CA, [2]MIT, Cambridge, MA.

Microtubules have dynamically growing plus ends and comparatively stable minus ends that are localized to microtubule organizing centers (MTOCs). The centrosome is the primary MTOC during cell division, but in differentiated cells, MTOC function is often reassigned to non-centrosomal sites (ncMTOCs). Unlike the centrosome, the components that are necessary to grow and localize microtubules at ncMTOCs are poorly understood. To address this gap in knowledge, we are identifying additional ncMTOC components using proximity labeling, a technique that can identify proximal protein networks in *vivo*. In particular, we developed TurboID, a promiscuous BirA mutant enzyme that rapidly catalyzes the covalent attachment of biotin to proximal proteins. Proteins tagged with biotin are then isolated and identified by mass spectrometry. To identify novel ncMTOC components, we fused TurboID to the microtubule minus end protein PTRN-1/Patronin and expressed this transgene in *C. elegans* embryonic intestinal epithelial cells. This strategy resulted in spatially restricted biotinylation at the apically localized ncMTOC and a list of 62 candidate ncMTOC components including the spectraplakin VAB-10B, which we verified as a PTRN-1 physical interactor by immunoprecipitation. Using tissue-specific degradation and mutant analysis of VAB-10B, we found that VAB-10B orchestrates microtubule localization during ncMTOC establishment, which is helping us understand the mechanisms by which microtubules are initially targeted to an ncMTOC in vivo. In addition, we find a role for VAB-10B in targeting PTRN-1 to the ncMTOC and are exploring the role of VAB-10B in targeting other microtubule-associated proteins. As the apical polarity protein PAR-3 is properly localized following VAB-10B depletion, we propose a model where VAB-10B serves as a scaffold to couple microtubule organization to polarity determinants. In addition to VAB-10B, we are currently testing the ncMTOC-related functions of other candidates from our proximity labeling dataset and will present our results.

P1051/B175

Growth Cone-localized Microtubule Organizing Center Determines Microtubule Orientation in Dendrites.

X. Liang, 94305[1], M. Kokes[1], R. Fetter[1], M. A. Pickett[1], M. D. Sallee[1], A. W. Moore[2], J. Feldman[1], K. Shen[1]; [1]Stanford University, PALO ALTO, CA, [2]RIKEN Brain Science Institute, Wako-shi, Saitama, JAPAN.

A polarized arrangement of neuronal microtubule arrays is the foundation of membrane trafficking and subcellular compartmentalization. Axons contain exclusively "plus-end-out" microtubules while dendrites contain a high percentage of "minus-end-out" microtubules. Here we show that the dendritic growth cone contains a non-centrosomal microtubule organizing center (ncMTOC), which generates minus-end-out microtubules along outgrowing dendrites and plus-end-out microtubules in the growth

cone. RAB-11-positive endosomes are responsible for localizing the microtubule nucleation complex γ-TuRC to this ncMTOC. The MTOC tracks the extending growth cone by kinesin-1/UNC-116-mediated endosome movements on distal plus-end-out microtubules and dynein-mediated endosome clustering near MTOC. Critically, perturbation of the function or localization of the MTOC causes reversed microtubule polarity in dendrites. These findings unveil the dendritic MTOC as a critical organelle for establishing axon-dendrite polarity.

P1052/B176

The Role of Microtubule Pushing Forces in Aster Translocation.

T. Sulerud, J. Oakey, J. Gatlin; University of Wyoming, Laramie, WY.

The cytoplasm of a eukaryotic cell is a complex and dynamic microenvironment that requires proper organization to insure cell function and homeostasis. The microtubule (MT) cytoskeleton plays a critical role in establishing this organization. During interphase, MTs serve as both a supportive scaffold for organelles and as an arborized system of tracks for intracellular transport. During mitosis, the position of the interphase MT aster determines the eventual location of the spindle apparatus and ultimately the cytokinetic furrow. Asters reliably move to the center of a cell, even in large blastomeres hundreds of microns in diameter and in unnaturally imposed cell geometries like squares and rectangles. These movements require the generation of positioning forces and in this context there are thought to be three primary forces: (i) MT pushing forces generated by the interaction between growing MT plus ends and the cell cortex, (ii) cortical pulling forces produced by MT dependent motors (dynein) anchored at the cell cortex, and (iii) cytoplasmic pulling forces generated by dynein-mediated transport of vesicular cargo through the viscous cytoplasm. How these different forces are integrated to position asters within cells of varied sizes, geometries, and in different systems remains an open question. To address it, we have developed the use of microfluidic devices and photolabile hydrogels to capture and release artificial microtubule organizing centers (aMTOCs) in geometrically defined hydrogel microenvironments. Combined with cell-free extracts, we use this system to dissect the integrated contributions of these three models for force generation in MT asters. We found that asters are able to find the geometric center of artificial microenvironments with similar kinetics to controls even when dynein motor activity was inhibited. To further test predictions of the different models, hydrogel barriers in the shape of a “V” with different interior angles were generated with aMTOCs positioned at their vertexes prior to MT nucleation. After the onset of MT nucleation, aMTOCs move away from the barriers. The velocity of their translocation was dependent on the “V”, with smaller interior angles producing faster speeds and increased distance away from the vertexes. Suggesting an underlying mechanism that relies more on proximity to a barrier and less on the MT center of mass. In summary, these data suggests that MT pushing forces contribute to aster translocation and positioning in *Xenopus laevis* egg extract and suggest that such forces could work over sufficient length scales to ensure aster positioning in vivo.

P1053/B177

Exploring the Mechanics of Microtubule Aster Positioning Using Photopatterned Hydrogel Enclosures.

A. Sami[1], T. Sulerud[1], M. Tomschik[1], A. Kloxin[2], J. Oakey[1], J. Gatlin[1]; [1]University of Wyoming, Laramie, WY, [2]University of Delaware, Newark, DE.

During interphase of the cell cycle, the microtubule (MT) cytoskeleton forms a radial aster with a center that is typically coincident with that of the cell. This centration insures proper positioning of the nucleus and sets up the antero-retrograde axis required for normal vesicular transport and cell function. Ultimately, it dictates the position of the mitotic spindle and the cytokinetic furrow, thus setting up a symmetric or asymmetric cell cleavage and proper partitioning of cytoplasmic contents between the two daughter cells. Despite intensive study, the molecular mechanisms and biomechanics that underlie aster positioning in different cell geometries and types remain elusive. Several aster centering models have been postulated, one class that relies on pushing forces generated by growing MTs as they impinge against the cell cortex and another that relies on cytoplasmic dynein-dependent pulling against either the cortex or elements in the cytoplasm. Progress in differentiating between these models and determining the exact underlying mechanism has been difficult, in part due to limitations with current experimental approaches. To overcome these limitations, we have developed a novel experimental approach that combines microfluidic-based technologies and photocatalyzable hydrogels to create defined geometries around MT asters in cell-free *Xenopus laevis* egg extract. Using this approach, we found that MT asters indeed center in cylindrical enclosures over a range of diameters and that the asters exhibit a tendency to rotate. Over the range of cylinder diameters tested, MTs exhibited buckling, an observation inconsistent with pulling force models. Interestingly, changing the geometry of the enclosures also had an effect on rotation, with angular velocity being inversely correlated with device diameter (i.e. faster rotation in smaller cylinders). Based on these observations, we believe that forces generated by growing MTs as they push against enclosure walls are responsible for the observed rotation, which implies that pushing forces can be exerted over length scales much larger than expected for unsupported, single MTs. We postulate that the aster MT array might be made more able to bear a compressive load by crosslinking or by motor-dependent packing of vesicular cargoes proximal to their centers.

P1054/B178

Self-organization of Microtubules in Cell-sized Droplets.

B. Cook; Princeton University, Princeton, NJ.

We combine droplet microfluidics and cell-free biological systems to examine the effect of confinement and nucleation on the assembly of microtubule (MT) networks. Central to the spindle assembly is the spatial organization of MTs, a long tubular structure formed through the polymerization of tubulin dimmers. Such organization is regulated by RanGTP, a GTPase associated with chromosomal activities and acting as part of a major nucleation pathway for MTs. RanGTP has been explored using Xenopus egg extracts, a model cell-free system for probing spindle assembly. Most extract-based assays were performed in a test tube where cell-sized confinement was missing. Therefore, we asked whether confinement can affect the MT networks. We used droplet microfluidics for encapsulating extract-based assays by generating monodisperse, extract-in-oil droplets. By varying droplet diameters and encapsulated Ran concentrations, we demonstrate that these two physical factors regulate the assembly of MT networks. Together, the two factors yield MT networks with various steady-state

architectures. Our results highlight the prominent role of MT nucleation in the self-organization of MTs in cell confinement and might have direct implications in nucleation-controlled soft material processing.

Sensory and Signaling Functions of Cilia

Cilia Protein Regulation of Actin Dynamics.

L. Brücker[1], M. Parsons[2], H. May-Simera[1]; [1]Johannes Gutenberg University, Mainz, GERMANY, [2]King's College London, London, UNITED KINGDOM.

Primary cilia are highly conserved multifunctional cell organelles that extend from almost every eukaryotic cell type. These microtubule-based appendages are vital for the development and homeostasis of different organs and tissues and play a role in the transduction of intra- and extracellular cues. Defects in the development of primary cilia can lead to a range of genetic disorders, collectively termed ciliopathies. The archetypical ciliopathy is the Bardet-Biedl syndrome (BBS), patients of which display many different phenotypes such as retinopathy, kidney dysfunction, obesity and polydactyly. Causative for this are mutations in the BBS genes, the proteins of which are predominantly involved in the intraflagellar trafficking inside the cilium. Recent data indicate that many ciliary proteins are also found at non-ciliary locations within the cell, for example at the cell membrane. This association might explain why loss of 'ciliary' function results in cell migration defects, possibly via regulation of the actin or microtubule cytoskeleton. To investigate the alternative functions of classically defined 'cilia' proteins, we performed a large-scale yeast-two-hybrid screen with the BBS proteins. One of the identified interactions was with the actin bundling protein Fascin. Further biochemical analyses validated a direct interaction between Fascin and BBS6 (MKKS). We could also show that this interaction may occur in an actin-dependent manner, since mutations in the actin-binding site of Fascin decreased the interaction. Live imaging of *Bbs* knockout fibroblasts also revealed a potential dysregulation of both Fascin and actin dynamics in the absence of Bbs, which is currently under further investigation. In addition, further analysis has revealed a transient interaction between Fascin and Inversin, a protein known to regulate migration and interact with several BBS proteins, suggesting potential two-way cooperativity between Fascin and cilia proteins. Our findings provide more insight into the molecular mechanisms of ciliary signaling and protein networks in the context of the Bardet-Biedl syndrome, which could further explain how cilia proteins affect cell migration and actin dynamics in a cilia-independent manner.

P1056/B181

Developmental and Odour Induced Localization of Olfactory Receptor Co-receptor Orco into the Olfactory Cilia of *Drosophila Melanogaster*.

P. Dutta, S. C. Jana, A. Jain, R. Patwardhan, M. Girotra, K. Ray; Department of Biological Sciences, Tata Institute of Fundamental Research(TIFR), Mumbai, INDIA.

Organisms have an amazing ability to sense and distinguish between a plethora of odours present in the environment. The ability to do so is encoded in the olfactory sensory neurons (OSNs) in the form of olfactory receptors (ORs). ORs localize in the olfactory cilia, which are microtubule-based bipartite structures extending from the dendrites of the olfactory sensory neurons (OSNs). In *Drosophila melanogaster*, the ORs associate with a co-receptor called Orco, forming a functional ORx/Orco complex

which is essential for the localization of the OR to the distal segment of the olfactory cilia [1]. However, the mechanisms by which the ORx/Orco complex localizes into the olfactory cilia is not well elucidated. To understand the dynamics of ORx/Orco complex localization into the olfactory cilia, we monitored the enrichment of Orco in the olfactory cilia during development. We find that a significant amount of Orco enters the outer segments of olfactory cilia in a biphasic manner just after the emergence of the adult fly from the pupa. Further, to understand the molecular players involved in the process of Orco localization, we looked at the role of Kinesin-2, a motor protein attributed in trafficking of ciliary cargoes [2]. We find that Orco localization is reduced in the olfactory cilia upon OSN specific knock down of Kinesin-2. Suggesting the requirement of Kineisn-2 in Orco transport. On looking at the dynamics of Kinesin-2 during the enrichment of Orco into the olfactory cilia, we find that there is no change in the levels and the rates of Kinesin-2 localization in the ciliary outer segment during this period. We also find that the levels of Orco localization in the ciliary outer segment increase upon odour stimulation. Altogether, our results suggest that developmental cues and odour stimulation regulate the Orco/ORx complex entry into the cilia, and Kinesin-2 motor could play an essential role in this process. **References:** 1. Primary Cilia Sense and Respond to Tubule Flow Changes Following Renal Ischemia-reperfusion Injury.

D. Z. Revell, K. A. Zimmerman, B. K. Yoder; University of Alabama at Birmingham, Birmingham, AL.

Primary cilia are small microtubule based appendages that are present on nearly every mammalian cell type. In the kidney, primary cilia are found extending into the lumen of the tubule off the epithelium where they have classically been thought to function as mechanosensors that detect changes in fluid flow. In response to changes in tubular flow rates, it is proposed that primary cilia regulate signals to the nucleus to alter gene transcription thereby influencing the biology and outcome of that cell. Our preliminary data using live intravital microscopy in mice receiving intravenous injection of a fluorescently tagged dextran indicate that unilateral ischemia-reperfusion (IR) injury to the kidney results in disrupted tubular flow in a majority of tubules. Further, our preliminary data indicate that dextran is taken up by proximal tubule epithelial cells experiencing normal flow and that the number of cells taking up the dextran is reduced following IR injury. The dextran can remain in cells initially experiencing tubular flow for up to two weeks following the initial injection, functioning as a long-term marker of cells that at one period had tubular flow. Our preliminary data using intravital imaging also indicate that some tubules that initially lost flow can regain it at a later time point after IR injury. In the future, we propose to utilize a combination of flow cytometry, single cell RNA sequencing, and longitudinal intravital imaging to determine what effect loss of tubular flow has on epithelial gene expression, primary cilia structure and function, and cell division. We will also determine transcriptional changes that occur in tubules that at one period had flow, lost it following IR injury, and then regained it at later periods. Lastly, we are also performing these studies in murine models in which primary cilia structure or function are disrupted to determine the importance of primary cilia for normal tubular injury and repair processes. This will allow us to elucidate novel pathways involved in the renal injury and repair pathways and their relation to the primary cilium.

Sensory Cilia Are a Sorting Nexus for Extracellular Vesicles.

J. Wang[1], J. Walsh[1], D. Hall[2], M. Barr[1]; [1]RUTGERS University, Piscataway, NJ, [2]Department of Neuroscience, Albert Einstein College of Medicine, Bronx, NY.

Extracellular vesicles (EVs) are emerging as a new dimension in intercellular communication. Compared to conventional intercellular signaling molecules such as hormones or cytokines, EVs allow donor cells to reprogram target cells through exchanging a package of proteins, lipids and genetic material. Understanding the cellular processes of EV biology is essential to shed light on the physiological and pathological functions of these vesicles as well as on therapeutic applications. We developed *C.elegans* as system to study EV functions and biogenesis mechanisms in a living animal (Wang et al 2014; Wang et al 2015). Cilia both shed and absorb EVs. Cilia are microtubule-based projections on the cell surface and serve as ubiquitous sensory organelles. Mutations in genes required for cilia formation or function result in wide spectrum of genetic diseases termed ciliopathies. By studying how cilia make and receive EVs, we aim to uncover fundamental principles of how cells communicate in health and disease. A subset of *C. elegans* sensory cilia make EVs abundantly. The ciliary receptor polycystin-1/LOV-1 and ciliary TRP channel polycystin-2/PKD-2 are evolutionarily conserved EV cargoes in both *C. elegans* and human. Polycystin-containing EVs are released into environment directly and function in animal-to-animal communication. Using fluorescently-tagged EV cargoes such as PKD-2::GFP combined with superresolution Airyscan confocal imaging, we identified two sites of ciliary EV production: at the cilia base and at the cilia tip, and that different mechanisms drive EV base and tip shedding. The biogenesis of the ciliary tip EVs depends on intraflagellar transport. The ciliary tip is a nexus of EV cargo sorting: different types of EV cargoes are sorted to EVs independent of each other. Strikingly, ciliary tip EVs are made in response to sensory activity of the cilia. In contrast, ciliary base EV biogenesis does not depend on ciliary trafficking and activity. Our work reveals how polycystin-containing EVs are made by cilia, adding an important component to understanding the fundamental biology of EVs and their potential relationship to ciliopathies.

P1059/B184

APEX2-proximity Proteomics Reveals That Trypanosome Flagellum Tip Is a Cell Signaling Focus.

D. Velez-Ramirez, M. Shimogawa, E. Nakahara, A. Elliott, K. Hill; UCLA, Los an geles, CA.

Trypanosoma brucei is the protozoan parasite causative of sleeping sickness, a vector borne disease that disrupts the sleep-awake cycle and is fatal if left untreated. The flagellum of *T. brucei* plays critical roles in parasite biology, transmission and pathogenesis. As the flagellum emerges from the cytoplasm, it is surrounded by membrane and is laterally connected to the cell body, forming a flagellum attachment zone (FAZ) along almost its entire length, with a short distal tip that extends beyond the cell body. An emerging concept in flagellum biology is the idea that the organelle is organized into subdomains, each having specialized composition and function. A critical gap in knowledge is the proteome of each flagellum subdomain. We have therefore used APEX2-proximity proteomics to examine protein composition from flagellum subdomains in *T. brucei*. Four different flagellar proteins were APEX2-tagged: one from the axoneme, two from the flagellar membrane at the tip, and one from the flagellar membrane along the FAZ. As expected, the axoneme proximity proteome gives good overlap with known proteomes from purified axonemes, validating the APEX2 system in trypanosomes. The tip proteome is distinct from the axoneme proteome and comparing the relative abundance of proteins in

the tip and FAZ proteomes allowed us to identify proteins concentrated in the flagellum tip. Interestingly, the flagellum tip is enriched with signaling proteins, including several proteins involved in cAMP and Ca++ signal transduction. We have independently assessed the localization of several proteins to the flagellum tip, validating our tip proteome. We have also tested roles in cell viability and are currently testing roles in social motility, a behavior known to depend on cAMP signaling at the flagellum tip. Finally, we have been able to combine APEX2-proximity labeling with TiO_2-dependent phosphopeptide enrichment. We have preliminary data showing that some of the proteins identified in the tip are indeed phosphorylated. Considering that phosphorylation is a hallmark of cell signaling, we are interested in studying the cAMP-dependent phosphorylation at the flagellum tip, and its role in social motility. In summary, we have demonstrated APEX2-proximity proteomics is effective in trypanosomes and can be used to resolve proteome composition of flagellum subdomains.

P1060/B185

Intraflagellar Transport Is Deeply Integrated in Hedgehog Signaling.

G. J. Pazour, P. B. Desai, B. Lv, M. W. Stuck; University of Massachusetts Medical School, Worcester, MA.

Cilia monitor the extracellular environment through ciliary-localized receptors allowing the cell to coordinate its physiology with surrounding cells. Hedgehog signaling, the best studied ciliary pathway, plays fundamental roles during development and many of the developmental defects due to ciliary dysfunction are caused by abnormal hedgehog signaling. Key components of the pathway are enriched in the cilium and their localization changes in response to pathway activation. In the off-state, patched-1 (Ptch1) accumulates in cilia and prevents smoothened (Smo) ciliary accumulation and activation. Upon binding of ligand, Ptch1 exits the cilium, Smo is derepressed and accumulates in the cilium. This subsequently activates downstream signaling, leading to Gli transcription factors accumulation at the ciliary tip before their modification and translocation to the nucleus where they modulate expression of target genes. Ciliary trafficking of hedgehog components is poorly understood. Their movement is partly facilitated by intraflagellar transport (IFT) and perturbing IFT disrupts hedgehog signaling. IFT, which is critical for ciliary assembly and maintenance, involves motor driven transport of IFT particles consisting of ~30 proteins organized from IFT-A, IFT-B and BBSome subcomplexes. The IFT particle provides binding sites for diverse ciliary cargoes. We previously showed that Ift25 and Ift27, subunits of IFT-B, are not required for ciliary assembly. Instead, they work with Lztfl1 and the BBSome to regulate hedgehog signaling and maintain proper levels of Smo and Ptch1 in cilia during signaling. In this work, we explore how hedgehog controls the dynamics of Smo's ciliary localization by controlling Smo's interaction with the IFT machinery.

P1061/B186

***Ex Vivo* Live-cell Imaging of Outer Segment Traffic in Mouse Photoreceptors.**

J. Martínez-Márquez, **J. Pearring**; University of Michigan, an n Arbor, MI.

Photoreceptor cells are polarized cells that traffic a large volume of protein to their modified primary cilia, the outer segment. While the ciliary outer segment membrane is contiguous with the plasma membrane surrounding the cell body there is a diffusional barrier between the two compartments that allows for proteins to be specifically retained in or excluded from the outer segment. Previous work has shown that many outer segment-resident proteins (e.g. rhodopsin, peripherin, R9AP) contain a protein motif that targets them specifically to the outer segment. Interestingly, when these targeting motifs are

mutated the protein still reaches the outer segment but also non-specifically "spills" into the membrane surrounding the rest of the cell. The subtle differences in the kinetics, trafficking routes and delivery of outer segment-targeted and non-targeted membrane proteins remains unknown. To examine this, we generated a protein reporter to monitor the live dynamics of intracellular trafficking in *ex vivo* mouse retinas. A luminal, pH-sensitive fluorescent probe (superecliptic pHluorin, SEP) was fused to a single-pass transmembrane domain followed by cytosolic mCherry and rhodopsin's C-terminus with or without its targeting signal. Both constructs were then in *vivo* electroporated into wild-type mouse rods to confirm their expression and localization patterns. We then performed live time-lapse imaging from fresh, *ex vivo* sections of electroporated mouse retinas to compare the dynamics, kinetics and trafficking route of outer segment-targeted vs non-targeted membrane proteins. In the future, we will expand this system to other targeting signals used to reach the outer segment as well as explore how retinal degeneration impacts outer segment trafficking overall.

P1062/B187

The Role of Matrix Stiffness on Ciliogenesis.

S. Leung[1], I. Williantarra[1], Y. S. Choi[2], S. R. McGlashan[1]; [1]University of Auckland, Auckland, NEW ZEALAND, [2]University of Western Australia, Perth, AUSTRALIA.

Primary cilia are small immotile microtubule based appendages that are present on most cell types. They act as cellular sensors that receive diverse signals from the extracellular environment. Upon ciliogenesis, the cilium can adjust its length in response to chemical and/or mechanical stimuli, and in turn, can enhance signal detection. Conversely, cilia shortening or resorption decreases responsiveness to signals, providing a mechanism of sensory signal adaptation. The modulus of elasticity, or stiffness, of the extracellular matrix (ECM) has been demonstrated to be a major determinant of ciliogenic activity. In addition to ECM stiffness, the actin cytoskeleton is also a dominant inducer of ciliogenesis. Recent studies revealed that actin destabilisation increases ciliogenesis and cilia length. The yes-associated protein (YAP), and transcriptional co-activator of the PDX-motif (TAZ) proteins are intracellular mediators of mechanical cues and ECM rigidity. Increased intracellular stresses caused by culture on stiff substrates leads to nuclear accumulation of YAP/TAZ, whereas spatial confinement or a soft substrate promotes YAP/TAZ cytoplasmic retention. More recently, cytoplasmic retention of YAP/TAZ was shown to correlate with ciliogenesis in cells treated with actin destabilisers, supporting a direct connection between the actin network, ciliogenesis and mechanosensing. However, the relationship between tissue mechanics, actin network and primary cilia are still not well understood. Therefore, we examined the effect of matrix stiffness on the primary cilia structure and function and its role in mechanosignalling. The role of the ECM in cellular mechanosensing is commonly studied in *vitro* using engineered hydrogels of tunable stiffness. Here, we used gelatin methacrylol with a stiffness gradient from 5 to 45 kPa. Murine articular chondrocytes were seeded on hydrogels for 24 hours, followed by low serum media for 48 hours, and fixed in 4% paraformaldehyde. Cells were then immunofluorescently labelled with ARL13B (ciliary protein), YAP (mechanosensitive protein) and phalloidin (F-actin). Our results showed an increased number of actin stress fibres with an increased substrate stiffness. There was also a positive relationship between increased YAP nuclear retention in the cells with increased substrate stiffness. However, our results showed that cilia length and frequency had an inverse linear relationship with an increased substrate stiffness. The length shortened from 3 µm to 1.7 µm and the percentage of ciliation decreased from 35% to 25% across the stiffness gradient hydrogel. We show that substrate stiffness

alone can fine tune cilia length, and therefore, lead to increased sensitivity in mechanosensing in the cells.

A Cytoplasmic Protein Kinase in *Chlamydomonas* Links an Adhesion Receptor-activated Ciliary Signal to Cyclic AMP-mediated Cellular Responses, Including Mobilization of More Adhesion Receptors to the Cilia.

M. Awasthi, P. Ranjan, W. J. Snell; Department of Cell Biology and Molecular Genetics, University of Maryland, College Park, MD, USA., College Park, MD.

Use of cilia to respond to environmental cues arose early in evolution. cAMP-mediated ciliary signaling in vertebrates is crucial for development and homeostasis, and disruption of cilia is associated with multiple human disorders. Many cilium-based signalling pathways rely on regulated redistribution of membrane signaling proteins between the organelles and the rest of the cell, yet we know little about the mechanisms that couple ligand binding on the cilium to a cellular responses. During sexual reproduction in the bi-ciliated green alga*, Chlamydomonas*, interactions between adhesion receptors on the cilia of gametes of opposite mating type (SAG1 on mating type *plus and* SAD1 on *minus*) trigger the sexually quiescent cells to become activated for fusion. cAMP produced by a ciliary adenylyl cyclase activated by SAD1-SAG1 interactions triggers cells to release their extracellular matrix, erect fusogenic membrane protuberances between the cilia; and, in a positive feedback loop, rapidly (< 5 min) mobilize a pool of SAG1 from the plasma membrane to the ciliary membrane to maintain and enhance adhesion. Here, we report identification of a gamete-specific protein kinase (GSPK), present primarily in the cytoplasm, that couples SAG1-based ciliary adhesion to responses in the cell body. Gametes bearing a mutant allele of *GSPK* retain ciliary adhesiveness, but are incapable of gamete fusion. Immunoblotting studies with cells expressing HA-tagged GSPK show that the protein is gamete-specific and present primarily in the cell body. *gspk* mutant gametes are capable of initial SAG1-dependent ciliary adhesion, but fail to mobilize SAG1 from the plasma membrane and thus fail to maintain ciliary adhesiveness. Failure to recruit SAG1 is a reflection of the overall inability of the mutant gametes to become activated by adhesion: fusion organelles fail to form and the extracellular matrix remains intact. On the other hand, *gspk* mutant gametes are fully capable of being activated by a cell-permeable form of cAMP. Moreover, cAMP assays show that ciliary adhesion in the mutant gametes fails to trigger the large, sustained increases in cAMP characteristic of adhering wild type gametes. Our results support the model that GSPK is essential for coupling the adhesion-induced increase in ciliary cAMP to the increase in cAMP in the cytoplasm required for gamete activation, and raise the possibility that cAMP-mediated responses to ciliary signalling in multicellular organisms might also depend on cytoplasmic production of cAMP.

A Centriole-less Pericentriolar Material Serves as the Base of *C.elegans* Sensory Cilia.

S. Eskinazi, J. Magescas, J. L. Feldman; Stanford University, Stanford, CA.

Cilia are microtubule-based cellular appendages that assemble on basal bodies, which in some cell types are derived from centrioles. Perturbation of cilia related genes leads to a large scope of diseases, ciliopathies, such as retinal degeneration and polycystic kidney disease. While the assembly of cilia by basal bodies is shared among unicellular organisms and animal cells, in the nematode *Caenorhabditis*

elegans basal bodies are necessary for ciliogenesis, but are degraded upon cilia maturation. This raises the question of how ciliary microtubules are maintained in the absence of the basal bodies from which they are templated. We used CRISPR-generated endogenously tagged alleles to assess the localization of centrosomal proteins. Surprisingly, although the base of cilia lacks an association with centriole proteins or the PCM protein SPD-2/CEP192, SPD-5, ZYG-9/XMAP-215, TAC-1/TACC3 and the conserved microtubule nucleating γ-tubulin ring complex (γ-TuRC) localize to this region. Superresolution microscopy revealed distinct subdomains of these proteins, with a subset localizing more proximal to the ciliary axoneme and others localizing more distally to a region nucleating the assembly of dynamic microtubules into the cell body, confirming that the base of cilia is a microtubule organizing center (MTOC). Using tissue-specific degradation, we tested the role of γ-TuRC and SPD-5 at the base of cilia at different time points in development. Degradation of SPD-5 and the γ-TuRC component GIP-1/GCP3 after cilia maturation did not grossly impact cilia structure or function and γ-TuRC was not required for SPD-5 localization to the base of cilia. However, degradation of SPD-5 during ciliogenesis perturbed cilia structure, suggesting that SPD-5 is required to maintain the axoneme in the absence of a canonical basal body. Unlike at the centrosome, the localization and regulation of SPD-5 appears to be independent of mitotic kinases, as CDK-1/CDK1 and PLK-1/PLK1 do not localize to the base of cilia. Further degradation and imaging studies will reveal a more complete map of the base of cilia and explain the molecular control of both ciliogenesis and MTOC function. Additionally, we hypothesize that the base of cilia represents a pure MTOC structure stripped from the centrosome and so these studies are likely to reveal novel regulation of MTOC function at the centrosome.

Location-dependent Noncanonical Elemental Composition and Cellular Architecture of the Statolith and Underlying Cells in the Early-diverging Metazoans, *Beroe Ovata* and *Mnemiopsis Leidyi*.

A. G. Moss, W. Hames; Auburn University, Auburn, AL.

Ctenophores, the largest animals that move primarily by means of beating cilia (the comb plates), are thought to have diverged from all other multicellular animals at least 350 mya, and the ultimate origin of the entire group is probably set much deeper in time. In this context, the remarkable observation by Tamm's group recently of the unusual organization, mechanisms of construction and cellular origin of the statolith has considerable import, because it describes for the first time an alternative, extremely ancient solution to a common problem: the organization and structure of a gravity-sensing organ. Here, we explore further the exceptional characteristics of these cells. A common characteristic of bio-deposited gravity sensing structures across animals is that they are calcareous: containing calcium. We sought to determine the composition and organization of the lithocyte concretions in order to better appreciate how this ancient group would respond to changing pH in the world's oceans. We confirmed, using DNA staining (Hoechst 33342, 1 µg/mL), that the lithocytes are MOSTLY nucleated; not all labeled with the stain. Newly forming lithocytes were not associated with Hoechst-positive staining. We used energy dispersive spectroscopy (EDS) and electron microprobe analysis (EMPA) to compare and contrast the composition of ctenophore lithocytes from the Woods Hole (WH) region and the northern Gulf of Mexico (nGOM). We found several distinct features common to all of the ctenophores, with distinct differences by location. 1) lithocytes from both species, whether examined by EDS or EMPA, lacked Ca or Mg and did not display any divalent cations. 2) the primary composition of the positive ion was that of Na, and in some cases, potassium, although sodium was the most common positive univalent ion present. 3) Oxygen, which was detectable by EDS but no by our EMPA system, was always present. 4)

Sulfur was always present. 5) Cl was much more evident in the nGOM samples. 6) Crystal structure was very uniform in the WH samples. There was variable structure in the nGOM crystal arrays in dried down samples, but 7) intact lithocytes, while very refractile, were distinctly non-birefringent. The relative contribution of the different elements varied somewhat by location, probably indicative of the local nutrient available to the animals, which could reflect a very adaptive and opportunistic metabolism. We interpret these unexpected results to be indicative of an ancient metabolism carried down to the present day. We acknowledge the generous help of Dr. Oldenbourg, and Mr. L. Kerr, Marine Biological Laboratory. Supported by Auburn University, Office of the Vice President for Research.

Probing Photoreceptor Outer Segment Status Using Genetically-encoded Secreted an nexin V.

A. Jensen, J. Willoughby; University of Massachusetts, Amherst, MA.

The Jensen laboratory is interested in how photoreceptor outer segments develop and are maintained. Vertebrate photoreceptors are specialized light sensing neurons that have unique cellular morphology and die in retinal degeneration diseases, including macular degeneration, retinitis pigmentosa and many other inherited retinal degenerations. The photoreceptor outer segment is a highly modified primary cilium where photons of light are captured and translated into changes in membrane potential that alter synaptic neurotransmitter release. The rod outer segment (ROS) has the typical ciliary axoneme but, in addition, alongside the axoneme, are hundreds of densely packed, stacked, descrete intramembranous discs that concentrate membrane-associated phototransduction proteins. Outer segments are continuously regenerated or renewed throughout the life of the animal through the combined processes of proximal outer segment growth and distal outer segment shedding. The shed outer segment material is ingested and digested by the neighboring retinal pigmented epithelium (RPE). We seek to define the principles and molecular mechanisms that control proximal growth, distal shedding and total length of outer segments during development (net outer segment elongation) and during homeostasis in the adult. It was reported that ROS tips are labeled with an nexin V (A5) in isolated live mouse retina preps in which the RPE was peeled away from the outer segment tips (Ruggiero et al., *PNAS* 109:8145-8148, 2012). A5 is used to probe live cells for surface binding to phosphatidylserine, which has been flipped from the inner leaflet to the outer leaflet, that serves as an 'eat-me' signal to phagocytic cells. To help reveal molecular mechanisms and the dynamic process of ROS shedding, we sought to develop a method to conditionally and temporally express a V5-epitope tagged secreted A5 (secA5 ^{V5}) in live zebrafish retina. We generated a transgene construct in which a tetracycline response element (TRE) controls secA5^{V5} expression. To observe mosaic gene expression and to produce sources of secA5^{V5}, we injected this construct into three different transgenic lines we made that express a tetracycline-controlled transactivator (tTA) under cell specific promoters: RPE specific expression (*rpe65a* promoter), cone specific expression (*UV opsin* promoter), rod specific expression (*rhodopsin* promoter). Using anti-V5 antibodies and confocal microscopy we examined outer segments and found no elevated V5 labeling at outer segment tips, although cone outer segments were weakly labeled along their entire length. We propose that either V5-binding is poor in intact live retinas in our experiments or that the V5 binding previously reported is a product of mechanical force following removal of the RPE.

P1067/B192

TTBK2 and Primary Cilia Are Essential for the Connectivity and Survival of Cerebellar Purkinje Neurons.

E. Bowie, S. Goetz; Duke University, Durham, NC.

Primary cilia are essential microtubule-based signaling organelles found on nearly all mammalian cells, including glia and neurons. While cilia play a well-known role in neural development, their function within the adult nervous system remains largely unknown. Tau Tubulin Kinase 2 (TTBK2) is a critical regulator of ciliogenesis. Additionally, mutations in *Ttbk2* are linked to a dominantly inherited neurodegenerative disease, spinocerebellar ataxia type 11 (SCA11). Recent work from our lab found that SCA11-associated alleles of *Ttbk2* dominantly interfere with cilia formation and function, highlighting a new role for this protein in cilium stability. Using mouse models, we aim to further define the requirements for TTBK2 and cilia in adult neural function, and to examine the links between ciliary dysfunction and neurodegenerative diseases like SCA11. To address this goal, we used conditional alleles of *Ttbk2* and *Ift88* crossed to an inducible, ubiquitously expressed Cre (*UBC-CreER*) to genetically remove cilia throughout the brain under temporal control. *Ttbk2*$^{f/f}$*;UBC-CreER* (*Ttbk2*$^{c.mut}$) animals exhibit rapid loss of cilia throughout the cerebellum upon Cre induction following completion of cerebellar development (P21). These animals develop motor coordination deficits as well as loss of synapses on Purkinje cell (PC) dendrites by four months of age. Similarly, *Ift88*$^{c.mut}$ have cilia defects throughout the cerebellum, and show the same loss of PC synaptic connections. By six months of age we observe a loss of PCs in both *Ttbk2*$^{c.mut}$ and *Ift88*$^{c.mut}$ animals, reminiscent of models of SCA subtypes. Additionally, we have found that these changes result predominantly from cell-autonomous defects to the PCs: We have found that *Ttbk2*^{PCP2} animals, in which recombination occurs specifically in PCs, exhibit nearly identical phenotypes to those of *Ttbk2*$^{c.mut}$ animals. Taken together, our data demonstrate that primary cilia in the adult brain are essential to maintain the connectivity and viability of a key population of neurons. Our findings also point to ciliary dysfunction as a potential cellular mechanism underlying some types of neurodegeneration.

P1068/B193

RAB-28 Regulates Ciliary Extracellular Vesicle Formation.

J. Akella[1], S. P. Carter[2], K. C. Nguyen[3], S. Tsiropoulou[2], A. L. Moran[2], M. Silva[4], F. Rizvi[1], B. N. Kennedy[2], D. H. Hall[3], M. M. Barr[1], O. E. Blacque[2]; [1]Rutgers University, Piscataway, NJ, [2]University College Dublin, Dublin, IRELAND, [3]Albert Einstein College of Medicine, Bronx, NY, [4]University of Utah, Salt Lake City, UT.

Extracellular vesicles (EVs) are tiny communication devices that cells release to influence cell, tissue, and organism behavior. One locale that cells release EVs from is the cilium- adding signal releaser to the previously ascribed role as a signal receiver. Given the cilium's profound importance as a signaling organelle, two questions that need to be studied are- 1. How do cilia make and release EVs? 2. What is the function of ciliary EVs? the EV releasing neurons (EVNs) of *C. elegans* provide an excellent in *vivo* system to study ciliary EVs. *C. elegans* release evolutionarily conserved EV cargoes such as the polycystin PKD-2 into the environment. Environmentally released EVs are bioactive and regulate animal-to-animal communication. Transcriptional profiling of the EVNs provided a list of candidates for a role in EV biology including *rab-28* - a ciliary GTPase associated with autosomal cone-rod dystrophy in humans. Previous studies showed that *C.elegans rab-28* acted in neuronal cilia to regulate sensory pore size possibly via neuron signaling to glia. The unidentified nature of the neuronal signal to glia, and EVN enrichment of *rab-28* prompted us to examine whether RAB-28 functions in ciliated cells via regulating

EVs. We find that *C. elegans* RAB-28 is a negative regulator of EV shedding using a combination of genetics, live imaging, and transmission electron microscopy. In wild type animals, EVs are predominantly observed within sensory organs in a lumenal space surrounding the base of the cilium with fewer EVs observed in the part of the lumen that surrounds the distal regions of cilia. *rab-28* mutants however, accumulate an excessive amount of EVs in the lumenal space surrounding distal regions of cilia. Interestingly, *bbs-8* mutants phenocopy *rab-28* EV and sensory pore expansion phenotypes revealing a functional relationship between the two. We also identify that lipidated RAB-28GTP is first trafficked to the periciliary membrane, and then to the ciliary membrane. This sequential trafficking of RAB-28 depends on the BBSome and PDE6D respectively. Thus, our studies also indicate a transport relationship between BBS-8 and RAB-28. We conclude that RAB-28 and BBS-8 are in *vivo* negative regulators of ciliary EV shedding within sensory organs and that one function of ciliary EVs may be to mediate neuron to glia communication within a sensory organ.

Septin-mediated Rhoa Activation Regulates Ciliary Assembly and Trafficking.

D. Safavian, M. Kim, W. Trimble; Hospital for Sick Children, Toronto, ON, CANADA.

Primary cilia are non-motile protrusion of the plasma membrane found on nearly every vertebrate cell. The organelle senses and transduces diverse signals to regulate cell physiology, development and organ homeostasis. Mutations disrupting ciliary structure and function cause a wide range of human disorders collectively known as ciliopathies that affect nearly all organs. In order to perform the critical functions, both the lipid and protein compositions of ciliary membranes are distinct from those of the contiguous cytosol and plasma membrane. This specialized composition of the cilium is mediated by the transition zone at the junction between the basal body and the axoneme. The transition zone functions as a ciliary gate to control the protein entry and exit from the cilium and the possible trafficking of essential ciliary components. One of the septin family genes, SEPTIN2 was previously identified to be crucial for ciliogenesis where it mediates the localization of transition zone components to the ciliary base. Septins are filamentous GTPases that act as macromolecular scaffolds and as regulators of membrane protein diffusion that have been implicated in diverse biological processes including cytokinesis, cell morphogenesis and motility, and ciliogenesis. The goal of this study was to further examine the requirement of septins and its molecular mechanism in the context of ciliogenesis. Research in our lab has shown that SEPTIN9 is essential for the proper formation of primary cilia in RPE cells and regulates RhoA signalling at the base of cilia by binding and activating a specific guanine nucleotide exchange factor for Rho, the septin-associated Rho-GEF. Given that the exocyst complex, which functions in docking secretory vesicles to sites of polarized secretion, is a downstream effector of RhoGTPases, we have shown that potential ciliary proteins are trafficked to the base of cilia by the exocyst complex to maintain the ciliary composition. Thus, our work has provided a mechanistic explanation of how SEPTIN9, through activating RhoGTPase and its downstream effector exocyst, mediate ciliary assembly and trafficking.

Volumetric Electron Microscopy Reveals New Details of Primary Cilia Organization and Potential Function in the Brain.

C. Ott[1], R. Torres[2], A. Weigel[1], N. da Costa[2], J. Lippincott-Schwartz[1]; [1]HHMI Janelia Research Campus, Ashburn, VA, [2]Allen Institute, Seattle, WA.

Signaling through primary cilia contributes to both development and function of the brain, but we currently have few insights into the roles and spatial organization of cilia on different cell types. Neuropeptides and neurotransmitters emerge from, and pass through, the dense network of axons, dendrites and glial processes known as the neuropil to activate cilia-mediated signaling pathways. For practical reasons, most strategies implemented to study primary cilia visually isolate cilia from this complex network. To elucidate the context in which primary cilia reside in brain tissue, we analyzed cilia on more than 200 mouse visual cortex cells in volumetric transmitted electron microscopy (TEM) data. In addition, we characterized a cilium from the nucleus accumbens in an isotopic focused ion beam-scanning electron microscopy (FIB-SEM) volume. We investigated both the structural features of neuronal and astrocytic cilia and the cellular and extracellular environment surrounding them. In the neuropil, cilia were proximal to glial processes, axons and dendrites. In addition, many neuronal and astrocytic cilia were adjacent to at least one synapse - close enough to theoretically detect spillover signals if they contain relevant receptors. On pyramidal neurons, cilia emerged at a distance from the axon initial segment and either traveled along the edge of the soma for part of their length, or projected directly into the neuropil. In contrast, most astrocyte cilia in the visual cortex were recessed in a deep ciliary pocket. We observed endo/exo-cytic events on the plasma membrane adjacent to the cilium, as expected. However, we also found areas where the plasma membrane hosted extensive endoplasmic reticulum-plasma membrane contact sites adjacent to where the cilium abutted the plasma membrane. Tracking cilia into the neuropil using volumetric TEM also revealed structural differences between neuronal and astrocytic cilia. Together, FIB-SEM and volumetric TEM of primary cilia are providing a new nanoscale understanding of cilia structure and cellular organization. The resolution and large volume of these data allow us, for the first time, to quantify differences between cilia of different cell types, measure changes along the lengths of cilia, and generate hypotheses about the origin of ciliary signals in the brain.

P1071/B196

For the LOV of CRISPR: Generating Endogenous L*OV-1* Alleles to Study Polycystin Mediating Signaling in Cilia and EVs in *C. Elegans*.

J. Walsh, M. Barr; Rutgers University, Piscataway, NJ.

Human autosomal dominant polycystic kidney disease (ADPKD) is one of the most common inherited ciliopathies and common cause of end-stage renal failure. The polycystins PKD1 and PKD2 are mutated in ~95% of ADPKD cases with PKD1 mutations occurring most often at around 85% of cases. C. elegans provided one of the first links between cilia and human disease. The C. elegans polycystins LOV-1 and PKD-2 localize to cilia and function in a sensory capacity to regulate male mating behaviors. Remarkably, polycystin localization to cilia and extracellular vesicles (EVs) is conserved, suggesting an ancient function in these signaling organelles. EVs are tiny (100-200 nm) membrane-bound vesicles that deliver lipids, nucleic acids, and proteins to neighboring cells. Cilia are important sites for EV release and interaction. In humans, evidence suggests that polycystin-1 and polycystin-2 form a complex as a 1:3

heterotetramer whose function remains an enigma 25 years after their identification. The worm is a powerful model for understanding the fundamental biology of the polycystins, cilia, and ciliary EVs. Moreover, PKD-2 location on ciliary EVs is essential for EV bioactivity. To determine the function of the polycystins in cilia and ciliary EVs, we use CRISPR/cas9 genome editing and fluorescent microscopic techniques to engineer tagged-versions and disease causing mutations. LOV-1 molecular functions have not been well studied because of its size (355 kDa). To tackle this problem, we tagged endogenous LOV-1 with an N-terminal scarlet tag and C-terminal NeonGreen tag. Our data show that LOV-1 highly expressed in male-specific EV-releasing neurons and localizes to cilia and ciliary EVs. LOV-1 and PKD-2 overlap in localization, consistent with co-trafficking and function as a complex. Preliminary data suggests that LOV-1 is cleaved, presumably at the conserved GPS proteolytic site, and the N-terminal and C-terminal cleavage products may traffic together or independent of each other. To understand the function of this evolutionary conserved cleavage site we are now generating mutants to see how removal of this site affect LOV-1 trafficking, localization to cilia/ciliary EVs, and function in male behaviors and ciliary EV signaling. Our findings will reveal in vivo functions of the polycystins in cilia and ciliary EVs, which may inform understanding of the human polycystins in normal and ADPKD states.

P1072/B197

Unraveling the Role of the Jade Protein Family in Cilia Biology, Cell Cycle Regulation, and Renal Cell Carcinoma.

L. K. Ebert[1,2], T. Benzing[1,2], B. Schermer[1,2]; [1]Department II of Internal Medicine and Center for Molecular Medicine Cologne, University of Cologne, Cologne, GERMANY, [2]Cologne Excellence Cluster on Cellular Stress Responses in Aging-Associated Diseases (CECAD), University of Cologne, Cologne, GERMANY.

ecent groundbreaking studies could demonstrate that primary cilia play a pivotal role in the pathogenesis of cystic kidney diseases and cancer biology. As sensory organelles cilia transmit signals from the environment into the cell and modulate multiple signaling pathways. Over the last decades genetic studies have identified numerous disease-causing mutations in a multitude of genes that can cause cystic kidney disease and related ciliopathies. Here, we focus on the cilia associated E3 ubiquitin ligase JADE1 and its family members JADE2 and JADE3. JADE1 targets the Wnt downstream effector ß-catenin for proteasomal degradation and has been found to interact with various ciliopathy-associated proteins including pVHL, NPH proteins and polycystin-1. pVHL is the major tumor suppressor in the kidney, while mutations affecting NPH proteins or polycystin-1 can cause different types of (poly)cystic kidney diseases. Thus, JADE1 might modulate the pathogenesis of both, renal cell carcinoma and cystic kidney disease. To understand the in *vivo* function of Jade1 we generated a whole body knockout mouse model. These mice do not show any obvious phenotype. This is in accordance with our hypothesis that due to the high similarity of the Jade protein family members and their expression in the kidney, there could be compensatory mechanisms in place. Further experimental evidence reveals shared functions of Jade proteins and supports this notion: Co-immunoprecipitation experiments demonstrate that JADE2 and JADE3 interact with previously described interactors of JADE1, including NPHP1, NPHP4, and pVHL. Moreover, we could show that JADE1/2/3 are co-precipitating with each other respectively. To further elucidate the function of Jade2 and Jade3 and their potential to compensate for Jade1 in *vivo* we also successfully generated whole body knockout mouse models for Jade2 and Jade3. Furthermore, we generated and validated Jade1/2/3 deficient murine inner medulla collecting duct cell lines. These cell lines show alterations in the proliferation rate while the knockout of one individual Jade family member affected expression levels of the remaining Jade proteins. First unbiased MS/MS analyses revealed only

subtle changes in protein expression. We will now use these cell lines, together with cell lines expressing endogenously GFP-tagged Jade proteins, to analyze the function of Jade proteins as transcription factors using RNA-Seq and ChIP-Seq studies combined with proteomic profiling. In summary, our data suggest that the high structural similarity of the Jade protein family members is recapitulated in their ability to perform overlapping functions. Moreover, we demonstrate novel functions of Jade proteins which points out a fundamental role of Jade proteins in kidney epithelial cells.

Spindle Assembly 1

P1073/B199

Opposing Active Forces Provide Mechanical and Functional Robustness in the Mammalian Spindle.

L. Neahring, S. Dumont; UCSF, San Francisco, CA.

During cell division, microtubules and motors generate force to build the spindle. At metaphase, the spindle reaches an active, energy-consuming steady state in which dynein provides contractile force via microtubule minus-end clustering, and the kinesin Eg5 drives extensile microtubule sliding. These motors antagonize each other: dynein depletion leads to unfocused and turbulent spindles, while Eg5 depletion causes spindles to contract into monopoles. When both are absent, however, the spindle can establish its normal bipolar architecture. Here we ask what role these opposing forces play, and whether their functional advantages outweigh their energetic cost. We generate doubly-inhibited spindles by knocking out NuMA, thereby preventing dynein-based end-clustering, and inhibiting Eg5 with STLC. We find that these spindles attain a typical bipolar shape, fully align their chromosomes, and proceed through anaphase. However, despite their shape and mitotic progression, doubly inhibited spindles are less mechanically robust: under external force, they exhibit dramatic shape instabilities. Further, they give rise to more lagging chromosomes, suggesting that their altered mechanics compromise their function. Thus, opposing contractile and extensile forces in the spindle are critical to ensure that chromosome segregation occurs accurately despite internal and external stresses. Our findings provide insight into energy consumption as a strategy to promote robustness, an engineering design principle found in diverse biological contexts such as metabolism, phosphoregulation, and membrane fission and fusion.

***In Vitro* Sliding of Microtubules by XCTK2 Molecular Motors: Towards an Understanding of Microtubule Flux in the Spindle.**

S. Fürthauer[1], B. Lemma[2], P. J. Foster[3], S. C. Ems-McClung[4], C. Yu[2], C. E. Walczak[4], Z. Dogic[2], D. J. Needleman[5], M. J. Shelley[1]; [1]CCB, Flatiron Institute, New York, NY, [2]UCSB, Santa Barbara, CA, [3]MIT, Cambridge, MA, [4]Indiana University, Bloomington, IN, [5]Harvard University, Cambridge, MA.

We present experiments and theory on a system of stabilized microtubules driven by the molecular motor protein XCTK2. Through photobleaching experiments, we demonstrate that in this system microtubules are aligned along the long direction of the system and travel through the gel at a velocity independent of the local average polarity. We show that this result is most naturally understood in the framework of an active gel theory that goes beyond pairwise microtubule interactions and treats the gel as highly cross-linked. Our theory bridges the length scales from the microscopic mechanical behavior of motor-filament interactions to the large scale behavior of the active gel and generalizes to describe

different kinds of cytoskeletal assemblies. Importantly, it might explain the physical origin of microtubule sliding in similar in *vivo*system like the spindle.

P1075/B201

Kinesin-5 Cross-linking and Sliding Ensures the Stability and Function of Nascent Bipolar Spindles.

A. Y. Leary, S. Sim, M. Milchberg, E. Nazarova, K. Shulist, R. Genthial, S. Yang, K. Bui, P. Francois, J. Vogel; McGill University, Montreal, QC, CANADA.

One of the most important properties of the mitotic spindle is its bipolar structure. But how a nascent bipolar spindle is established and maintains a stable structure capable of efficient chromosome capture and generating kinetochore tension is poorly understood. The budding yeast mitotic spindle is an outstanding model system for this study due to its minimal microtubule architecture, allowing structural investigation by electron microscopy and the wealth of tools for live cell fluorescence imaging that we used probe new questions regarding the formation and properties of nascent spindles and the proteins that influence these properties. Here, we use live cell fluorescence microscopy to show that the monopolar (duplicated but unseparated spindle poles) to bipolar spindle transition is one of the fastest steps in spindle assembly and is irreversible. Using Kinesin-5 mutants that target its ability to slide apart microtubules we determine that microtubule crosslinking and not sliding by Kinesin-5 is the main driver of this transition from monopolar spindles to nascent bipolar spindles. By fluorescently tagging the microtubule associated proteins that have been implicated in bipolar spindle formation we demonstrate that Cin8 (Kinesin-5) is the first to load onto the monopolar spindle prior to bipolar spindle formation even when its microtubule sliding capacity is inhibited. This is consistent with the electron microscopy tomography analysis we have undertaken that reveal that the monopolar spindle's microtubule architecture is comprised principally of short high angle microtubules unsuited for ensemble Kinesin-5 sliding. Following this fast and irreversible transition we show using live cell imaging that nascent spindles require Kinesin-5 sliding to ensure a stable equilibrium length that allows for further spindle elongation prior to anaphase onset. If Kinesin-5 sliding is inhibited it gives rise to shorter nascent spindles that exhibit larger length fluctuations that persist to anaphase onset. Finally, our preliminary results show that when Kinesin-5 sliding is inhibited mitotic spindles present defects in kinetochore clustering. Such Kinesin related defects may reveal that how one of the earliest steps in spindle assembly may have long range effects in chromosome segregation.

P1076/B202

Mammalian Kinetochore-fibers Set Their Length and Dynamics Independently of Spindle Poles.

M. Richter, S. Dumont; UCSF, San Francisco, CA.

How do cells use the same nanometer-scale components to build different micron-scale structures? During mitosis, cells reorganize tubulin building blocks into various microtubule structures to build the spindle. In mammalian cells, bundles of dynamic microtubules called kinetochore-fibers (k-fibers) extend from chromosomes to poles, driving chromosome segregation. While the length of the spindle is important for its function, and many proteins that modulate spindle length are known, the basic principles underlying length establishment remain poorly understood. To define the role of spindle architecture in this process, I generate barrel-shaped spindles using a dynein inhibitor, where k-fiber minus-ends no longer focus into a pole. I find that these spindles' k-fibers have an unchanged mean length, but more varied lengths within each cell, and yet that each k-fiber's length is maintained over

time. This suggests that pole-independent mechanisms establish and also maintain the k-fiber's length scale, and that pole activities contribute to homogenizing lengths. Further, my preliminary work shows that k-fibers flux poleward and can regrow after ablation in these spindles. Thus, the pole is not essential in regulating and coordinating plus- and minus-end dynamics, contrary to proposed models. Furthermore, laser ablation of barrel k-fibers reveals that k-fiber microtubules modulate their dynamics in a length-dependent manner. Together, my findings suggest that length is an emergent property of k-fibers, independent of global spindle architecture or of dynein-based contractile forces. Thus, using physical and molecular approaches, I aim to dissect how k-fibers 'know' their length, a micron-scale property, to actively regulate their local dynamics at the nanometer-scale.

The Partitioning of the Genome into Chromosomes Affects Mitotic Spindle Metaphase Behavior but Not Spindle Assembly.

C. J. Edelmaier, J. K. Moore; University of Colorado an schutz Medical Campus, Aurora, CO.

A fundamental question in biology is how the partitioning of the genome into a set number of chromosomes impacts the fidelity of mitosis. Here we test the hypothesis that the number of chromosomes determines the structure and function of the mitotic spindle, using an approach that integrates computational models of mitosis in fission and budding yeast with experiments. Using the interspecies modeling approach, where the organisms package a similarly sized genome into 3 (fission) and 16 (budding) chromosomes, we demonstrate that changes to chromosome number disrupt mitotic fidelity and identify interdependent relationships between chromosome number, microtubule dynamics, and kinetochore-microtubule binding properties. One key difference between models is that budding yeast requires slower microtubule dynamics. In addition, we present preliminary experimental data from yeast cells in which chromosomes have been fused to decrease the total number to understand how the spindle can adapt to these changes. Spindle assembly is similar, but spindles are longer with larger length fluctuations during metaphase, in chromosome fusion strains when compared to the wild type. These results from modeling and experiment suggest that the number of chromosomes do affect the structure and function of the mitotic spindle, especially in metaphase.

P1078/B204

Probing Force Balance in the S. Pombe Mitotic Spindle by Laser Ablation.

P. Zareiesfandabadi, **M. W. Elting**; North Carolina State University, Raleigh, NC.

The S. pombe mitotic spindle forms as a single bundle of parallel and antiparallel microtubules. During elongation, the spindle extends via antiparallel microtubule sliding by molecular motors. These extensile forces from inside the spindle resist compressive forces from the nucleus and pushing by astral microtubules. We probe the source of this force balance via laser ablation of spindles at various stages of mitosis. We find that spindle pole bodies collapse toward each other following ablation, but that spindle geometry is often rescued, in some cases allowing spindles to resume elongation and chromosome segregation to complete. While this basic behavior in response to ablation has been previously observed [1,2], many open questions remain as to the timing, mechanics, and molecular requirements of these phenomena. The earlier work suggested that the spindle collapse after ablation was due to viscoelastic relaxation of the chromosomes and nuclear envelope. However, here we simultaneously observe the behavior of microtubules and the nuclear envelope during spindle collapse

and find that it is inconsistent with compressive pushing from the envelope as the sole source of spindle collapse. These data suggest that some other force is bringing the ablated halves of the spindle together. We also quantify the time scales of both the relaxation and rescue responses and begin to probe the molecular requirements affecting both spindle collapse and rescue. [1] A. Khodjakov, S. Analysis of Kinetochore Movements Suggests Deterministic Nature of Mitotic Spindle Assembly.

F. Renda[1], C. Miles[2], I. Tikhonenko[1], A. Mogilner[2], A. Khodjakov, 12201-0509[1]; [1]Wadsworth Center, Albany, NY, [2]New York University, New York, NY.

The goal of cell division is to segregate chromosomes equally into two daughter cells. To achieve this goal, each chromosome must attach to the opposite poles of the 'mitotic spindle', a self-assembling molecular machine built from microtubules. Attachments are formed via capture of dynamic microtubules by the 'kinetochores', a pair of macromolecular assemblies residing on the opposite sides of the chromosome's centromere. A major postulate of the popular "search & capture" (S&C) hypothesis is that capture is stochastic and therefore kinetochores become attached to microtubules independently at different times. Here we test this postulate by following 3-D movements of spindle poles and all kinetochores in human cells at 5-s temporal resolution. Machine-learning analysis of kinetochore trajectories reveals three distinct chromosome behaviors during prometaphase: 1) chromosomes that continuously remain near the equator of forming spindle, 2) chromosomes that initiate movement towards a spindle pole but rapidly return to the equator, and 3) chromosomes that become associated with a spindle pole for a prolonged time. Relative frequencies of these three behaviors change to various extents when the activities of dynein and CenpE, two molecular motors residing at the kinetochore, are inhibited individually or together. Further, we identify characteristic signatures in the chromosome trajectories, such as the amount of active movement, timing of centromere rotations, changes in the distance between sister kinetochores, and patterns of chromosome oscillation. By utilizing these quantitative signatures to cluster chromosome trajectories, we reconstruct the sequence of molecular events that gives rise to each of the three chromosome behaviors. Our analyses suggest that stable equatorial position is achieved via two distinct pathways. In the first pathway, chromosomes initiate transient lateral interactions with spindle microtubules during the early stages of spindle assembly but do not undergo extended active movements within the spindle. In the second, initiation of lateral interactions with microtubules is delayed but the active movements at the later stages of spindle assembly are prominent. Our analyses also suggest that transition from lateral interactions with microtubules to stable attachments of sister kinetochores to the opposite spindle poles (biorientation) occurs in synchrony at the stage determined by spindle geometry. Thus, chromosome behavior during prometaphase is not consistent with the predictions of S&C hypothesis. This mechanism of spindle assembly appears to be deterministic rather than stochastic.

P1080/B206

Towards Measuring In-vivo Ndc80c Binding Kinetics from Flim-fret Fluctuations.

W. Conway, T. Yoo, D. Needleman; Harvard University, Cambridge, MA.

The coupling of the kinetochore to microtubules drives many aspects of chromosome motion during cell division. Despite recent advances in understanding the composition and assembly of the kinetochore, the mechanism of force generation at the kinetochore remains poorly understood. The NDC80complex (NDC80c) is believed to be the primary coupler between microtubules and the kinetochore. The two most widely discussed models of forces production are the biased diffusion model, in which the N80c is proposed to transiently and dynamically associate with microtubules, and a conformational wave model, in which the NDC80c is proposed to engage in stabile, cooperative interactions with microtubules. Our group has previously developed a FLIM-FRET based method to precisely measure the fraction of NDC80c at individual kinetochores in U2OS cells bound to microtubules. Here, we first investigate the role of Hec1 N-terminal tail kinetochore microtubule coupling. We find that mimicking phosphorylation of the Hec1 N-terminal tail significantly alters the fraction of bound NDC80c. Second, we propose an extension of this methodology to measure the dynamics and cooperativity of NDC80c binding and unbinding to microtubules at kinetochores via analysis of fluctuations in the FLIM-FRET signal. We still present theory, simulations and preliminary pilot experiments using diffusing dyes and DNA hairpins arguing that the proposed approach is promising. The same methodology could be applied to study the kinetics of other biochemical reactions in-vivo, on timescales from seconds to microsecond. Third, we explore the impact of microtubule-kinetochore binding on k-fiber dynamics. We will present preliminary results from photoactivation experiments examining the impact of microtubule-kinetochore coupling on k-fiber structure and tubulin turnover. We aim to use these photoactivation measurements to test models of k-fiber dynamics.

P1081/B207

Understanding the Forces That Move Chromosomes and Position the Spindle.

M. I. An jur-Dietrich, D. J. Needleman; Harvard University, Cambridge, MA.

During cell division, the mitotic spindle, a dynamic, microtubule-based molecular machine, attaches to and exerts forces on chromosomes to first align them along the spindle equator and then move them apart. The position and orientation of the spindle determine the cell's cleavage plane, which ultimately determine how cellular contents are split between the two daughter cells. Therefore, dynamic and precise of regulation of the forces within the spindle that align and separate chromosomes and the positioning forces on the spindle itself is of crucial importance to mitosis. Previous studies have identified many molecular players involved in chromosome separation, however it has been difficult to investigate mechanical forces over the course of mitosis in live cells, mainly due to a lack of tools. We used a magnetic tweezer system to apply forces of varying magnitude and timescale on the spindle with intracellular magnetic beads. Preliminary results show that for short pushes, the spindle recovers its original position, however for longer pushes, the equilibrium position of the spindle appears to move and the original position is not recovered. By combining molecular perturbations with physical measurements, we plan to dissect the mechanistic details of chromosome motion and spindle positioning.

P1082/B208

Measuring the Force Generated by the Fission Yeast Mitotic Spindle.

P. Real Calderon[1], P. Suresh[1], S. Dumont[1], R. Rodriguez-Daga[2], F. Chang[1]; [1]UCSF, San Francisco, CA, [2]Universidad Pablo de Olavide, Sevilla, SPAIN.

Measuring forces within cells is an important step in understanding how cellular processes function mechanically. An open question in mitosis is how much force the mitotic spindle exerts to segregate chromosomes. In fission yeast, the spindle can be regarded as a simple bundle of overlapping microtubules that elongates during anaphase to push the nuclei and chromosomes apart. We have discovered conditions under which the majority of cells to fail in anaphase. In these cells, chromosomes cannot fully segregate and the spindle continues to elongate and gradually adopts a bent shape rather than its normal straight shape. Ultimately these spindles fail abruptly, by either breaking in half or by one pole disassociating from the chromosomes. We hypothesize that spindles exert pushing forces to elongate and bend their microtubules into this shape. Using simple beam theory, we estimate that the spindle exerts nanoNewton forces to bend itself, and that similar forces are needed to break the spindle [1][2]. This magnitude of force is consistent with the predicted action of 100's of motor proteins which each provides picoNewton forces [3]. Future directions include determining what factors, such as motor proteins and crosslinkers, contribute to force production. Our findings in fission yeast provide quantitative measurements and will ultimately shed light on the contribution of mitotic components in force production for more complex spindles such as in animal cells.

P1083/B209

Modeling the Dynamics of Centrosome Movement.

D. Mercadante, A. Manning, S. Olson; Worcester Polytechnic Institute, Worcester, MA.

Mitosis is the process of cell division, resulting in two genetically identical daughter cells. This process is regulated by the mitotic spindle, composed of a complex network of microtubules (MTs) and motor proteins. These structures generate pushing and pulling forces allowing the formation of a bipolar spindle, with each pole organized around a single centrosome. Disruptions in force generating activities through protein depletions or alterations to centrosome number corrupt spindle structure and affect the fate of the cell in mitosis. Centrosome amplification, a common characteristic of cancer cells, promotes multipolar spindle formation and multipolar division, which results in daughter cells with decreased viability. As such, cancer cells actively cluster extra centrosomes to form a functional bipolar spindle and undergo a bipolar division. To define forces that are required for efficient spindle pole clustering, we are developing a novel biophysical model of spindle formation in cells with extra centrosomes by solving force balance equations to determine the position of the centrosomes in time. We consider stochastic force generators at the cell cortex and between interpolar microtubules. To inform the model and test explicit predictions that it generates, we are using live-cell imaging and image processing to track centrosome movement in cells.

P1084/B210

Kinetochore-fibers Locally and Slowly Dissipate Force to Maintain Robust Mammalian Spindle Structure.

A. F. Long, P. Suresh, S. Dumont; University of California San Francisco, San Francisco, CA.

At cell division, the mammalian kinetochore binds many spindle microtubules that make up the kinetochore-fiber. To segregate chromosomes, the kinetochore-fiber must be dynamic, and must both generate and respond to force. How the kinetochore-fiber responds to force remains poorly understood: it cannot be reconstituted in vitro, and exerting forces on it in vivo remains challenging. Based on Nicklas' classic work, we developed a microneedle manipulation assay to pull on mammalian kinetochore-fibers close to kinetochores and probe how force regulates their dynamics and structure. We show that force lengthens kinetochore-fibers by persistently, and reversibly, favoring their growth versus shrinkage, rather than by increasing growth rate. Using photomarking, we demonstrate that lengthening occurs by preventing depolymerization at both microtubule plus- and minus-ends, and not by microtubules sliding within the bundle. Finally, even under forces sufficient to rupture kinetochore-fibers we do not observe detachment from kinetochores or poles. Together, this work suggests strategies for spindle structural homeostasis under force: kinetochore-fibers locally dissipating force at both ends, behaving mechanically as a single unit, and having strong spindle connections at force dissipation sites. These simple engineering principles may be helpful for understanding a broad range of dynamic, force-generating cellular machines.

P1085/B211

Cortical Pulling Force Drives Pronuclear Migration and Rotation, and Spindle Positioning and Oscillation.

H. Wu[1], E. Nazockdast[2,3], R. Farhadifar[1,2], C. Yu[1], H. Chang[4], M. J. Shelley[2,5], D. J. Needleman[1]; [1]Harvard University, Cambridge, MA, [2]Simons Foundation, New York, NY, [3]University of North Carolina, Chapel Hill, NC, [4]Institute of Atomic and Molecular Sciences, Academia Sinica, Taipei, TAIWAN, [5]New York University, New York, NY.

In the *C. elegans* early embryo, the pronuclei complex migrates to the cell center and rotates such that the mitotic spindle forms along the anterior-posterior axis. Subsequently, the spindle undergoes transverse oscillations as it moves toward the posterior. This asymmetric spindle positioning is crucial for asymmetric cell division and proper development. The contributions of pushing, cortical pulling, and cytoplasmic pulling forces to those dynamic centrosome positioning events are not fully understood. To study these processes, we constructed a novel laser ablation system capable of creating nearly arbitrary 3D cuts of astral microtubules at any desirable timing. We used this system to dissect the relative contribution of pushing and pulling forces throughout pronuclei and spindle motions. Our results suggest that all of these motions are dominated by net pulling. We used microinjected fluorescent nanodiamonds to track cytoplasmic fluid flow, which indicates that cortical pulling forces dominate over cytoplasmic pulling at all stages. We used computer simulations and mathematical modeling to interpret our experimental data. Taken together, our results strongly argue that cortical pulling drives pronuclear migration and rotation, metaphase spindle positioning, asymmetric spindle positioning and all aspects of spindle oscillations.

P1086/B212

Hierarchical Regulation of Spindle Scaling during Development.

E. M. Rieckhoff[1,2,3], F. Berndt[1,2,3], S. Golfier[1,2,3], F. Decker[1,2,3], J. Brugués[1,2,3]; [1]Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, GERMANY, [2]Max Planck Institute for the Physics of Complex Systems, Dresden, GERMANY, [3]Center for Systems Biology Dresden, Dresden, GERMANY.

Cells need to regulate the size and shape of their organelles for proper function. For example, the mitotic spindle adapts its size to changes in cell size over several orders of magnitude, but we lack a mechanistic understanding of how this is achieved. We have recently shown that the upper spindle size is set by the limited activity of microtubule nucleators around chromosomes, even when components are unlimited. For small spindles, however, it has been shown that microtubule dynamics correlate with spindle size during development. Thus, the mechanisms of cell-size dependent spindle scaling are still unclear due to the lack of experimental data on the underlying microtubule processes in a system that covers the full regime of spindle size scaling. Here, we combine quantitative microscopy, laser ablation, and modelling in zebrafish embryos and encapsulated *Xenopus* egg extract to reveal the relative contributions of microtubule length dynamics and nucleation to cell-size dependent spindle scaling. We find a hierarchical regulation of spindle scaling. In large spindles, microtubule dynamics and turnover are independent of spindle size—implying a scale-invariant microtubule length. Below a threshold cell size, microtubule polymerization dynamics and turnover correlate with spindle size. However, the change in microtubule dynamics alone is not sufficient to account for the observed spindle scaling. Instead, we find that microtubule nucleation is the main biophysical process that scales spindle size across all cell sizes, although microtubule dynamics still fine tune spindle size in small cells. We hypothesize that this hierarchical regulation of spindle scaling is an inherent consequence of building spindles from microtubules that are smaller than the size of the spindle. The gradual transition from a microtubule nucleation-based to a microtubule dynamics-based mechanism of spindle assembly implies a change in spindle architecture, and may ensure faithful chromosome segregation by spindles of all sizes.

P1087/B213

Microneedle Manipulation of the Mammalian Spindle Reveals Specialized, Short-lived Reinforcement Near Chromosomes.

P. Suresh, A. F. Long, S. Dumont; University of California, San Francisco, San Francisco, CA.

The spindle generates force to segregate chromosomes at cell division. In mammalian cells, kinetochore-fibers (k-fibers) connect chromosomes to the spindle. Yet, how the dynamic spindle anchors k-fibers in space and time remains poorly understood since we lack tools to directly challenge this anchorage. Based on Nicklas' pioneering work, we develop a microneedle manipulation assay to exert local forces on the mammalian spindle with spatiotemporal control. Pulling on k-fibers in the lateral axis away from the spindle reveals the spindle's ability to retain local architecture in response to forces applied for seconds. Upon pulling, sister, but not neighbor, k-fibers remain tightly coupled, and the spindle globally shortens rather than k-fibers detaching from poles or chromosomes. The deformed shape of k-fibers reveals that they can freely pivot around poles, but not kinetochores, remaining unbent within the first 2µm near kinetochores. This local reinforcement near kinetochores has a lifetime of ~20 s under force, and requires the microtubule crosslinker PRC1. Together, these observations suggest strong, short-lived, and specialized reinforcement of the k-fiber in the spindle center. Such reinforcement could help the

spindle robustly retain its local structure at dynamic sites of force generation, while allowing spindle remodeling on longer timescales.

P1088/B214

The Mitotic Crosslinking Protein PRC1 Acts as a Viscous Dashpot Against Relative Microtubule Sliding.

S. Forth; Rensselaer Polytechnic Institute, Troy, NY.

Cells use cytoskeletal networks to perform complex physical tasks throughout diverse processes such as the assembly of the mitotic spindle during cell division. These dynamic networks consist of microtubules that are organized, bundled, and transported by motor and non-motor proteins that produce 'active' pushing and 'passive' frictional forces to achieve proper assembly and perform mechanical work. How these mesoscale forces are regulated at the micron-scale by ensembles of nanometer-sized proteins has been unclear. We are addressing this knowledge gap by directly measuring force production across microtubule bundles using optical tweezers and simultaneously observing by single molecule fluorescence microscopy the localization of key proteins that regulate network stability. Here, we demonstrate that ensembles of PRC1, an essential non-motor crosslinking protein needed both to assemble bridging fibers during metaphase and build the central spindle in anaphase, are viscous frictional elements whose resistance to motor-driven microtubule sliding scales linearly with velocity and local protein concentration. Our direct experimental measurements and computational simulations describe how PRC1 molecules can both diffuse within the overlapping microtubule network and track a partially reflective barrier at microtubule plus-ends in order to act as a viscous dashpot against microtubule sliding motions. This mechanical property can then help to establish stable rates of both chromosome and pole separation. These results set the groundwork for understanding higher-order microtubule networks as "machines" that use simple rules to modulate their force production and control the spatiotemporal organization of the dynamic cytoskeleton.

P1089/B215

A Minimal Spindle-Midzone Protein Module Differentially Regulates Single Microtubules and Crosslinked Microtubule Arrays.

N. Mani, S. Jiang, R. Subramanian; Harvard Medical School / Massachusetts General Hospital, Boston, MA.

A remarkable feature of the microtubule cytoskeleton is the co-existence of distinct sub-populations with different stabilities in the cellular cytoplasm. A striking example is the spindle midzone, an array of antiparallel microtubule bundles that encodes positional cues for accurate cytokinesis in dividing cells. At the cell center, these stable bundles exist alongside dynamic microtubules that are thought to contribute to midzone organization. How do stable bundles and dynamic single microtubules coexist at the center of the dividing cell? Here we reconstitute a minimal system composed of the antiparallel microtubule crosslinker PRC1, and its binding partners Kif4A and CLASP1, midzone-associated proteins that suppress and promote microtubule growth respectively. We find that the activity of these proteins on dynamic microtubules results in a system with stable bundles and elongating single microtubules. An alysis of the protein-protein interactions reveals that two parameters are sufficient to explain the differential regulation of single and bundled microtubules: (i) higher microtubule affinity of CLASP1 over Kif4A and (ii) higher PRC1 affinity of Kif4A over CLASP1. Together with cell biological analyses, our findings provide new insights into how antagonistic regulators of microtubule dynamics can

differentially regulate proximal subsets of microtubules for midzone assembly. More broadly, our findings illuminate the design principles that can confer different stabilities to microtubule sub-populations that coexist at the same subcellular site.

P1090/B216

The Mechanical Integrity of the Mammalian K-fiber and Its Molecular Origin.

M. A. Begley[1], E. M. Davis[1], R. Ohi[2], M. W. Elting[1]; [1]North Carolina State University, Raleigh, NC, [2]University of Michigan, an n Arbor, MI.

During mitosis, the mitotic spindle, a self-constructed microtubule-based machine, segregates chromosomes into two eventual daughter nuclei. Microtubule bundles that align and anchor chromosomes, called kinetochore-fibers (k-fibers), are vital for the structural and functional integrity of this spindle, yet the composition and dynamics of k-fibers are still not well-understood. To probe k-fibers in mammalian PtK2 cells, we perform both high-resolution single-molecule speckle fluorescence imaging and mechanical perturbation by targeted laser ablation. In searching for the identities of microtubule crosslinking proteins that mechanically support k-fiber integrity, we biochemically and genetically perturb candidate molecules in spindles, ablate k-fibers, and subsequently quantify the physical response of the k-fiber. While speckle microscopy experiments in unperturbed spindles demonstrate that k-fibers act as mechanically cohesive units that are held together along their lengths, laser ablation of k-fibers often results in the splaying of the remaining stubs. Together, these results suggest that forces holding k-fibers together are tuned to be of similar magnitude as other cellular forces. Following ablation, it has previously been shown that stub minus-ends are typically detected and pulled poleward, repairing the spindle. In spindles with reduced NuMA, a molecule that recruits dynein to microtubule minus-ends and mediates the post-ablation poleward transport, splaying is reduced, suggesting that when splaying occurs, it is may be because k-fibers are torn apart during poleward transport. Additionally, pharmacological inhibition of kinesin-12 Kif15 microtubule binding increases the frequency of post-ablation splaying, while inhibition of its motor activity but not its microtubule binding does not affect splaying, suggesting that Kif15 may fortify and stabilize k-fibers. Interestingly, inhibition of Kif15 also results in dramatically delayed reincorporation of ablated k-fibers, although the process by which Kif15 impacts spindle repair remains unclear.

P1091/B217

Self-organization of Spindle-like Microtubule Structures.

J. L. Ross; Syracuse University, Syracuse, NY.

Microtubule self-organization is an essential physical process underlying several essential cellular functions, including cell division. In cell division, the dominant arrangement is the mitotic spindle, a football-shaped microtubule-based machine responsible for separating the chromosomes. We are interested in the underlying fundamental principles behind the self-organization of the spindle shape. Prior biological works have hypothesized that motor proteins control the proper formation of the spindle. Many of these motor proteins are also microtubule-crosslinkers, so it is unclear if the critical aspect is the motor activity or the crosslinking. In this study, we seek to address this question by examining the self-organization of microtubules using crosslinkers alone. We use a minimal system composed of tubulin, an antiparallel microtubule-crosslinking protein, and a crowding agent to explore the phase space of organizations as a function of tubulin and crosslinker concentration. We find that the

concentration of the antiparallel crosslinker, MAP65, has a significant effect on the organization and resulted in spindle-like arrangements at relatively low concentration without the need for motor activity. Surprisingly, the length of the microtubules only moderately affects the equilibrium phase. We characterize both the shape and dynamics of these spindle-like organizations. We find that they are birefringent homogeneous tactoids. The microtubules have slow mobility, but the crosslinkers have fast mobility within the tactoids. These structures represent a first step in the recapitulation of self-organized spindles of microtubules that can be used as initial structures for further biophysical and active matter studies relevant to the biological process of cell division.

P1092/B218

Using a Small Molecule Inhibitor of Spastin to Probe Nuclear Envelope Reformation.

M. E. Kelley, L. Carlini, A. Aher, T. M. Kapoor; the Rockefeller University, New York, NY.

In order to divide and propagate, cells must distribute replicated chromosomes into nascent daughter cells. In metazoans this occurs by “open mitosis,” in which disassembly of the protective nuclear envelope is required for the attachment of spindle microtubules to chromosomes at kinetochores. Strong connections between spindle microtubules and kinetochores are necessary to evenly distribute replicated chromosomes during anaphase, but persistent connections can impede subsequent nuclear envelope reformation. Recent work has proposed that spastin, a microtubule-severing AAA+ ATPase, is responsible for severing microtubules at chromatin interfaces in late anaphase, allowing the nuclear envelope to fully encapsulate chromosomes within minutes of segregation. However, spastin also has well characterized roles in endosomal trafficking during interphase and intercellular bridge disassembly at the end of mitosis. Standard genetic perturbations, which can take days before effects are observed, are therefore unable to resolve spastin’s specific role in nuclear envelope reformation. To overcome this limitation, we used spastazoline, a recently developed small molecule inhibitor of spastin, to acutely inhibit spastin activity during nuclear envelope reformation in late anaphase. Using live cell imaging, we tracked spastin accumulation at the reforming nuclear envelope and measured changes in spastin foci dynamics after inhibition with spastazoline. On average, individual spastin foci persisted at the nuclear envelope approximately 1.5-fold longer in the presence of spastazoline, while the average number of spastin tracks detected per cell increased 3.4-fold. We go on to use multimodal imaging to examine spastin foci and microtubules in late anaphase, characterizing the effects of spastin inhibition and expanding spastin’s role in nuclear envelope reformation.

P1093/B219

Understanding the Role of an euploidy and Chromosomal Instability in Chronic Inflammation.

B. Johnson, Y. Dong, T. Li, T. Chen, R. Li; Johns Hopkins School of Medicine, Baltimore, MD.

While the link between inflammation and cancer has been noted for well over 150 years, the molecular mechanisms driving this relationship remain unclear. In inflammatory bowel disease (IBD), which is characterized by chronic inflammation of the gastrointestinal tract, cells with abnormal chromosome stoichiometries (aneuploid) arise frequently. The questions of how these altered cells arise and what role they play in driving evolution from chronically inflamed tissue to cancerous lesion have yet to be explored. Our study aims to characterize the extent of karyotypic heterogeneity and mechanisms that drive emergence of aneuploidy and chromosomal instability (CIN), the process which gives rise to aneuploidy, in IBD. Gene set enrichment analysis reveals increased expression of genes associated with

CIN in colonic biopsies of IBD patients. Novel methods for analysis of single cell RNA sequencing data are utilized to identify karyotype abnormalities and alterations in inflammatory pathways in individual epithelial cells from patients with IBD. The influence of chronic inflammation on the karyotype of intestinal epithelial cells is studied in colon organoids derived from a DSS-induced mouse model of colitis. Our findings have the potential to unveil the mechanisms of progression from chronic inflammation to cancer, opening the door for preventive strategies to target these malignancies before they occur.

P1094/B220

Understanding the Role of Tp53 in Mediating an euploid Cell Fate in Different Mammalian Cells and Patient Derived Organoids.

A. Narkar, P. Bharne, B. Johnson, A. Nelliat, J. Zhu, D. Biswas, V. Padmanaban, R. Li; Johns Hopkins University School of Medicine, Baltimore, MD.

Equal partitioning of replicated chromosomes to daughter cells is an essential phenomenon to maintain genome stability. Chromosome mis-segregation events and aneuploidy are prevalent in majority of mammalian tumors. The role of tumor suppressor TP53 and its downstream target CDKN1A have been implied in regulating numerical and structural chromosomal aberrations in certain tissue types. The multi-layered complexity arising from different ways to induce aneuploidy and the role of tissue architecture make it difficult to study aneuploid cell fate in a rigorous and standardized manner. In this study acute aneuploidy was generated by inhibiting an essential spindle assemble checkpoint regulator MPS1, which resulted in cells passing through mitosis with irregular kinetochore and microtubule attachments and higher number of mis-segregated chromosomes in daughter cells. Using biochemical and genetic approaches on a comprehensive panel of cell lines and organoids from human and mouse we investigated the differential regulation of aneuploid cells by the TP53 pathway. External factors like adherence properties of 2D monolayer cells show a dependence on TP53 pathway to limit the proliferation of aneuploid mammalian cells. Whereas suspension culture, neural progenitor cells and mammalian organoids from colon and breast show an increased tolerance to aneuploid cell proliferation and indicate the presence of other molecular pathways to regulate aneuploid cell fate. These results indicate how altering the TP53 response can allow certain tissue types to tolerate higher amounts of aneuploidy and elucidating a possible route to aneuploidy-mediated genomic instability in carcinogenesis.

P1095/B221

Quantitative an alysis of the Signaling Dynamics of the Spindle Assembly Checkpoint Utilizing Crispr-cas9-mediated Genome Editing.

C. Chen, L. Humphrey, A. P. Joglekar; University of Michigan, an n Arbor, MI.

The spindle assembly checkpoint (SAC) is a signaling pathway that delays anaphase onset in the presence of unattached kinetochores in a mitotic cell. How the number of unattached kinetochores changes the SAC signaling output is not fully understood. This knowledge will help us comprehend how the SAC prevents premature anaphase onset in the presence of a decreasing number of unattached kinetochores during normal mitotic progression. To address this question under physiological conditions, we used CRISPR-Cas9-mediated genome editing to fuse mNeonGreen to 3 of the core SAC signaling proteins in HeLa cells (Bub1, BubR1, and Mad1) and utilized GSK923295 (a CENP-E inhibitor) or

nocodazole to induce small or large numbers of unattached kinetochores in mitotic cells. To evaluate the importance of the abundance of Bub1, BubR1, and Mad1 to the robustness of the SAC in the presence of various numbers of unattached kinetochores, we partially knocked down each protein with RNA interference against mNeonGreen-tagged alleles. We observed that BubR1 knock-down is the most impactful compared to Bub1 and Mad1 at similar knock-down efficiencies, leading to a significant reduction in the duration of the mitotic arrest in cells containing small (but not large) numbers of unattached kinetochores. As the recruitment of Bub1, BubR1, and Mad1 to unattached kinetochores is crucial for the conventional SAC signaling pathway, we then quantified their localization in the presence of various numbers of unattached kinetochores. In mitotic cells containing small numbers of unattached kinetochores, each unattached kinetochore recruits significantly higher amounts of Bub1, BubR1, and Mad1. Importantly, the fold increase in BubR1 and Mad1 recruitment is significantly higher than in Bub1 recruitment. Finally, since Bub1, BubR1, and Mad1 localize to MELT motifs of the SAC scaffold protein Knl1 (each putatively has 19 such motifs in human) at unattached kinetochores, we studied the importance of the number of MELT motifs in each molecule of Knl1. We replaced the endogenous Knl1 with recombinant versions containing either 6 or 3 MELT motifs to examine how the SAC strength is affected. Cells exhibit a drastic enhancement in their SAC signaling strength when there are 6 MELT motifs per Knl1 compared to 3, but again only in cells containing small numbers of unattached kinetochores. Together, these results implicate BubR1 and the number of MELT motifs in Knl1 as key determinants of the robustness of the SAC in the presence of small numbers of unattached kinetochores.

P1096/B222

Paradoxical Mitotic Exit Induced by a Small Molecule Inhibitor of APC/C^{Cdc20}.

K. Richeson[1], T. Bodrug[2], K. L. Sackton[1], M. Yamaguchi[3], J. A. Paulo[1], S. P. Gygi[1], B. A. Schulman[4], N. G. Brown[2], R. W. King[1]; [1]Harvard Medical School, Boston, MA, [2]University of North Carolina School of Medicine, Chapel Hill, NC, [3]St. Jude Children's Research Hospital, Memphis, TN, [4]Max Planck Institute of Biochemistry, Martinsried, GERMANY.

The an aphase Promoting Complex/Cyclosome (APC/C) is a mega-dalton ubiquitin ligase that initiates mitotic exit by targeting substrates for degradation. The APC/C is activated by Cdc20, which acts as a substrate receptor, and is inhibited by the mitotic checkpoint complex (MCC), which delays mitotic exit when the spindle assembly checkpoint (SAC) is activated. We previously identified apcin, a small molecule ligand of Cdc20, as an inhibitor of APC/C^{Cdc20}. Surprisingly, we found that apcin paradoxically accelerates substrate degradation and promotes mitotic exit in cells with high SAC activity. Biochemical studies indicate that apcin cooperates with p31^{comet} to relieve MCC-dependent inhibition of APC/C. Apcin's behavior as an antagonist of Cdc20 can thus result in either net inhibition of APC/C, delaying mitotic exit when SAC activity is low, or net activation of APC/C, promoting mitotic exit when SAC activity is high. Genetic experiments suggest that the dual behaviors of apcin arise from targeting a common binding site in Cdc20 that is required for both substrate ubiquitination as well as efficient APC/C inhibition by MCC. We therefore establish a new mechanism through which a small molecule, by targeting a single site on a dynamic protein interface, can lead to opposing biological effects depending on the regulatory context.

Deciphering the Roles of Discoidin Proteins in Controlling Cell Mechanics.

L. Nguyen, D. Robinson; Johns Hopkins School of Medicine, Baltimore, MD.

Processes such as cytokinesis, migration, and chemotaxis require robust cell shape changes. To complete these processes, cells need to integrate internal and external cues through a mechanoresponsive machinery that includes actin filaments, myosin II motors, actin crosslinkers, and other scaffolding proteins. Uncovering and understanding the broad underlying network of proteins that drive and control this machinery is a prime interest of our research in our lab. Using *Dictyostelium discoideum*, we identified through proteomics and genetics interactors of the actin crosslinker cortexillin I and the scaffolding protein IQGAP2 as two key nodes of the machinery. We uncovered a network of biochemical interactors that potentially contribute to the activity and integrity of the system. Among those, discoidin proteins I and II are the focus of my research. I aim to decipher the roles and functions of discoidin proteins in the context of cell mechanics. Discoidin proteins are sugar binding proteins containing a lectin domain and a discoidin domain. Though several previous studies have identified roles of discoidin in cell adhesion and development, the exact functions of discoidins remain elusive. We previously found that discoidin I interacts with myosin II and cortexillin I in *vivo*. Now, I have used CRISPR-Cas9 to generate knockouts of discoidin and am investigating the defects in these knockouts using various mechanical indicators such as growth rates, number of multinucleated cells, assembly of myosin II, and the accumulation of mechanoresponsive proteins in response to applied mechanical stress. Further results will be discussed in the poster.

P1098/B224

Mitosis Specific Dynein Adaptor Hook2, Regulates the Cell Cycle Progression and Its Mitotic Localisations Are Regulated by the Mitotic Kinase Plk1.

D. Dwivedi, S. Rathi, M. Sharma; Indian Institute of Science Education and Research, Mohali, Mohali, INDIA.

In addition to intracellular microtubule-based retrograde transport, cytoplasmic dynein also regulates events like centrosome separation, chromosome alignment and separation, spindle orientation and focusing during mitosis. Association of dynein, with its activator dynactin, dramatically enhances the processivity of dynein motor. This interaction is mediated by various adaptor proteins which form a stable ternary complex containing dynein, dynactin and the adaptor. The adaptors also link the cargo vesicle to dynein, thereby facilitating their transport. Hook proteins are coiled-coil proteins that regulate dynein motility by enhancing the association between dynein and dynactin. Unlike lower organisms where there is a single Hook gene, mammals express three Hook paralogs having distinct cellular localisation and non-redundant functions. In this study, we report that human HOOK2, a centrosomal protein also localises to central spindles and midbody during anaphase-B and cytokinesis, respectively. Furthermore, we noted that these additional localisations of HOOK2 depend on translocation of HOOK2 from centrosomes to these transient structures and require the activity of mitotic kinase PLK1. While the dynein association of HOOK2 is regulated by its evolutionarily conserved N-terminal Hook domain, a

second site in C-terminal region is crucial for binding to dynactin subunit p150^{glued}. The interaction of HOOK2 with dynein and dynactin is enhanced during mitosis. At the onset of mitosis, HOOK2 regulates anchorage of the centrosome to the nucleus, and microtubule nucleation from the centrosome and its RNAi mediated depletion results in a mild increase in mitosis duration, defects in mitotic spindle positioning, chromosome misalignment during metaphase. Furthermore, cytokinesis failure leading to the formation of binucleated cells was also observed upon HOOK2 depletion. HOOK2 mediates the interaction between dynein and dynactin and regulates their localisation on central spindles during anaphase. Further, HOOK2 via its ability to regulate dynein/dynactin also promotes dynactin-dependent recruitment of centralspindlin complex component MKLP1 to spindle midzone, thereby controlling the cleavage furrow ingression required for completion of cytokinesis. Our study reveals a novel role of centrosomal protein HOOK2 as a mitosis specific dynein adaptor, thereby regulating cell cycle progression.

P1099/B225

Elucidating Mechanisms Regulating an illin Function for Cytokinesis.

N. P. Pham, D. Beaudet, A. Piekny; Concordia University, Montreal, QC, CANADA.

Cytokinesis describes the physical separation of a dividing cell into two daughter cells. This process is driven by the formation and constriction of a RhoA-dependent contractile ring that forms at the cell equator in anaphase. Cytokinesis must occur properly as failure can lead to aneuploidy and cell fate changes, which are hallmarks of cancer. Thus, multiple pathways coordinate to couple ring assembly and ingression with chromosome segregation. While the dogma is that the anaphase spindle provides cues to control RhoA activity for cytokinesis, we recently found that a chromatin-sensing pathway also influences the contractile ring. This chromatin pathway functions via active Ran, which forms an inverse gradient to importins. Human anillin, a key cytokinesis regulator, contains an NLS that binds to importins and is required for its cortical recruitment. An illin also has binding sites for active RhoA and microtubules, and we are studying how they are coordinated. Reducing active RhoA enriches anillin's localization to microtubules, while increasing microtubules via MCAK (kinesin-13, microtubule depolymerase) RNAi decreases anillin's cortical localization. Thus, RhoA and microtubules compete with each other. An illin's cortical affinity is also reduced when the NLS is mutated. To determine how microtubule binding is altered in the NLS mutant, we performed co-sedimentation assays and found that anillin's binding domains for microtubules and importin partially overlap. Moreover, importin weakly competes for anillin's microtubule binding in vitro. This suggests that the NLS mutant should have reduced localization to microtubules in cells, and its decrease in cortical recruitment may not be caused by the same phenomenon as in MCAK RNAi cells. In support of this, FRAP experiments revealed that the NLS mutation and MCAK RNAi both cause an increase in the immobile fraction, but only the NLS mutation causes an increased off-rate. This supports the model that importin-binding is required for the robust cortical recruitment of anillin, by feeding back to stabilize anillin's interaction with RhoA or the membrane.

Determining the Role of TTLL12 and the Tubulin Code during Cell Division.

J. Ceglowski[1], E. Thomas[1], C. Janke[2], R. Prekeris[1]; [1]University of Colorado an schutz, Denver, CO, [2]Institut Curie, Paris, FRANCE.

Post-translational modifications of tubulin regulate both the stability of microtubules as well as the interactions with microtubule motors and other microtubule-associated proteins. The patterning of these modifications has been proposed to constitute a tubulin code that functions in a variety of cellular events. However, despite the importance of microtubules in mediating cell division, what role, if any, the tubulin code plays during mitosis remains unknown. To investigate the potential role of the tubulin code in regulating mitosis, we analyzed the levels of tubulin glutamylation and glycylation during different stages of mitotic cell division. Our data show that mitotic spindle microtubules are heavily poly-glutamylated during metaphase and early anaphase. Interestingly, glutamylation levels significantly decrease during late anaphase and telophase. Finally, we found no evidence that mitotic or central spindle microtubules are glycylated. Thus, our data reveal that the tubulin code undergoes dynamic changes during mitotic cell division, although the function of these changes remains to be determined. The tubulin tyrosine ligase-like (TTLL) family catalyzes either glycylation or glutamylation of tubulin tails, and recently, we have identified TTLL12 as a potential regulator of mitotic cell division. Therefore, to determine the involvement of TTLL12 in regulating cell division we created a HeLa TTLL12 knock out cell line. Importantly, TTLL12 KO cells have an increase in multinucleation, suggesting an increase in mitotic failure. Furthermore, our data indicate that TTLL12 may regulate early steps of mitosis, such as mitotic spindle formation and metaphase-to-anaphase transition. TTLL12 is a unique member of the TTLL family since its enzymatic function remains unclear. To identify if a tubulin post-translational modification is mediated by TTLL12 we next analyzed the effect of TTLL12 knock-out on the tubulin modification levels during metaphase. Interestingly, our data show that TTLL12 depletion leads to an increase in tubulin poly-glutamylation while having little effect on acetylation or tyrosination. Overall our data suggest TTLL12 does not directly modify tubulin but rather acts a negative regulator of poly-glutamylation, consequently, mediating dynamic changes in the tubulin code during mitotic cell division.

P1101/B227

Spikes of Intracellular Calcium Accompany Fission Yeast Cytokinesis.

A. Poddar, O. Sidibe, Q. Chen; University of Toledo, Toledo, OH.

Cytokinesis is the final stage of cell division during which two daughter cells separate. In some animal embryos, cytoplasmic calcium concentration increases sharply at the cell division plane during cytokinesis. *However, it remained unclear whether this process is evolutionally conserved and important for cytokinesis. To* address these questions, we measured intracellular calcium concentration during cytokinesis of the fission yeast *Schizosacchromyces pombe* with quantitative fluorescence microscopy. We employed GCaMP, a genetically encoded fluorescence calcium reporter, in our study. Expressed from an integrated genomic locus, GCaMP distributed homogenously throughout the cytoplasm. Intracellular fluorescence remained low among most GCaMP expressing cells, although it exhibited a weak correlation with the cell morphogenesis. Hypo-osmotic stress, a well-known stimulus of intracellular calcium, triggered instant spikes of the GCaMP fluorescence, confirming that GCaMP reports the intracellular calcium concentration of fission yeast cells as well. Among the dividing cells, very few calcium spikes were found during mitosis. In contrast, during cytokinesis, two distinct spikes of

intracellular calcium were recorded in almost all (>90%) dividing cells. The first one was concomitant with the initiation of the cleavage furrow ingression, agreeing with what was found in the animal cells. The second spike accompanied the initiation of cell separation, but it appeared asymmetrically between the two daughter cells. A calcium chelator EGTA reduced the rate of ring closure and triggered post-cytokinesis cell lysis in a dosage-dependent manner, suggesting that calcium homeostasis may be important for the fission yeast cytokinesis. We conclude that intracellular calcium spike accompanying cytokinesis is an evolutionally conserved process and calcium may play an important role in both the furrow ingression as well as the cell separation.

P1102/B228

A Putative Trp Channel Pkd2p an tagonizes the Sin Pathway to Maintain Cell Integrity during Fission Yeast Cytokinesis.

D. Sinha, M. Chetluru, Q. Chen; University of Toledo, TOLEDO, OH.

A Putative TRP Channel Pkd2p an tagonizes the SIN Pathway to Maintain Cell Integrity during Fission Yeast Cytokinesis Debatrayee Sinha, Madhurya Chetluru and Qian Chen* Fission yeast Pkd2p is a putative transient receptor potential (TRP) channel *and* the homologue of human polycystins. Our lab recently found that Pkd2p localizes to the cleavage furrow and is essential for the cell separation. However, it remains unclear how this ion channel contributes to cytokinesis. *Here we show that a key role of Pkd2p during cytokinesis is to maintain the cell integrity during cell separation by antagonizing activities of the SIN pathway. The* Septation Initiation Network (SIN) is an essential Hippo-like signaling cascade that regulates cytokinesis. We first identified strong positive genetic interactions between *pkd2* mutants and many SIN mutants. Even though the SIN pathway activity is essential for both the cell integrity and septation, during cytokinesis. Pkd2p only antagonizes its role in maintaining cell integrity. Depletion of Pkd2p in the SIN mutants prevented these cells from lysis. The activity of the SIN pathway can be directly measured by the asymmetric distribution of Cdc7p between two spindle pole bodies (SPB). In the *pkd2* mutant, this asymmetry is enhanced. Cdc7p-GFP molecules exited significantly sooner from the SPBs of the p*kd2* mutant, compared to the wild type. Additionally, Pkd2p may also suppress the cytokinetic localization of the SIN pathway protein Mob1p. In the *pkd2* mutant, the peak molecular numbers of Mob1p on the spindle pole bodies and the contractile ring increased by more than 10%, compared to wild-type cells. We concluded that one key role of Pkd2p in cytokinesis is to maintain the cell integrity by modulating the activity of the SIN pathway.

Parallel between Retroviral Budding and Cytokinesis: a Novel Factor for MBR an choring at the Cell Surface.

A. Presle[1], S. Frémont[1], C. Berlioz-Torrent[2], N. Gupta-Rossi[1], A. Echard[1]; [1]Pasteur Institute, Paris, FRANCE, [2]Cochin Institute, Paris, FRANCE.

Cytokinesis is the last step of cell division, leading to the physical separation of daughter cells. In animal cells, a dense structure located at the centre of the intercellular bridge, called the Midbody (MB), recruits the proteins necessary for abscission. The abscission occurs successively on each side of the MB, releasing a Midbody Remnant (MBR). The MBR is inherited asymmetrically by one of the daughter cells, and then roams over the cell surface during several hours before being eventually internalized and degraded in lysosomal compartments. Distinct MBR release and accumulation behaviours have been

observed according to the cell type, suggesting post-cytokinetic roles for MBRs. Interestingly, it has been proposed that the MBR could act as a signalization platform and regulate cell fate. For instance, the MBR has been shown to contribute to establishing the dorso-ventral axis in *C.elegans* embryo, and promoting primary ciliogenesis in mammalian cells. Despite the new focus on the post-mitotic roles of the MBR, the molecular mechanisms underlying these functions are still unknown but recent evidence indicates that its interaction with the cell surface promotes cell proliferation. However, which proteins interact and retain the MBRs at the cell surface are still poorly understood. Using MS/MS proteomic analysis of pure MBRs from human HeLa cells, we identified a tethering factor that is enriched at the midbody both during cytokinesis and on post-cytokinetic MBRs. Using the CRISPR/Cas9 knock-out technology, we reveal that this tethering factor is recruited to the MB prior to abscission, and then promotes the anchoring of the MBR at the cell surface, thus preventing its release. Mechanistically, a mutant form of this protein is unable to localize properly at the MB, and cannot efficiently tether the MBR. Intriguingly, this protein also promotes virion attachment to the cell surface. This work sheds new light on how MBRs remain attached to the cell surface, and reveals a new and unexpected parallel between viral restriction and cytokinesis.

Coacervates of the Chromosomal Passenger Complex (CPC) Promote Microtubule Nucleation to Generate Complex Microtubule Structures.

E. Niedzialkowska, P. Stukenberg; University of Virginia, Charlottesville, VA.

The Chromosomal Passenger Complex (CPC) is a major regulator of mitosis. It is composed of kinase Aurora B and its regulatory subunits Survivin, Borealin, and INCENP. The CPC interacts with complex microtubule structures in *vivo* including preformed K-fibers and spindle midzones in anaphase. Recently we have found that ISB, a subassembly of the CPC composed of $INCENP^{1\text{-}58aa}$, Survivin and Borealin can form liquid demixed coacervates in *vitro* that concentrate free tubulin. Moreover, the CPC coacervates nucleate microtubules at concentrations of free tubulin below the critical concentration and bundle these microtubules into complex structures. We hypothesize that the CPC directly nucleates and bundles microtubules in preformed K-fibers and midzones. We have purified the full *Xenopus* CPC complex from *E. coli* and show that it undergoes phase separation similar to the ISB subassembly. CPC coacervates also induce microtubule nucleation, polymerization, and bundling in *vitro*. This reaction is rapid, and occurs below the critical concentration of tubulin. Activating Aurora B kinase activity by adding ATP generates distinct structures from those generated in the absence of kinase. Prc1 (protein required for cytokinesis 1), the midzone-associated microtubule crosslinker, interacts with microtubules nucleated by the CPC and further organizes them into more complex structures. We suggest the CPC generates nonmembranous organelles at inner centromeres and midzones to nucleate microtubules to generate complex microtubule structures that are essential for faithful chromosome segregation and cytokinesis.

P1105/B231

Critical Roles of a Rhogef-anillin Module in Septin Architectural Remodeling during Cytokinesis.

X. Chen, K. Wang, T. Svitkina, E. Bi; University of Pennsylvania, Philadelphia, PA.

Critical roles of a RhoGEF-anillin module in septin architectural remodeling during cytokinesis Xi Chen*, Kangji Wang*, Tatyana Svitkina, and Erfei Bi How septin architecture is remodeled from an hourglass to

a double ring during cytokinesis in fungal and animal cells remains unknown. Here, we show that septins in budding yeast form a striking "zonal architecture" in which paired filaments along the mother-bud axis lay the foundation for the entire transitional hourglass whereas the RhoGEF Bud3, the anillin-like protein Bud4, and circumferential single filaments localize exclusively to the outer zones while the myosin-II filaments occupy the middle zone. Deletion of *BUD3* or its coding sequence for the Bud4-interacting domain, but not the RhoGEF domain, completely abolishes single filament assembly whereas deletion of *BUD4* or its coding sequence for the anillin-homology and PH domains, which also mediate its interaction with Bud3, destabilizes the transitional hourglass, especially at the mother side. This and further analysis indicate that Bud3 stabilizes the single filaments whereas Bud4 fastens the junction between the paired and single filaments. Not surprisingly, deletion of *BUD3* and *BUD4* together abolishes transitional hourglass and double ring assembly. We also demonstrate that the septin double ring is dispensable for cytokinesis unless the actomyosin ring is also compromised. Thus, the two cytokinetic structures, which are pre-patterned by and simultaneously generated from the transitional hourglass, normally act in concert to ensure efficient cytokinesis. This study establishes a mechanism and function for the role of a RhoGEF-anillin module in septin architectural remodeling at the cell division site.

P1106/B232

Aurora B Functions at the Apical Surface After Specialized Cytokinesis during Morphogenesis in *C. Elegans*.

X. Bai[1], M. Melesse[2], C. Sorensen-Turpin[2], C. Chen[3], W. Wang[3], P. Lee[3], D. Sloan[4], J. Simmons[2], B. Nebenfeuhr[5], D. Mitchell[6], L. Klebanow[7], N. Mattson[8], E. Betzig[9], B. Chen[3], D. Cheerambathur[10], **J. Bembenek**[4]; [1]NIH, Bethesda, MD, [2]University of Tennessee, Knoxville, TN, [3]Academia Sinica, Taipei City, TAIWAN, [4]University of Michigan, an n Arbor, MI, [5]University of Colorado, Boulder, Boulder, CO, [6]University of Idaho, Moscow, ID, [7]Parker Hannefin, Macedonia, OH, [8]USFDA/CDER/OPQ/OBP/DBRRI, Silver Springs, MD, [9]Janelia Research Campus, Ashburn, VA, [10]University of Edinburgh, Edinburgh, UNITED KINGDOM.

While cytokinesis has been intensely studied, the way it is executed during development is not well understood, despite a long-standing appreciation that various aspects of cytokinesis vary across cell and tissue types. To address this, we investigated cytokinesis during the invariant *C. elegans* embryo lineage and found several reproducibly altered parameters at different stages. During early divisions, furrow ingression asymmetry and midbody inheritance is consistent, suggesting specific regulation of these events. During morphogenesis, we found several unexpected alterations to cytokinesis including apical midbody migration in polarizing epithelial cells of the gut, pharynx and sensory neurons. Aurora B kinase, which is essential for several aspects of cytokinesis, remains apically-localized in each of these tissues after internalization of midbody ring components. Aurora B inactivation disrupts cytokinesis and causes defects in apical structures, even if inactivated post-mitotically. Therefore, cytokinesis is implemented in a specialized way during epithelial polarization and Aurora B has a new role in the formation of the apical surface.

P1107/B233

Actin-independent, Microtubule-dependent Cytokinesis In*Chlamydomonas*.

M. Onishi[1], J. E. Little[2], T. Frej[3], J. R. Pringle[1]; [1]Stanford University, Stanford, CA, [2]Gunn High School, Palo Alto, CA, [3]Carnegie Institution for Science, Stanford, CA.

Cytokinesis in unikonts (animals, fungi, slime molds, and their close relatives) involves the "contractile ring", which contains F-actin, myosin II, and other proteins. The force generated by actin-myosin II interaction is widely viewed as the primary driver of cleavage-furrow ingression. However, many types of unikont cells can form furrows even in the absence of normal myosin-II activity. Furthermore, the wide diversity of non-unikont eukaryotes do not possess myosin II, yet most of them divide by furrowing, using mechanisms that are very poorly understood. Thus, we lack understanding of the division mechanism of the last eukaryotic common ancestor and thus of the true role and evolutionary advantage of the contractile ring in the unikonts.To address these questions, we are studying the mechanisms of cytokinesis in *Chlamydomonas*, an alga that has no myosin II yet divides by forming cleavage furrows. We previously showed that although F-actin is enriched in the cleavage furrow, it is dispensable for its ingression. Unexpectedly, division of the large chloroplast was delayed in these cells, suggesting a novel role for F-actin in coordinating the timing and location of cell division and chloroplast division. The furrows formed in the absence of F-actin are still associated with microtubules, and pharmacological dissolution of microtubules completely blocked furrowing, indicating that these cytoskeletal elements, unlike F-actin, are essential for furrow formation. Furthermore, the localization and movements of the plus-end-binding protein EB1 and the minus-end-directed kinesin KCBP suggest the possibility that stable rootlet microtubules located in the furrow region act as non-centrosomal organization centers for nucleation of other, more dynamic microtubules that may be involved in membrane addition to the furrow region, similar to the furrow-associated array in animals and the phragmoplast in plants. The implications of these observations for the evolution of eukaryotic division mechanisms will be discussed.

P1108/B234

The DNA Repair Protein Nopo Has a Mitotic Function That Suppresses Neuronal Stress Response to Prevent Microcephaly.

R. S. O'Neill, C. J. Fagerstrom, N. M. Rusan; National Heart, Lung, and Blood Institute, NIH, Bethesda, MD.

Microcephaly is a reduction in brain size caused by a loss of neuronal proliferation and survival. Most genes linked to microcephaly primarily function at either the mitotic spindle or in DNA replication and repair (DRR) pathways, and thus microcephaly is thought to arise via one of two pathways. However, in many cases the precise roles of microcephaly-related genes in brain development have not been studied directly. One such gene is *TRAIP*, which is mutated in a severe form of microcephaly and is well studied for its roles in DRR. Accordingly, *TRAIP* microcephaly is thought to arise via delays in S-phase and accumulation of DNA damage. We characterized *nopo*, the *Drosophila* homolog of *TRAIP*, and found a novel mitotic function, thereby linking the two microcephaly pathways in a single gene. *nopo* mutants have microcephaly-like defects in a pair of brain structures called the mushroom bodies (MBs). MBs are normally made of ~2000 neurons that arise from four neuroblasts (NBs); *nopo* mutant MBs have reduced size and neuron numbers. Contrary to its canonical role in DRR, we did not find evidence for increased DNA damage in *nopo* mutant MB neurons or NBs. Instead, the MB NBs of *nopo* mutants are

often multi-nucleate, suggesting mitotic failure, and are progressively lost during development via caspase-dependent cell death. Consistent with its established DRR functions, Nopo has nuclear localization during interphase; however, it has dynamic localization in mitosis, streaming along mitotic spindles and concentrating at the cytokinetic furrow. Deleting the nuclear localization sequence (NLS) evicts Nopo from the nucleus during interphase, presumably abrogating any DRR functions; nonetheless, expressing Nopo lacking the NLS fully rescues the *nopo* mutant microcephaly-like phenotype. Together, these results reveal a novel mitotic function for *nopo* that is critical for neurogenesis, thus raising questions about the current model of *TRAIP* microcephaly and whether other microcephaly-related genes also play dual roles. Finally, by screening for downstream pathways in *nopo* mutants, we discovered that inhibiting the neuronal stress pathway MAP3K *wnd*/*DLK* suppresses microcephaly-like phenotypes. Thus, the *wnd*/*DLK* pathway is identified as a novel key factor and is a potential therapeutic target for minimizing neuron loss in microcephaly.

P1109/B235

Physical Integration within *Xenopus* Egg Extract Microtubule Asters Suggests Aster Movement Is Driven by Dynein-dependent Surface Forces and Actomyosin Contraction.

J. Pelletier[1,2,3], C. Field[1,2], S. Fürthauer[4], N. Fakhri[3], T. Mitchison[1,2]; [1]Harvard Medical School, Boston, MA, [2]Marine Biological Laboratory, Woods Hole, MA, [3]Massachusetts Institute of Technology, Cambridge, MA, [4]Flatiron Institute, New York, NY.

The eukaryotic cytoplasm includes dynamic networks of cytoskeletal polymers and membranous organelles that mutually interpenetrate and mechanically interact via steric and molecular interactions. During telophase, forces on astral microtubules cause centrosomes to move away from the division plane to partition into daughter cells and position the cleavage furrow. In *Xenopus laevis* eggs, centrosomes travel hundreds of microns away from the midplane after anaphase of first mitosis. This occurs before astral microtubules reach the cortex, so forces must be generated within bulk cytoplasm. Two related questions are unanswered: How are asymmetric forces on asters generated, and do asters move relative to other cytoplasmic components, or collectively with them? Using *Xenopus* egg extracts, we co-imaged microtubules, F-actin, endoplasmic reticulum (ER), mitochondria, and a soluble probe in interphase asters as they grew, interacted, and moved. Aster movement was triggered in two ways: away from boundaries where asters interacted, and by dynein attached to the coverslip, which caused periodic motion under some conditions. Within moving asters, multiple cytoplasmic networks tended to move in the same direction at the same velocity, suggesting physical integration. Photorelease of soluble fluorescein showed that even small molecules are advected with the moving aster network. Dynein-mediated transport did cause inwards movement of ER and mitochondria. Inwards velocity was maximal at aster surfaces, suggesting force generation by organelle-bound dynein is mostly restricted to the aster surface. Centrosomes moved predictably away from aster boundaries, leading to regular spacing of the centrosomes. We expected this movement to be dynein-dependent, but inhibition experiments revealed a large role for actomyosin contraction away from regions of low actin density at aster boundaries. Our results inform a multicomponent active gel model of aster movement, in which dynamic, interpenetrating cytoplasmic networks mechanically interact to separate centrosomes and position the egg cleavage plane.

P1110/B236

Excitable Extract Makes Waves.

J. Landino[1], M. Leda[2], A. Michaud[3], W. Bement[3], A. Vecchiarelli[1], A. Goryachev[2], A. L. Miller[1]; [1]University of Michigan, an n Arbor, MI, [2]University of Ediburgh, Edinburgh, UNITED KINGDOM, [3]University of Wisconsin, Madison, WI.

Reconstitution of biological systems is an essential tool for uncovering the molecular mechanisms that underlie cellular function. Here we describe the development of an *ex vivo* system that reconstitutes cortical excitability on a supported lipid bilayer. In cells, cortical excitability is a phenomenon characterized by waves of active Rho (Rho-GTP) and actin polymerization that are thought to "prime" cells to initiate actomyosin-dependent events such as cytokinesis and cell migration. Our group has previously characterized cortical excitability in developing *Xenopus laevis* embryos and starfish oocytes[1]. We found that cortical waves are amplified by overexpression of the RhoGEF Ect2 and inhibited by actin filaments (F-actin). These results suggest that cortical excitability exists as an activator-inhibitor system, where both positive (Ect2-dependent) and negative (F-actin-dependent) feedback loops exist simultaneously to induce wave formation and propagation. We have generated an excitable *ex vivo* system using actin-intact *Xenopus* egg extract on a supported lipid bilayer[2]. These components sufficiently reconstitute a robust wave of Rho-GTP followed by a wave of actin polymerization. The phase shift between the waves of Rho-GTP and F-actin is comparable to in *vivo* cortical waves. This single wave, however, is quickly extinguished by the formation of a dense network of bundled actin filaments, which inhibits continued wave propagation. We find that adding a drug that inhibits actin polymerization creates an environment where multiple waves of Rho-GTP can travel, unobstructed, on the bilayer. These propagating waves of active Rho have a regular periodicity and exhibit patterning that closely resembles F-actin waves in *Xenopus* embryos. This work raises new questions about F-actin-mediated negative feedback in cortical excitability; for example, how is active Rho "turned off" in the absence of actin polymerization? Additionally, the excitable extract system provides a powerful environment for investigating the role of RhoGAPs, select lipids (e.g. $PI(4,5)P_2$, $PI(3,4)P_2$), as well as other downstream effectors (Anillin, Myosin II), in mediating negative feedback that regulates cortical wave patterning. 1. Bement *et al*. (2015) Activator-inhibitor coupling between Rho signaling and actin assembly make the cell cortex an excitable medium. *Nat Cell Biol*. 17(11): 1471-1483. 2. Nguyen *et al*. Intramolecular Regulation of an illin during Cytokinesis.

D. Beaudet, N. Pham, N. Skaik, A. Piekny; Concordia University, Montreal, QC, CANADA.

Cytokinesis describes the separation of a cell into two daughters, which occurs due to the ingression of an actomyosin ring. Cytokinesis must occur with high fidelity to avoid fate changes and aneuploidy. Recently, we uncovered a novel mechanism whereby the ring protein anillin is regulated by importins during cytokinesis. Importins bind to cargo proteins that contain nuclear localization signals (NLS) and mediate their transport into the nucleus. Active Ran is enriched in the nucleus and competes with importins to release the cargo. During mitosis, the Ran gradient persists around chromatin, where it regulates spindle assembly. The dogma is that importins bind to the NLS of spindle regulators to block interactions with partners required for their function. Thus, active complexes assemble the spindle near

chromatin, where active Ran is high. Our data supports a very different function for the regulation of cortical proteins by importin-binding. We found that importins function as a ruler during cytokinesis, where optimal levels facilitate anillin's cortical recruitment. This mechanism permits precise sensing of chromatin position to ensure that the contractile ring is properly positioned. Here, we determined how importin-binding regulates anillin's cortical enrichment. An illin has a RhoA-binding domain (RBD) required for recruitment to the equatorial cortex, and we found that the RBD autoinhibits the adjacent NLS-containing C2 domain. Our model is that binding to active RhoA causes a conformational change in anillin that increases accessibility to the C2 domain, and importin-binding stabilizes this change for cortical recruitment. Our data supports this model. We found that active RhoA facilitates importin-binding, while inactive RhoA or mutating the RBD decreases importin-binding. Through live-imaging and FRAP experiments we found that mutating the NLS alters anillin's cortical properties. An illin's localization and function are abolished when NLS mutations are combined with mutations that weaken the interface between the RBD and C2 domain. Stronger interface mutations similarly fail to localize to the furrow and rescue loss of endogenous anillin. This data shows that the interface is crucial to drive feedback between the C2 domain and the RBD for recruitment to the equatorial cortex. We propose that other cortical proteins could be regulated by importin-binding during mitotic exit, and to reconsider the dogma of how importin-binding could impact protein function.

Detection of Key Proteins of the Chromosomal Passenger Complex in Different Phases of Mitosis.

A. Ketkar, A. Chandrasekaran, S. Raj S; Thermo Fisher Scientific, Bangalore, Bangalore, INDIA.

The accurate and timely orchestration of chromosomal, cytoskeletal events regulated by the chromosomal passenger complex (CPC) leads to seamless cell division. CPC is a heterotetrameric complex consisting of an enzymatic component Aurora B along with three regulatory components INCENP (Inner centromere protein), Survivin and Borealin which are responsible for the activity and the localization of the Aurora B kinase. The CPC dynamically localizes to different subcellular locations to regulate key mitotic phases such as correction of kinetochore-microtubule attachment errors, activation of the mitotic spindle assembly checkpoint as well as assembly and maintenance of the outer kinetochore. Loss of CPC function results in lagging chromosomes, segregation errors and cytokinesis failures. This promotes genomic instability, which contributes to oncogenesis by altering the balance of critical growth and death pathways, along with the overall expression of oncogenes and tumor suppressors. Given their importance, it is imperative to have antibodies that specifically recognize these proteins and work in different functional assays. Towards this we have developed &/or validated antibodies against Aurora B, Plk1, INCENP and Survivin in relevant cell models, applications (Western blot and Immunocytochemistry) as well as confirmed for specificity using cell treatment, relative expression (different phases of cell cycle) and knock-down approach. The data demonstrates that during cell division, CPC localizes along the chromosome arms and at centromeres during prophase. It is restricted to the inner centromere region from prometaphase to metaphase. During anaphase, it moves to the central spindle microtubules and finally accumulates in the mid-body region at telophase thus establishing differential subcellular localization of CPC proteins during different phases of mitosis.

Cytoskeletal Networks Inhibit Contractile Ring Assembly and Ingression.

A. Koscove, M. Glotzer; the University of Chicago, Chicago, IL.

The GTPase RhoA is a central regulator of cytokinesis in metazoan cells. Failure to activate this GTPase blocks cleavage furrow formation. Conversely, local RhoA activation induces the formation of an ingressing furrow. RhoA activation can be induced with a high level of spatiotemporal control in any region of the cell cortex with a light-controlled probe that modulates recruitment of RhoGEF to the plasma membrane (Wagner & Glotzer, 2016). Local RhoA activation suffices to induce a furrow in anaphase cells, mitotic cells, and rounded interphase cells. However, light-mediated RhoA activation fails to generate a cytokinetic furrow in adherent interphase cells with strong actin networks present. To determine whether cell adherence or the presence of cytoskeletal networks interferes with the ability of a cell to assemble an ingressing contractile ring in response to optogenetic RhoA activation, we generated adherent interphase HeLa cells lacking robust actin networks. Upon activation, adherent cells with robust cytoskeletal elements accumulated additional actin and myosin in pre-existing networks, but lacked the ability to form a furrow. In contrast, adherent cells lacking stress fibers were able to build contractile rings and ingress. These results indicate that pre-existing actin networks may block the formation of a contractile ring, and that cell rounding during mitosis and cytokinesis may enhance the disassembly of cytoskeletal structures, thereby permitting contractile ring assembly.

P1114/B240

The Kinetic Landscape and Interplay of Protein Networks in Cytokinesis.

H. Okada, B. MacTaggart, E. Bi; University of Pennsylvania, Philadelphia, PA.

Cytokinesis is a complex process involving force production, membrane trafficking, and extracellular matrix (ECM) remodeling. While individual proteins have been analyzed for their roles in cytokinesis in different model systems, the behaviors and interplays of protein networks involved in distinct aspects of cytokinesis have not been analyzed in any system. To address this question, we attempt to determine the accumulation kinetics of all major cytokinetic proteins in budding yeast using quantitative live cell imaging. We quantified more than twenty GFP-tagged core cytokinetic proteins involved in each of the functional modules such as assembly and constriction of the actomyosin ring (AMR), and formation and degradation of ECM. Strikingly, individual proteins involved in different functional modules showed module-specific patterns, reaching their peaks at the division site in a strict temporal order. These data suggest that cytokinesis is accomplished by distinct and sequentially acting modules. Proteins that are known to function in two different modules displayed a peak between the peaks of the two modules. For example, Iqg1 (yeast IQGAP) is known to function in AMR assembly and ECM formation, and Iqg1 reached its peak between the peaks of Myo1 and Chs2, which play an essential role in AMR assembly and ECM formation, respectively. Thus, the unique accumulation kinetics of Iqg1 likely reflects its function in coupling AMR to ECM formation. To determine the interplays between protein networks, we deleted *CYK3* (*cyk3*Δ), which encodes a putative activator of Chs2, and then monitored its impact on ECM formation (Chs2) and AMR constriction (Myo1). We found that the localization kinetics of Chs2 in *cyk3*Δ was comparable to that of Chs2 in wild-type cells until the peak, but disappeared significantly slowly, which was coupled with delayed AMR constriction. This phenotype was also observed in the *chs2* mutant whose catalytic activity is substantially reduced. This result supports the postulated molecular function of Cyk3 and indicates that a defect in PS formation can feedback to AMR constriction. Taken

together, our study indicates that proteins involved in cytokinesis are organized into distinct functional modules and connectors, each with a unique accumulation profile at the division site. This comprehensive analysis is significant not only for understanding cytokinesis at the system level, but also for predicting functions of those proteins with a defined accumulation pattern at the division site during the cell cycle.

P1115/B241

Understanding Central Spindle Assembly and Maturation in the *C. Elegans* Embryo.

S. M. Hirsch[1], F. Edwards[2], M. Shirasu-Hiza[1], J. Dumont[2], J. C. Canman[1]; [1]Columbia University, New York, NY, [2]Institut Jacques Monod, Paris, FRANCE.

Cytokinesis in animal cells is driven by constriction of an equatorial actomyosin contractile ring that is dependent on the central spindle, an antiparallel bundled array of microtubules that forms between chromosomes in early anaphase and matures to form the midbody. The central spindle has at least two functions in cytokinesis: the early central spindle controls contractile ring constriction and the final mature midbody serves as a template for abscission, the final step of physical separation of the daughter cells. While the early stages of central spindle formation (microtubule nucleation and bundling) have been well studied, less is known about how the central spindle changes morphologically throughout cytokinesis and forms the mature midbody. In the one-cell *C. elegans* embryo, early central spindle formation is controlled by CLASP^{CLS-2}, which is localized by BUB-1 and CENP-F$^{HCP-1/2\ and}$ nucleates central spindle microtubules just after anaphase onset, and by microtubule crosslinking protein PRC1$^{SPD-1\ and}$ the centralspindlin complex, which bundle central spindle microtubules. Using genetic mutants as a sensitized background, we are currently taking a targeted, candidate-based RNAi approach to identify molecules that transform this early central spindle into the midbody and promote cytokinesis. This work will reveal novel insights into how this dynamic signaling hub forms and supports successful cell division.

Type 2 Interphase Node Proteins Operate in Tandem to Localize Sid2p to the Contractile Ring for Timely Completion of Cell Division.

S. Stensland, E. M. Magee, J. W. Goss; Wellesley College, Wellesley, MA.

The conserved NDR-family kinase Sid2p is the terminal member of the Septation Initiation Network (SIN) signaling pathway that localizes to the contractile ring during fission yeast cytokinesis to promote ring constriction, septation, and completion of cell division. Previous studies have found that the Type 2 interphase node proteins Blt1p, Gef2p, and Nod1p contribute to localization of Sid2p and its regulatory protein Mob1p at the division site. This in turn promotes constriction of the contractile ring and completion of septation. However, their relative contributions and whether they operate in the same or parallel pathways has been unclear. In this study, we quantify the respective roles of Blt1p, Gef2p, Nod1p, and Klp8p in Sid2p/Mob1p recruitment and characterize the effect of single, double, and triple deletion mutants on contractile ring dynamics and completion of cell division. We find that the Type 2 interphase node proteins work in the same pathway to localize the NDR-family kinase Sid2p and its regulatory partner Mob1p to the division site, thereby promoting timely completion of cell division.

P1117/B243

Coarse-grained Simulations of Cytokinetic Node Protein Mid1 and Path to Dimeric Structure.

A. Hall, B. G. Horan, D. Vavylonis; Lehigh University, Bethlehem, PA.

The anchoring of the cytokinetic ring at the cell equator in animals and fungi depends crucially on the anillin scaffold proteins. During fission yeast mitosis, annilin-related Mid1 binds to the plasma membrane and helps establish cytokinetic nodes in a broad band near the cell center. Recent experiments revealed that Mid1 consists of a globular domain with two potential regions for membrane binding and an N-terminal intrinsically disordered region that is regulated by phosphorylation. We used the available structural information in molecular dynamics simulations with an established coarse grained potential to explore the possible modes of Mid1 binding to the membrane and its dimerization/multimerization properties. The coarse-grained model used represents each residue by a single interaction site located at the Cα atom. Mid1 globular domains were treated as rigid bodies fixed in their known crystallographic structure. Disordered regions were treated as flexible and simulations reproduced prior measurements of their radius of gyration. Replica exchange simulations of the ordered regions identified possible binding modes of the Mid1 dimer. This informed a Mid1 membrane-bound model, which was shown to preferentially reinforce the dimer binding mode seen in prior X-ray crystallography data. Fixing binding modes of interest and adding in disordered regions allowed us to investigate how membrane-bound Mid1 may fill space in nodes and compare these results to recent super-resolution node measurements. In the future, this method may help resolve Mid1 structural interactions in nodes.

An Engineered System for Measuring Multimeric Nuclear Protein Interaction Dynamics in Live Cells Enables a Quantitative Understanding of the Cell-cycle Entry Decision.

L. H. Daigh, L. R. Pack, T. Meyer; Stanford University, Stanford, CA.

Protein-protein interactions are a critical regulatory point for many cellular processes. Characterizing interactions between proteins has traditionally been performed through biochemical techniques. However, this approach neglects contributions from the cellular environment. Fluorescence recovery after photobleaching (FRAP) can be used to quantify biomolecular interactions in living cells, but measurement of interactions between freely diffusing proteins is not amenable to FRAP. Herein, we present a generalizable method for quantifying interactions between nuclear proteins in live cells. To achieve this, we tethered one interaction partner to an engineered, stabilized nuclear lamin construct and fluorescently labeled other interaction partners, enabling FRAP-based measurement of off-rates. Moreover, we demonstrate that our technique can be used for both chemical and genetic perturbations of protein interactions. We therefore present a powerful method for achieving a quantitative understanding of complex cellular-level interaction networks. We applied this method to systematically measure off-rates between the cyclins, cyclin-dependent kinases (CDKs), and CDK inhibitory proteins (CIPs) that regulate G1-phase cell-cycle progression. We found that both the CDK4/6-cyclin D interaction and CDK2-cyclin E interaction are moderately strong, and interaction strength is greatly increased in the presence of CIPs. Interestingly, we also detected transient binding of CDK2 to cyclin D1. We then investigated how various disease-causing mutations in cyclin D1 and p16 affect CDK4 binding,

correlating interaction strength to cellular phenotype. Finally, we analyzed how inhibition of major growth-signaling pathways can alter G1 regulator protein-protein interactions. Thus, our method enabled a quantitative molecular understanding of how major G1 regulatory proteins dictate cell-cycle entry decisions.

Mitogen-independent Cell Cycle Progression in B Lymphocytes.

A. Singh[1], M. Spitzer[2], J. P. Joy[1], G. P. Nolan[2], R. Sen[1]; [1]Gene Regulation Section, Laboratory of Molecular Biology and Immunology, National Institute on Aging, Baltimore, MD, [2]Microbiology and Immunology - Baxter Labs, Center for Clinical Sciences Research, Stanford, CA.

Clonal expansion determines effectiveness of adaptive immune responses where activation of lymphocytes leads to selection of a tiny proportion of lymphocytes to proliferate robustly and execute the immune program. Proliferation studies in lymphocytes are carried out with persistent mitogenic stimulation, presumably reflecting our bias that mitogenic re-stimulation is necessary to get robust clonal expansion. The classical view, obtained largely from population analyses of fibroblasts, posits that a mitogenic signal is required at the end of each mitosis for cells to progress through the next G1 phase. However, recent analyses of tumor cell lines have shown that a subset of cells within a population retains the ability to undergo G1 progression without additional signaling. For B lymphocytes the germinal centers (GC) proliferation shows good evidence of mitogen-independent proliferative phase in dark zone (DZ). Even, CD8+ T cells have been shown to have similar properties, suggesting that this may be a common feature of cell cycle regulation in lymphocytes. Despite its uniqueness and likely physiological relevance, this form of proliferation has received scant attention. Our study characterizes mitogen-independent proliferation in primary murine B lymphocytes. We demonstrate that, regardless of the initiating stimulus, commitment to DNA replication (S phase) programs B cells to undergo several rounds of cell division in the absence of overt mitogenic signaling and the extent of division is limited by cell death rather than by return to quiescence. High dimensional cytometry identifies mitogen-independent cell cycle progression is driven by unique characteristics of the G1 phase of cells that have divided once, large cell size, low levels of p27 and phosphorylated-Rb. In contrast to studies in cell lines, B cell division under these conditions requires CDK4/6 activity to traverse the second G1 phase. Transcriptional and protein analyses revealed up-regulation of survivin (Birc5) in the G1 phase of B cells past first mitosis and pharmacological inhibition of survivin function blocked G1 progression of cells undergoing mitogen-independent proliferation, but not of naïve B cells stimulated with mitogens. These observations indicate that, in contrast to textbook models of the cell cycle, B cells inherit a partially active G1 phase after cell division that permits them to move quickly to the next S phase in the absence of exogenous G1 progression signals. We propose that these mechanisms may assist in rapid cell division without differentiation that is required for clonal expansion in response to antigen and in B cell proliferation in the GC-DZ.

Understanding the Effects of Atrazine on Human Keratinocytes.

A. An tonyan, S. Cholak, V. Krajcz, F. Volpe, R. Belanger, N. A. Najor; University of Detroit Mercy, Detroit, MI.

Atrazine is the second most used herbicide in the United States and the most common chemical detected in American groundwater. Despite being banned from various European countries, the EPA has deemed concentrations below 3.0 parts per billion (ppb) to be safe for use. Atrazine can enter the body via inhalation, ingestion, or penetration where it is then converted into metabolites in the bloodstream. Many studies have labeled atrazine as a carcinogen due to the reproductive defects it causes in rats, fish, and amphibians at levels as low as 0.1 ppb. In 2009, the herbicide was observed as being a potential cause of birth defects and reproductive complications in humans (Pathak, Dikshit; 2011). Some reports have also shown that atrazine causes mitochondrial dysfunction in human liver cells (HepG2). While it is known that atrazine can have an impact on many organ systems, its effect on the skin remains understudied. The importance of this research is underscored by the fact that the skin is our first line of defense and primary means to combat toxins, ultraviolet radiation, and mechanical insults. The goal of this research is to identify whether exposure to atrazine could promote a cancerous phenotype in human keratinocytes. We hypothesize that higher levels of atrazine may act as a carcinogen, affecting cell cycle, adhesion, and morphology.To identify this effect, keratinocytes were exposed to varying concentrations of atrazine that exceeded the EPA's standards. Immunofluorescence was employed to visualize DNA double-stranded breaks with the marker γH2AX, a version of the H2A protein that composes the histone octamer and gets phosphorylated upon DNA damage. Additional cell cycle markers and DNA damage pathways were investigated in keratinocytes treated with atrazine. Our preliminary data suggests that that keratinocytes treated with increasing atrazine concentrations induces DNA damage, alters cell morphology, and causes changes in cell adhesion.Knowledge gained from this work will provide new insights into a previously understudied area.

A Heterogeneous Nuclear Ribonucleoprotein (hnRNP) Homolog in Chlamydomonas Functions as a Cell-cycle Repressor in the Retinoblastoma Cell-size Control Pathway.

D. Liu[1,2], C. Lopez-Paz[1], J. Umen[1]; [1]Donald Danforth Plant Science Center, Saint Louis, MO, [2]University of Missouri, St. Louis, Saint Louis, MO.

Coordination of growth and division in eukaryotic cells is thought to be mediated by cell-size checkpoints, but the mechanisms for size homeostasis are largely unknown. The green alga *Chlamydomonas reinhardtii* divides by a multiple fission cell cycle, where two control points are used to couple cell size to cell cycle progression: the Commitment checkpoint ensures that enough growth has taken place to allow completion of at least one division cycle, and the DNA synthesis/mitosis (S/M) checkpoint ensures mother cells undergo the correct number of divisions to produce uniform-sized daughters. The *tny1-1* mutant was identified in a forward insertional mutagenesis screen and exhibits a recessive small-size phenotype due to defects at both the Commitment and the S/M size checkpoints. *TNY1* encodes a predicted hnRNP A-related RNA binding protein with two N-terminal RNA recognition motifs (RRMs) and a low complexity glycine-rich C-terminus, a structure shared by many other of eukaryotic hnRNPs. Immunofluorescence showed that TNY1 is cytosolic throughout the cell cycle. Immunoblotting revealed that daughter cells are born with a fixed amount of TNY1 whose absolute

abundance remains constant on a per-cell basis during G1 phase, but whose overall cellular concentration decreases as cells grow. *TNY1* mRNA and protein levels peak during cell division and are reset to their highest concentration in newly-formed daughters. Altering the dosage of TNY1 in diploids or by overexpression impacted daughter cell size, indicating a quantitative relationship between TNY1 protein levels and mitotic size control. Epistasis experiments placed TNY1 upstream of the cyclin dependent kinase CDKG1 [1], whose substrate is the MAT3/RB (retinoblastoma tumor suppressor homolog). CDKG1 is produced just before cells divide and is eliminated upon mitotic exit, but in *tny1-1* strains post-mitotic CDKG1 remains detectable, suggesting that TNY1 inhibits CDKG1 production or turnover. North-Western assays showed that TNY1 binds to the unusually long and uridine-rich 3' UTR of *CDKG1* mRNA but not to its CDS or 5' UTR. Taken together, our data suggest a model where TNY1 influences cell-size homeostasis through dosage-dependent repression of the activator CDKG1, possibly mediated through direct binding of TNY1 to the *CDKG1* 3'UTR. Experiments to test this model are ongoing. [1] a new class of cyclin dependent kinase in Chlamydomonas is required for coupling cell size to cell division. (2016). eLife 5, e10767.

Human Cdc14A and Cdc14B Affect Cell Cycle Progression through Their Impact on Ciliogenesis.

P. Partscht[1], B. Uddin[2], E. Schiebel[1]; [1]Zentrum für Molekulare Biologie der Universität Heidelberg, Heidelberg, GERMANY, [2]University of Bristol, Bristol, UNITED KINGDOM.

Budding yeast Cdc14 phosphatase has a central role in cell cycle regulation, most prominently in mitotic exit and cytokinesis. Puzzlingly, a uniform picture on the function of the three human hCDC14 paralogues hCDC14, hCDC14B and hCDC14C in cell cycle control has not emerged to date. An explanation for this deviation may be the functional redundancy of the three phosphatases or the only partial depletion of the hCDC14 phosphatase by siRNA in human cells. To address these possibilities, we tested for the expression of *hCDC14* phosphatases *and* analysed cell cycle progression of cells with single and double deletion of *hCDC14*. Our data suggest that *hCDC14C* is not expressed in human RPE1 and HCT116 cells excluding a function of hCDC14C in both cell lines. Deletion analysis of *hCDC14A*, *hCDC14B* and *hCDC14AB* knockout (KO) RPE1 cells indicates that both phosphatases are not important for global cell cycle regulation. However, *hCDC14A* and *hCDC14AB* KO cells show reduced staining for the proliferation marker Ki-67, reflecting a delay in S phase entry. This delay was caused by the formation of elongated cilia in *hCDC14A* and *hCDC14AB* KO cells. In contrast, *hCDC14B* KO executed S phase faster. An increase in the number of ciliated *hCDC14B* KO cells was identified as the cause for the faster S phase progression. *hCDC14A* and *hCDC14B* KO cells both showed an increase in DNA damage. *hCDC14A*, *hCDC14B* and *hCDC14AB* KO cells did not affect mitotic exit and cytokinesis. Thus, loss of function of hCDC14A and hCDC14B only mildly affects cell cycle progression suggesting that human hCDC14 phosphatases function in other cell processes, such as ciliogenesis.

P1123/B249

Persistent Dna Repair Signaling during Mitosis Facilitates Acentric Dna Segregation.

D. Clay, E. Jezuit, H. Bretscher, D. Fox; Duke University, Durham, NC.

Cells must promptly respond to DNA damage to maintain genome stability. DNA breaks occurring in actively cycling cells frequently lead to DNA damage checkpoint-triggered cell cycle arrest prior to the next cell division. However, some DNA breaks do not trigger these checkpoints. More recently, cellular

responses to DNA breaks that persist into mitosis have been appreciated, but their molecular regulation remains to be fully determined. Uncovering regulation of these responses is crucial, as failure of such responses can lead to micronuclei, which are aberrant nuclear structures formed from persistent broken DNA that are attributed to disease phenotypes. We have established *Drosophila melanogaster* rectal papillar cells (hereafter papillar cells) as a highly accessible model to study how broken chromosomes segregate and avoid micronucleus formation during mitosis. We have previously identified that papillar cells lack active interphase checkpoints and therefore frequently enter mitosis with broken chromosomes. Strikingly, these aberrant chromosome segregate properly despite lacking centromeres/kinetochores. In addition to having inactive interphase checkpoints, we previously showed that papillar cells accumulate persistent DNA breaks during S-phases that occur several days before mitosis. This long delay between DNA breakage and mitosis allows us to easily investigate interphase and mitotic DNA breakage responses separately. Our prior work[1] revealed that conserved Fanconi an emia proteins underlie micronucleus prevention in dividing papillar cells. Here, we report that DNA damage induced during S-phase results in the robust recruitment of homologous recombination repair machinery in papillar cells. However, unlike in cells with active interphase checkpoints, which repair double-stranded DNA breaks within 24 after damage, damaged papillar chromosomes retain specific DNA homologous recombination proteins for several days. These repair proteins are required for papillar cell survival following DNA breakage. Further, these same repair proteins are not present immediately after mitosis, suggesting that repair of broken DNA may initiate in the first interphase after mitosis. We propose that DNA damage which escapes cell cycle arrest requires initiated, but not completed, repair via homologous recombination in order to segregate broken chromosomes. We hypothesize that this mechanism is relevant to any cell with inactive cell cycle checkpoints or in cases where DNA damage persists into mitosis. 1. Bretscher and Fox (2016), *Dev Cell* 37(5):444-57.

P1124/B250

Probing the Mesoscale Rheology of the Metaphase Spindle.

L. Carlini[1], G. Brittingham[2], L. Holt[2], T. Kapoor[1]; [1]Rockefeller University, New York, NY, [2]New York University, New York, NY.

Measuring the viscosity and characterizing the overall structure of the metaphase cytoplasm is critical to understanding spindle mechanics. However, probing this space has been challenging due to a lack of tools that could enter the spindle region with minimal disruption. Here, we study the motion of mesoscale Genetically Encoded Multimeric (GEM) particles during metaphase. Our measurements reveal that GEM diffusivity is ~ 40% higher in the metaphase cytoplasm (0.75 ± 0.13 $\mu m^2/s$) as compared to interphase. To test whether GEM diffusion is driven by the movements of motor proteins during metaphase, we study the anomalous nature of particle trajectories in control cells and after pharmacological perturbations. We further characterize the spatiotemporal variations in cytoplasmic viscosity, including those which are normally associated with materials near the glass transition point. Collectively, these results will classify the physical nature of the metaphase cytoplasm and further our understanding of the forces which must be overcome by the metaphase spindle.

P1125/B251

Size-Dependent Expression of the Cdc13 and Cdc25 Mitotic Activators Redundantly Regulate Cell Size in Fission Yeast.

M. Ohira[1], M. Pickering[1], X. Sun[2], S. Marguerat[2], **N. Rhind**[1]; [1]UMass Med School, Worcester, MA, [2]MRC London Institute of Medical Sciences, London, UNITED KINGDOM.

The coordination between cell growth and division is a highly regulated process that is intimately linked to the cell cycle. Despite a wealth of knowledge about cell growth and division, little is known about the mechanisms that regulate the cell cycle in response to cell size. Efforts to identify a signaling system that measures cell size and conveys that information to the cell-cycle machinery have been unsuccessful. Instead, we propose that size control is an intrinsic function of the basic cell cycle machinery. Using both population-level and single cell assays we have shown that two key positive regulators of the G2/M transition—Cdc13, the B-type cyclin that forms CDK with the Cdc2 kinase, and Cdc25 [1], the phosphatase that activates CDK—accumulate in a size dependent manner. That is, unlike most proteins which maintain a constant concentration as cells grow, Cdc13 and Cdc25 increase in concentration as cells get bigger. Crucially, we have shown that Cdc13 and Cdc25 accumulation is directly proportional to size (i.e., they act as sizers), as opposed to being proportional to the amount of time cells stay in G2 (i.e., they do not act as timers). Since both Cdc13 and Cdc25 are dose-dependent activators of mitosis, their size-dependent accumulation provides a mechanism by which cells can regulate their size [2]. We have shown that Cdc25 is regulated transcriptionally [1]. We have gone on to show that a 100-bp promoter is sufficient to drive size-specific expression of Cdc25. This promoter contains motifs conserved within the promoters of the three other fission yeast species. We will present evidence that this promoter could regulate size-dependent expression via a nuclear-sites-titration model. Cdc13, on the other hand, is regulated translationally or post translationally. Its mRNA maintains a constant, size-independent concentration, but produces a size-dependent concentration of protein. We have localized the determinants of size-dependent expression to the 5' UTR or the ORF. We will continue to narrow down their location, be they in the transcript or protein. 1) Keifenheim et al., (2017) Size-Dependent Accumulation of the Mitotic Activator Cdc25 Suggests a Mechanism of Size Control in Fission Yeast. E2F-dependent Genetic Oscillators Control Endoreplication.

M. Kim, N. Moon; McGill University, Montreal, QC, CANADA.

Polyploidy is an integral part of development and is associated with cellular stress, aging and pathological conditions such as cancer. Across many organisms, the endoreplication cycle, comprised of successive alternations of G and S phases without cell division, is commonly employed to produce polyploid cells. To maintain the endocycle, oscillation of Cyclin E (CycE)/Cdk2 activity is required, where low Cdk2 activity during G phase allows pre-replicative complex (pre-RC) formation and high Cdk2 activity triggers origin firing. Previous studies have identified E2F1 as one of the core molecular machineries that drives the biphasic G-S oscillations. In this study, we provide mechanistic insight on how endoreplication cycles are maintained by E2F proteins. Specifically, we show that the biphasic oscillation of E2F1 and CycE requires the recently described alternate isoform of E2F1, E2F1b, which is

necessary for development of polyploid tissues in Drosophila. The impact of E2F1b deregulation was analyzed using the Fluorescent Ubiquitination-based Cell Cycle Indicator (FUCCI) in actively endoreplicating larval salivary glands. Genetic experiments revealed that E2F1b regulates the circuitry of timely S phase entry and exit during endoreplication by activating a subset of E2F-target genes. E2F1b regulates the Drosophila ortholog of CDK inhibitor Dacapo (Dap) to precisely time S phase entry by controlling the CycE/Cdk2 activity threshold. Dap-mediated inhibition of CycE/Cdk2 allows G phase cells to accumulate CycE and pre-RC components, such as Double Parked/Cdt1, prior to entering S phase. Upon entry to S phase, E2F1b-dependent burst of Proliferating Cell Nuclear antigen (PCNA) expression establishes a negative feedback loop through the PIP box-mediated degradation of E2F1. This mechanism is critical for ensuring proper downregulation of E2F1 target genes and S phase exit. Overall, our study uncovered a network of E2F-dependent genetic oscillators that are critical for the periodic transition between G and S phases during endoreplication.

Investigating the Role of the SWI/SNF Chromatin Remodeling Complex in the Differentiation of the Invasive Phenotype.

J. Smith, N. Parsan, W. Zhang, D. Matus; Stony Brook University, Stony Brook, NY.

The success of many metazoan developmental programs relies on the ability of specialized cells to transgress basement membranes (BMs). Cancer progression also relies on cellular invasion. Though the developmental and clinical importance of cell invasion is evident, studying its dynamics in *vivo* has proven to be challenging. Using high-resolution microscopy, as well as genetic and cell biological techniques, we study the process of anchor cell (AC) invasion into the vulval epithelium during *C. elegans* development as a model for cellular invasion. We have demonstrated that the conserved nuclear hormone receptor transcription factor, NHR-67, is required to maintain the AC in G1/G0 cell cycle arrest, a requirement for invasive behavior. Independent of cell cycle arrest, the AC utilizes the histone deacetylase, HDA-1, for the generation of invadopodia, and the expression of pro-invasive genes. These results suggest that invasion is a differentiated cellular behavior requiring cell cycle arrest and epigenetic modification of the genome. To identify additional chromatin modifiers that mediate invasion, we are conducting a tissue-specific RNAi screen. To date, we have identified several new pro-invasive genes which encode subunits of the SWI/SNF chromatin remodeling complex. *The* SWI/SNF complex is pleiotropic and contributes to cell fate specification in the somatic gonad and cell-cycle exit and differentiation of muscle and intestinal precursors in *C. elegans*. Here, we show a conserved role for the SWI/SNF complex in coordinating cell cycle arrest, as loss of *swsn-1* results in a mitotic AC. We have endogenously GFP-tagged core SWI/SNF subunit SWSN-4 in order to confirm AC expression, and taking advantage of GFP-targeting nanobody technology, we are able to confirm a strong loss of invasion phenotype following SWSN-4::GFP depletion in the AC. Furthermore, we are examining the role of the SWI/SNF complex in maintenance of the post-mitotic state and the regulation of pro-invasive gene expression, through potential interactions with NHR-67, HDA-1, other chromatin modifiers and the cell cycle machinery. Using a DNA Helicase B-based CDK2 biosensor our lab has recently adapted to *C. elegans,* we are investigating the cell cycle state of the AC in chromatin modifier depleted states. Together, these results will provide insight into the role of the SWI/SNF complex in orchestrating invasive activity and coordinating exit from the cell cycle.

Quantitative Proteomics in G_1 Cells Reveals the Insulin Receptor Adaptor IRS2 as an APC/C^{Cdh1} Substrate.

S. Manohar, Q. Yu, S. P. Gygi, R. W. King; Harvard Medical School, Boston, MA.

The anaphase promoting complex/cyclosome (APC/C) is a ubiquitin ligase that controls progression through the eukaryotic cell cycle by targeting key substrates for degradation through the ubiquitin proteasome pathway. During G_1, the APC/C works in concert with its co-activator Cdh1 to recognize and ubiquitinate specific substrates during this phase of the cell cycle. To identify novel pathways and substrates regulated by APC/C^{Cdh1}, we conducted an unbiased proteomic screen in G_1-arrested RPE1 cells acutely treated with small molecule APC/C inhibitors. Combining these results with degron prediction analysis, we uncovered diverse putative APC/C substrates. We validated IRS2, a key adaptor protein involved in signaling downstream of the insulin and IGF1 receptors, as a novel direct APC/C^{Cdh1} target. We demonstrate that genetic deletion of IRS2 reduces the expression of proteins involved in cell division and functionally impairs the spindle assembly checkpoint. Together, these findings reveal a novel connection between the insulin/IGF1 signaling network and the cell cycle regulatory machinery.

P1129/B255

Assessing How Cells Enter and Exit the Endoreplication Cell Cycle.

K. Hartsough[1], S. Chen[2], J. Zhang[2], C. E. Walczak[1]; [1]Medical Sciences, Indiana School of Medicine - Bloomington, Bloomington, IN, [2]Department of Biology, Indiana University, Bloomington, IN.

Endoreplication is an alternative cell cycle wherein cells go through alternating G and S phases without completing mitosis. While endoreplication is a normal cellular mechanism that can be used to generate natural polyploid cells, it can also be co-opted by cancer cells and lead to genome instability and tumor evolution. We have developed a method to generate induced endoreplicating cells (iECs) by treatment with cell cycle kinase inhibitors to define the mechanisms that allow entry into and exit from endoreplication. Inhibition of Aurora B kinase resulted in a type of endoreplication called endomitosis in which cells enter mitosis but do not complete division. Cells treated with higher concentrations of inhibitor failed mitosis before the metaphase/anaphase transition, leading to large multi-lobed nuclei in the daughter cells. In contrast, cells treated with lower concentrations of inhibitor had a failure in cytokinesis, resulting in binucleate cells. These results suggest that Aurora B inhibition stops cells from progressing through mitosis in a dose-dependent manner. To ask how cells exit the endoreplication cycle, we generated iECs and used flow cytometry to isolate populations of cells with 2C/4C or 8C DNA and then allowed them to resume mitosis after drug washout. During outgrowth, we saw a lag in proliferation before cells began to rapidly divide and form colonies of mitotically dividing cells. After three weeks, the cells had returned to a diploid state but had increased chromosomal instability. To understand how the iECs resume division, we focused our studies on the critical time period during which proliferation begins. Using proliferation markers, we found that iECs in the lag phase were not Ki-67 positive nor did a significant proportion of cells undergo S phase. We also examined nuclear morphology at two-day time intervals during outgrowth. Initially, all of the cells had large multi-lobed nuclei, but over time we observed a small, but consistent increase in the proportion of binucleated cells. This suggested that binucleation may be an intermediate step between multi-lobed nuclei and the normal nuclear phenotype seen after outgrowth, suggesting that cells may exit endoreplication using the reverse mechanism of how they entered. We are currently using time-lapse imaging to examine the timing and morphology of the cells during the re-entry into rapid proliferation. Ultimately our goal is to

identify the key signaling pathways that facilitate the entry into and exit out of endoreplication to understand how cells use alternative cell cycles to contribute to genome instability and tumor formation.

Survivable Environmental Change Enhances Drug Survival and Promotes Genome Instability.

S. Sabatinos, K. Cheung, P. Patel; Ryerson University, Toronto, ON, CANADA.

Transient environmental stresses induce signaling pathways that alter cell metabolism to promote survival under changing conditions. DNA replication stress also induces survival mechanisms, primarily the DNA replication checkpoint. Our earlier work using temperature-sensitive alleles of replication proteins, and synchrony through nitrogen depletion, suggested that environmental stress alters cell response to replication stress. To test this prediction, we used fission yeast replication checkpoint mutants including *rad3^{ATR}Δ, mrc1^{CLASPIN}Δ*, and *cds1^{CHK1}*Δ. Under typical lab conditions, these mutants have 1% to 10% relative viability after 4h in hydroxyurea (HU). However, pre-conditioning cells with environmental stress before drug exposure significantly increases replication mutant survival after 4h in HU. Temperature shock, in particular, promotes excellent replication stress survival in mutants. Survival is directly correlated to the duration of temperature treatment, and is linked to adaptive environmental stress response and increased ribonucleotide reductase. Upon return to normal growth temperatures, enhanced HU-survival decays over time and with cell divisions. Yet, this improved temperature/HU-survival in replication mutants comes at a price; surviving cells show increased mutation rates and DNA mis-segregation. While environmental stress alters replication checkpoint response even as mutant cells become less drug sensitive. This altered drug sensitivity has implications for chemotherapy, showing the potential for environmental stress to generate a surviving sub-population that is altered by the now-survivable drug exposure.

Phosphoregulation Provides Functional Specificity to Biomolecular Condensates in the Cell Cycle and Cell Polarity.

T. Gerbich, A. Gladfelter; UNC-Chapel Hill, Chapel Hill, NC.

How cells control the position, timing and lifetime of phase-separated compartments in cells is not fully understood. The RNA-binding protein Whi3 regulates (or contributes to) the cell cycle, cell polarity and stress responses in the multinucleate, filamentous fungus *Ashbya gossypii*. When Whi3 is deleted or mutated, the nuclear division cycle in the continuous cytoplasm becomes more synchronous, the cells have difficulty establishing and maintaining polarized growth, and the cells show heightened sensitivity to certain environmental stresses. Whi3 contributes to these disparate cell processes by its ability to form different complexes with distinct spatial localizations and mRNA targets. For example, CLN3 (a G1 cyclin) transcripts are heterogeneously positioned near nuclei in a Whi3-dependent manner. BNI1 (a formin) transcripts are positioned at growing tips and nascent polarity sites in a Whi3-dependent manner. Additionally, the Whi3 protein can undergo a liquid-liquid phase separation in the presence of target mRNAs in vitro. We are using this system where distinct Whi3 complexes coexist in a single cell to address how, when and where specific identities are established for phase-separated compartments. We hypothesized that local post-translational regulation of Whi3 protein confers specificity to establish these distinct complexes and encodes their function. We found by mass spectrometry that certain sites

on Whi3 are phosphorylated specifically in response to perturbations in the cell cycle or environmental stresses. Creating genetic backgrounds in which these individual sites have been mutated to be phosphomimetic or unphosphorylatable allowed us to find separation of function alleles that are functional for cell polarity or nuclear cycling, but not both. Additionally, some complete loss of function alleles were identified that were still capable of forming condensates showing that phosphorylation is not simply serving as a cue to drive condensation or dissolution. This work furthers our understanding how post-translational modification can be used to regulate distinct populations of phase separated complexes with common components, and is an important part of understanding the physiological role and regulation of these compartments in all cells.

Dynamic Live-cell Visualization and Quantification of Cell Cycle and Pharmacological Response Using a Genetically-Encoded, Ubiquitination-Based Sensor.

L. A. Skerlos[1], N. J. Bevan[2], G. F. Lovell[2], S. Perez[2], R. J. Lister[1], G. S. Filonov[1], T. Dale[2], D. M. Appledorn[1], C. L. Schramm[1]; [1]Essen BioScience, an n Arbor, MI, [2]Essen BioScience, Welwyn Garden City, UNITED KINGDOM.

Monitoring the progression or disruption of the cell cycle is a relevant tool for the advancement of cancer and regenerative medicine research. The ability to view and analyze fluctuations in the cell cycle enables researchers to answer key questions around proliferation, toxicity, and mechanism of action of therapeutic compounds. Standard technologies to monitor cell cycle are often limited to end-point analysis. The IncuCyte® Live-Cell an alysis System is uniquely suited to visualize, monitor, and analyze cell cycle over time. Here we demonstrate the utility of the IncuCyte® Cell Cycle Red/Green Lentivirus Reagent, encoding a FUCCI (Fluorescence Ubiquitination Cell Cycle Indicator) multi-gene expression system to enable live-cell analysis. The sensor was transduced into a panel of cell lines, resulting in stable, non-perturbing expression of green or red fluorescent proteins during S/G2/M or G1, respectively. The IncuCyte® Cell-by-Cell an alysis Software Module was used to quantify subpopulations of cells within each stage of the cell cycle across multiple cell divisions. To study cell cycle synchronization, HeLa cells were treated with thymidine (2.5 mM, 24 h), a DNA synthesis inhibitor, to arrest cell growth in S/G2/M, resulting in 75% of cells expressing green fluorescence. Following release of the thymidine block, image-based measurements were acquired to track the synchronized progression of the cell population as it passed through three 17-hour cycles, as demonstrated by changes in fluorescence: S/G2/M (green), M/G1 (colorless), G1 (red), and G1/S (yellow). To demonstrate pharmacological disruption of cell cycle, a fibrosarcoma cell line (HT1080) was treated with cisplatin or 5-fluorouracil (5FU), resulting in concentration-dependent arrest of the cell cycle in S/G2/M or G1, respectively. Mechanism of action was demonstrated by treating a panel of breast cancer cell lines with diverse hormone receptor patterns (T47D, ER+ & HR+; AU565, ER- & HER2+; MDA-MB-231, TN) with highly targeted compounds. Tamoxifen binds the estrogen receptor and induced arrest only in T47D, while CB-839 showed activity only in triple negative MDA-MB-231 cells. In an additional study to couple observations of drug-induced cell cycle arrest with immune cell morphology and function, THP-1 monocytes were exposed to Phorbol 12-myristate 13-acetate (PMA; 100 nM). PMA-induced differentiation resulted in a decrease in cell proliferation and increase in cell area, along with an increase in percentage of cells expressing red fluorescence, indicative of cell cycle arrest in G1. Overall, these data highlight the utility of the IncuCyte Cell Cycle Red/Green Lentivirus Reagent to provide valuable kinetic measurement of cell cycle phase distribution by live-cell analysis.

P1133/B259

Cdc55-PP2A Dephosphorylation of Pds1 Is Required for Maintaining Genome Stability during Cellular Replication Stress.

C. Haluska, F. Jin, Y. Wang; Florida State University, Tallahassee, FL.

Genomic stability is essential for normal cellular development, protecting the cell from potential tumorigenesis or cell death. In the presence of replication stress or DNA damage, checkpoint pathways become activated to halt the cell cycle. Cyclin-dependent kinase (CDK) governs the cell cycle and its activity is highest during S and M phase. Mitotic exit pathways play a key role in CDK inactivation and the phosphatase PP2A(Cdc55) is a main component of these pathways. Cdc55, a protein kinase, is a component of the regulatory B-subunit within the PP2A complex. In *Saccharomyces cerevisiae*, securin (Pds1) is an anaphase inhibitor and plays an essential role in DNA damage and spindle checkpoint pathways. Pds1 becomes stabilized in response to DNA damage via phosphorylation by Chk1 (checkpoint kinase 1), a conserved serine/threonine kinase. We found that cells deficient in Cdc55 were highly sensitive when treated with the DNA synthesis inhibitor hydroxyurea (HU) and exhibited delayed recovery following HU release. We further showed that the elimination of Pds1-Chk1 phosphorylation sites in a cdc55 mutant greatly reduces HU sensitivity while the deletion of Chk1 along with Cdc55 resulted in a partial suppression of HU sensitivity. Furthermore, we were able to show that Pds1 levels remained stabilized in a Cdc55 mutant following HU treatment. Our results indicate that PP2A(Cdc55) may dephosphosphorylate Pds1 to allow the recovery from cell cycle arrest induced by a DNA synthesis block.

Binding of Methylated H3 by TopoisomeraseIIa Is Required for Resolving Tangled Genomic DNA during Mitosis for Faithful Sister Chromatid Disjunction.

S. Sundararajan[1], H. Park[1], S. Kawano[2], D. J. Clarke[3], Y. Azuma[1]; [1]University of Kansas, Lawrence, KS, [2]Okayama University, Okayama, JAPAN, [3]University of Minnesota, Minneapolis, MN.

TypeII DNA Topoisomerase (TopoII) is an essential enzyme that decatenates tangled genomic DNA for sister chromatid disjunction through its unique Strand Passage Reaction (SPR) activity. Loss of the TopoII SPR activity results in the formation of DNA bridges and/or Polo-like Kinase Interacting Checkpoint Helicase (PICH) coated ultra-fine bridges (UFBs) - indicators of flawed sister chromatids disjunction. Vertebrates carry two isoforms- TopoIIα and TopoIIβ, known to share a conserved catalytic core. However, TopoIIα is indispensable during mitosis and its function cannot be compensated by TopoIIβ. TopoIIα's exclusive function in mitosis is attributed to it by its distinct C-terminal domain (CTD) that is dispensable for SPR. In this study, we demonstrated that specific binding of TopoIIα to methylated histones governs the key difference between TopoIIα and TopoIIβ function in mitosis. TopoIIα-CTD contains the Chromatin Tether (ChT) domain at the end of its CTD that specifically interacts with methylated Histone H3. Using the Auxin Inducible Degron (AID) system in combination with the Tet-inducible expression of recombinant TopoIIα, we discovered that the ChT domain of TopoIIα plays critical role in resolving PICH - coated UFBs during mitosis. Together with the in vitro chromatin binding assay using TopoII-CTD fragments, we identified critical residues that governs TopoIIα specific function

in binding to methylated H3 and resolving UFBs. Taken together, we propose that TopoIIα-CTD recognizes specific methylated H3 - associated chromatin to facilitate the resolution of tangled genomic DNA during mitosis for proper sister chromatid disjunction.

The Role of Phosphorylation in the Elasticity of the Tethers That Connect Separating Chromosomes throughout an aphase.

E. Kite; York University, Toronto, ON, CANADA.

Elastic tethers stretch between the telomeres of all separating partner chromosomes during anaphase in animal cells. As anaphase progresses the tethers become less elastic. Our experiments look at the possible role of phosphorylation in regulating tether elasticity. Calyculin a (CalA), an inhibitor of phosphatases PP1 and PP2A, added to crane-fly spermatocytes during anaphase was reported to cause backwards movement of some chromosomes after they reached the poles. We assume the backwards movements were due to tethers. Since tethers become inelastic as anaphase progresses, we tested whether CalA would cause backwards chromosome movement when added after tethers were already inelastic. We inhibited dephosphorylation of tethers of different lengths by adding CalA to living crane-fly spermatocytes at various points in anaphase. When 50 nM CalA was added to cells with short tethers, in early anaphase, almost all chromosomes moved backwards after nearing the poles. When 50 nM CalA was added to cells when the tethers were longer, in mid anaphase, fewer chromosomes moved backward, and when the tethers were yet longer, in late anaphase, none moved backward. This suggests that tether elasticity is lost when tethers become dephosphorylated by either PP1 or PP2A. To distinguish between tether dephosphorylation being caused by PP1 versus PP2A we treated cells with okadaic acid. While 50 nM CalA blocks PP1 and PP2A equally well, the same concentration of okadaic acid blocks solely PP2A. A concentration ~100 times higher is needed in order to block PP1. Only the higher concentration of okadaic acid added to the cell when the tethers are short caused chromosomes to move backward. Thus, it appears that tether elasticity is moderated by dephosphorylation caused by PP1.

P1136/B262

Casein Kinase I Protein Hrr25 Regulates Sister Chromatid Cohesion during Mitosis in *Saccharomyces Cerevisiae*.

M. Bhondeley, A. Bhattarai, Z. Liu; University of New Orleans, New Orleans, LA.

Eukaryotic cell division requires the precise execution of an orderly sequence of cellular events to ensure the faithful separation of sister chromatids into daughter cells. One of the most important aspects of chromosome segregation depends on the cohesin complex that keeps the sister chromatids together until their separation at anaphase. The mitotic cohesin complex consists of four subunits, namely, Scc1, Scc3, Smc1, and Smc3. The establishment and maintenance of the cohesin complex in mitosis requires a number of proteins during and post DNA replication, including acetyltransferase Eco1, Ctf18/Dcc1/Ctf8 alternative replication factor C (Ctf18-RFC) clamp loader complex, cohesion maintenance protein Pds5, and chromatin-associated protein Ctf4. In budding yeast, Hrr25 is a protein kinase that has been implicated in many cellular processes including vesicular trafficking, ribosome biogenesis, autophagy, transcriptional regulation, meiosis, and DNA damage response. While the function of Hrr25 during meiosis has been well established, much less is known about its role in mitotic

cell division. Here we show that an *hrr25* mutation is synthetic lethal with mutations in *CTF4*, *CTF18*, *DCC1*, *CTF8*, *SCC1*, *SMC1*, *PDS5*, and *ECO1*. We further analyzed mutations in about 40 genes for synthetic interactions with an *hrr25* mutation, including those encoding proteins involved in DNA replication, microtubule function, spindle checkpoint, DNA damage checkpoint and DNA repair, and the gene encoding the histone 2A variant, *HTZ1*. We found that an *hrr25* mutation is synthetic lethal with mutations in genes encoding Cik1 and Kar3 that are required for the chromosome bipolar attachment to mediate sister chromatid separation. Additionally, we found an *hrr25* mutation leads to synthetic-slow growth defects with mutations in *HTZ1* and *CIN8*, encoding a kinesin motor protein, but not with mutations in genes encoding other kinesin-related proteins and dynein. Finally, we directly observed defects in sister chromatid cohesion in *hrr25* mutant cells. Together, our data suggest that Hrr25 plays an important role in chromosome segregation during mitosis.

P1137/B263

Numa Is Required for the Formation of a Single Nucleus After Mitosis.

A. Serra-Marques[1], R. Houtekamer[1,2], D. C. Hintzen[1,3], S. Dumont[1]; [1]University of California, San Francisco, San Francisco, CA, [2]University of Utrecht, Utrecht, NETHERLANDS, [3]The Netherlands Cancer Institute, Amsterdam, NETHERLANDS.

Eukaryotic cells pack their genome into a single nucleus at the end of mitosis, and failure to do so leads to DNA damage and loss of genomic integrity. However, how mammalian cells form a single and robust nucleus remains poorly understood. NuMA is a long coiled-coil protein essential for spindle structural stability and chromosome segregation. Impaired NuMA function results in nuclear fragmentation, and whether this is due to impaired mitotic function or to a direct role in nuclear formation remains unclear. Here, we show that NuMA plays a *bona fide* role in the formation of a single nucleus after mitosis, independent of its spindle role. We further demonstrate that NuMA is essential for forming a round, smooth nucleus, suggesting a structural role. We find that its coiled-coil is essential to the formation of a single nucleus, and to its stable incorporation in its nuclear structure. Finally, we show that the cell actively regulates NuMA's chromosome binding: NuMA's C-terminus binds chromosomes at interphase but its long coiled-coil prevents it from binding chromosomes at mitosis, keeping its action on distinct cellular structures compartmentalized. Together, our findings indicate that NuMA plays key, long-range structural roles throughout the cell cycle, keeping both the mitotic spindle and the nucleus intact.

P1138/B264

Extra Crossovers Negatively Impact Meiotic Chromosome Segregation in *C. Elegans* Oocytes.

J. Hollis[1], M. L. Glover[2], A. Schlientz[2], B. Bowerman[2], S. M. Wignall[1], D. E. Libuda[2]; [1]Northwestern University, Evanston, IL, [2]University of Oregon, Eugene, OR.

During meiosis, there is one round of DNA replication followed by two sequential divisions, enabling diploid organisms to cut their chromosome number in half to generate haploid gametes. This process depends on reciprocal recombination, or crossing over, between homologous chromosomes, which holds homologs together in chiasmata so that they can segregate to opposite spindle poles during the first meiotic division. In most organisms, the number of crossovers between homologs is limited by a mechanism called crossover interference, but why this interference process is so well conserved is not known. To understand the importance of crossover interference, we sought to determine whether extra crossovers affect the fidelity of the meiotic divisions in *C. elegans.* This organism exhibits strong

interference, with only one crossover per chromosome pair, resulting in a cruciform bivalent organized around a single chiasma. The bivalents then condense, and a complex of conserved proteins forms an essential ring-shaped structure around the interface between the homologs (the ring complex/"RC"), which is required for proper chromosome congression and segregation. Utilizing a *C. elegans* strain containing an end-on fusion of three chromosomes, we found that a large percentage of the fusion chromosomes had additional crossovers that led to extra chiasmata. At diakinesis, these fusion chromosomes exhibit abnormal chromosome structural patterning and multi-lobed bivalent structures in comparison to the normal cruciform shape. Subsequently, assembled RCs frequently appeared fragmented on these misshapen bivalents, and bivalents with altered RC shape were more likely to be misaligned on the spindle, suggesting that the structure of the RC affects its function. In an aphase I, the fusion chromosomes frequently exhibited segregation defects and a high prevalence of chromatin bridges; although sometimes these bridges were able to resolve, in other cases the bridges persisted, creating a "tether" between the incompletely-extruded polar body and the Meiosis II spindle. Depletion of LEM-3, a late-acting nuclease, increased the prevalence of these bridges, and persistent bridges were preferentially extruded during the second meiotic division, suggesting that there are both universal and oocyte-specific mechanisms for resolving anaphase bridging. These findings demonstrate that excess crossovers can severely impact chromosome patterning and segregation, highlighting the importance of limiting the number of recombination events between homologous chromosomes in meiosis.

P1139/B265

CDK-1 Controls Meiotic Chromosome Dynamics through Phosphorylation of the Synaptonemal Complex.

J. Brandt, 21211, K. Hussey, Y. Kim; Johns Hopkins University, Baltimore, MD.

Dramatic reorganization of chromosomes is essential for their proper segregation during meiosis. Prior to the first meiotic division, chromosomes pair, synapse, and recombine with their homologs to form the bivalent structure necessary for homolog segregation. The Polo-like kinases play widely conserved roles in orchestrating these processes. In *C. elegans*, PLK-2 is initially localized to pairing centers to promote pairing and synapsis. PLK-2 then relocates to the synaptonemal complex (SC) on the "short arm" relative to the crossover site by binding an SC component SYP-1 and drives a chromosome remodeling, ultimately defining where cohesion will be released during meiosis I. However, the mechanisms governing the dynamic behavior of PLK-2 have remained elusive. Here, we demonstrate that the cyclin-dependent kinase CDK-1 directs the recruitment of PLK-2 to the SC through phosphorylation of SYP-1. CDK-1 phosphorylates a conserved motif within SYP-1 along the entire length of the SC upon meiotic entry. However, pairing centers prevent the recruitment of PLK-2 to the SC until crossovers are designated. We find that the nucleoplasmic protein HAL-2 preferentially targets PLK-2 to pairing centers and that mutating the CDK-1 phosphorylation site on SYP-1 partially rescues PLK-2 targeting to pairing centers in *hal-2* mutants. Finally, we provide evidence that crossover formation is signaled in *cis* to enrich for SYP-1 phosphorylation and that this requires the kinase activity of PLK-2. Taken together, our work establishes a novel role for CDK-1 in orchestrating meiotic chromosome dynamics and provides a mechanism for dynamic PLK-2 targeting during meiosis.

P1140/B266

An Evolution-Guided Approach to Identifying Interaction Interfaces in the Synaptonemal Complex.

L. E. Kursel, S. Gordon, O. Rog; University of Utah, Salt Lake City, UT.

The Synaptonemal Complex (SC) is a proteinaceous structure that is essential for sexual reproduction. The SC ensures that offspring inherit the correct number of chromosomes by aligning parental chromosome pairs during meiotic prophase and regulating exchanges between them. Previous studies have shown that the SC consists of a few (<6) proteins which assemble along the length of paired meiotic chromosomes with a ladder-like ultrastructure. However, despite the essential role of the SC in meiosis and the conservation of its ultrastructure, SC subunits are thought to be dynamic and undergo constant rearrangements. This has led to the hypothesis that SC subunits may assemble by forming multivalent interactions, whereby each protein-protein interaction is weak or labile. As such, traditional techniques have had limited success in describing SC protein-protein interactions. We took an evolution-guided approach to determine protein-protein interaction interfaces in the SC in *Caenorhabditis elegans*. We identified a conserved five amino acid domain in the N-terminus of SYP-1 (one of the four SC proteins in *C. elegans*), and used CRISPR/Cas9 to randomly mutate each of the five residues in the endogenous *syp-1* locus. One mutant, *syp-1*^{mut1}, exhibited hallmarks of meiotic perturbation. Microscopy studies showed that *syp-1*^{mut1} fails to fully synapse a subset of chromosomes in most meiotic nuclei and loads abnormally onto unpaired homologs. Additionally, *syp-1*^{mut1} is temperature sensitive. Mutant animals are nearly sterile at 25ºC but produce near wildtype levels of progeny at 15ºC (wildtype animals are fertile at 15 and 25ºC). We reasoned that *syp-1*^{mut1} was defective in interacting with other SC proteins and that this interaction could be restored via compensatory (suppressor) mutations. To identify suppressors of *syp-1*^{mut1}, we performed saturating mutagenesis of *syp-1*^{mut1} with N-ethyl-N-nitrosourea and selected for suppressor animals that were fertile at 25ºC. We identified 23 suppressor strains and subjected each to mapping and whole genome sequencing. This revealed two revertants to wildtype *syp-1*, and 21 suppressors representing 11 additional point mutations in SC proteins. Importantly, both the original mutation and the majority of the suppressor mutations alter charged residues. Our results point to a multi-valent interaction interface between several *C. elegans* SC proteins, governed by charge-charge interactions that is essential for proper homolog synapsis.

P1141/B267

Cryo-ET an alysis of the Yeast Synaptonemal Complex in *Situ*.

L. Gan, O. X. Ma, S. Cai, J. Shi; National University of Singapore, Singapore, SINGAPORE.

The synaptonemal complex (SC) is the large proteinaceous scaffold that assembles between homologous chromosomes by the end of meiotic prophase. While its functions are numerous -- and mysterious, in yeast the SC is required for the phenomenon known as crossover interference. Knowledge of the native structure of this complex is needed to evaluate how the SC carries out its functions. Traditional electron microscopy and super-resolution light microscopy have revealed that in many organisms, the SC has a ladder-like structure: two rail-like lateral elements are bridged by a set of rung-like transverse filaments. The filaments are connected along their centers by a central element. To determine the 3-D architecture of the SC and nuclear macromolecular complexes in situ, we studied frozen-hydrated meiotic yeast cell cryosections by Volta electron cryotomography and subtomogram analysis. We find the predominant SC motif is a duster-like arrangement of densely packed triple-helical filaments, both of which are also abundant in the polycomplexes of pachytene-arrested cells. There was no evidence for a ladder-like organization. Partial dissolution by 1,6-hexanediol treatment suggests that these triple-helical filaments belong to the central region of the SCs and are most likely the abundant Zip1 transverse element protein. Subtomogram averaging revealed that the SC's triple helix is up to 12-

nm thick and has a rise of 5 nm and a pitch of 130 nm. Polymers thinner than the triple helix, such as single or double strands, were not detected; this observation is consistent with the strong self-oligomerization properties of SC proteins. The dense packing of SC subunits supports the notion that the SC's mechanical properties help coordinate the rapid end-to-end communication across synapsed chromosomes. Finally, our study provides a 3-D framework for understanding the other macromolecule machines of meiosis in *situ*.

P1142/B268

Identification of Novel Synaptonemal Complex Components in *C. Elegans*.

M. E. Hurlock[1], I. Čavka[2], J. M. Haversat[1], M. Wooten[1], Z. Nizami[3], R. Turniansky[1], P. Hoess[2], J. Ries[2], J. G. Gall[3], S. Köhler[2], Y. Kim[1]; [1]Johns Hopkins University, Baltimore, MD, [2]The European Molecular Biology Laboratory, Heidelberg, GERMANY, [3]Department of Embryology, Carnegie Institution for Science, Baltimore, MD.

Proper chromosome segregation during meiosis requires that chromosomes pair and undergo crossover recombination with their homologs. In most eukaryotes, crossover formation depends on the assembly of the synaptonemal complex (SC), a zipper-like protein scaffold that forms between paired homologs. The SC is a tripartite protein structure consisting of two parallel stretches of lateral elements that are held together by a central element. The SC central region in *C. elegans* is known to be comprised of four coiled-coil domain proteins, SYP-1, SYP-2, SYP-3 and SYP-4. The four SYP proteins were identified more than a decade ago, and it has been widely believed that they represent the entire set of SC components. Here we report the identification of two new SC components, SYP-5 and SYP-6. SYP-5 and SYP-6 localize along the SC between the two chromosome axes, and their recruitment depends on chromosome axes and other SC components. Using single-molecule localization microscopy, we demonstrate that SYP-5 and SYP-6 transverse the width of the SC in a head-to-head manner with the two N-termini at the center and the C-termini facing the chromosome axes. Interestingly, SYP-5 and SYP-6 are paralogous to each other and play redundant roles in synapsis, providing an explanation for why these proteins have not yet been identified by previous genetic screens. We further find that SYP-5 and SYP-6 contain stretches of low complexity amino acid sequences in their C-termini and that truncating these regions leads to aberrant synapsis and disruption of crossover control. Together, our findings establish SYP-5 and SYP-6 as *bona fide* components of the SC and will provide crucial insights into the mechanisms of SC assembly and its role in crossover regulation.

P1143/B269

A Time-Resolved Network of Meiotic Chromosome Associated Proteins.

S. Ur, R. Suhandynata, H. Zhou, K. Corbett; UCSD, La Jolla, CA.

Meiosis, a hallmark of sexual reproduction, reduces the ploidy of a cell by undergoing two chromosome segregations after a single round of chromosome replication. In order to accomplish this diploid-to-haploid transition, homologous chromosomes identify one another and physically associate through DNA recombination, before segregating from one another in the first meiotic division. Meiotic recombination initiates with programmed double strand breaks (DSB) on each chromosome, some of which are eventually resolved as inter-homolog crossovers. Many protein complexes are involved in meiotic recombination, and their spatial and temporal interplay is critical to the proper segregation of chromosomes in Meiosis I. The proteinaceous chromosome axis and synaptonemal complex organize

chromosomes and control their recombination, while other recombination complexes shuttle a subset of double-strand breaks to a crossover fate. Previous studies have globally interrogated the timing of meiotic protein expression and indeed, many individual meiotic complexes have been studied in detail. However, a comprehensive view of meiotic proteins' chromosome localization and interactions has not been performed. Here, we present a protocol to assess the localization of proteins to chromosomes throughout a synchronous *S. cerevisae* meiosis using chromatin-enriched fractions coupled with high resolution tandem mass spectroscopy. We demonstrate the ability of our assay to identify proteins from critical meiotic complexes such as the chromosome axis, synaptonemal complex, ZMM family, recombination complexes, and proteins responsible for resolving key crossover intermediates. By disrupting individual proteins from these stratified groups, we elucidate how meiotic complexes work together to manipulate meiotic chromosomes and promote homolog pairing and segregation during Meiosis I. With this tool we have created a temporal atlas for meiotic proteins, and defined how protein complexes assemble and disassemble from chromosomes to coordinate meiotic recombination.

A Mutation in NCAPD3, a Condensin II Complex Subunit, Links Mosaic Reversion and Microcephaly to Chromosome Hypercondensation.

C. Martin[1], A. Lawson[2], M. Hurles[2], A. Jackson[1]; [1]MRC Human Genetics Unit, Institute of Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, UNITED KINGDOM, [2]Wellcome Trust Sanger Institute, Hinxton, UNITED KINGDOM.

Compaction of chromosomes is essential for accurate segregation of the genome during mitosis. In vertebrates, two condensin complexes ensure timely chromosome condensation, sister chromatid disentanglement, and maintenance of mitotic chromosome structure. Here, we report a heterozygous missense mutation in *NCAPD3*, encoding a subunit of the condensin II complex, in a patient with microcephaly. Microarray and whole genome sequencing of patient saliva and blood revealed there is somatic loss of the disease causing mutation suggesting that revertant cells are under strong positive selection during development. Consistent with this, expression of the mutant protein NCAPD3^{R1411Q} in cultured cells and mice lead to growth restriction. At the molecular level, the mutation acts as a gain of function and mimics loss of phosphorylation at a critical CDK1 phospho-site during mitosis. Previously biallelic loss of function mutations in the condensin complex linked microcephaly to chromosome entanglements. In contrast, NCAPD3^{R1411Q} patient fibroblasts and mice do not display chromosome segregation errors but instead present with chromosome hypercondensation during mitosis. These findings establish chromosome hypercondensation as an additional disease mechanism for microcephaly and suggest that progressive somatic changes can arise as an adaptation to a growth restricting condition.

P1145/B271

A Physical Model of Pairing Chromosomes.

E. J. Navarro, 94122, J. C. Fung, W. F. Marshall; University of California, San Francisco, San Francisco, CA.

During Meiosis, each pair of homologous chromosomes must move through the nucleus in order to find each other and become spatially aligned along their entire length, a process known as homologous chromosome pairing. While pairing is taking place, the chromosomes are packaged as long linear polymers constrained to move within the confining nuclear volume. From a polymer physics perspective

this presents a difficult problem: How does the cell manage to align each pair of chromosomes in this dense polymer system, while avoiding interlocks? Our aim is to use a course grained molecular dynamics model to understand homologous chromosome pairing as a physical process. We are particularly interested in questions related to entanglement and interlock resolution during pairing. Our initial simulation data suggests that the length and density of eukaryotic chromosomes places them in the reptation regime of polymer physics (where diffusion is slow), but that fast reptational motion can be driven by the progressive zippering of pairing loci.

Investigating Distinct Roles of Histone H3 and Histone Variant H3.3 in the *Drosophila* Germline.

C. Chandrasekhara, X. Chen; Johns Hopkins University, Baltimore, MD.

Imbalance between self-renewal versus differentiation of stem cells can result in cancer, tumorigenesis, infertility, or tissue degeneration. Epigenetic mechanisms play a critical role in defining stem cell identity and the process of differentiation, where the epigenome undergoes dramatic remodeling. Therefore, understanding the basis of the mechanisms that regulate epigenomes at a cellular level is integral to better our understanding of how cells acquire distinct cell fates. Our lab studies the epigenetic mechanisms that specify cell fate decisions during asymmetric cell division (ACD) of germline stem cells (GSC). Adult stem cells have the unique capability of self-renewal and ability to differentiate. Our lab utilizes the *Drosophila melanogaster* male germline as a model system to investigate the distinct epigenetic mechanisms that regulate stem cell maintenance and differentiation processes. We use an irreversible DNA recombination to switch expression of histones from “old” to “new”. Intriguingly, histone H3 (H3) exhibits asymmetric inheritance during ACD of GSCs. In contrast, the histone H3.3 variant (H3.3), showed symmetric inheritance. How H3 and H3.3 uniquely define cell fate decisions during ACD is a long-standing question. H3 and H3.3 are 97% identical at the amino acid sequence level. Of the four distinct amino acids in the primary sequence of H3 and H3.3, the role of three amino acids in the main body of histones (HFD) has been well defined. However, little is known about their distinct amino acid located at the N-terminal tail. I utilize established genetics and cell biology methods to systematically study the differences between H3 and H3.3 at their N-termini and examine the role they have in defining stem cell fate. At residue 31 in the N-terminal tail of H3 and H3.3, we generated point mutations to create hybrid proteins of H3 and H3.3(H3A31S encoding H3.3 N-term_H3 HFD and H3.3S31A encoding H3 N-term_H3.3 HFD). My preliminary data suggests that inheritance patterns are altered in GSCs expressing these hybrid proteins. We also observed unique cellular defects in these testes. Collectively, this work will allow us to gain insight into how histone variants regulate complex ACD processes in a well-established metazoan model organism.

P1147/B273

A Protein Complex Essential for *C. Elegans* Meiosis Is Comprised of Distinct Structural Domains.

H. E. Horton, N. S. Divekar, S. M. Wignall; Northwestern University, Evanston, IL.

During meiosis, a single round of DNA replication is followed by two rounds of division in order to give rise to haploid gametes. Female gametes (oocytes) of most species undergo meiosis in the absence of centrosomes. In *C. elegans* oocyte meiosis, microtubules form lateral associations with the chromosomes instead of end-on attachments to facilitate chromosome movement. Additionally, a ring-shaped protein complex wraps around the central region of the bivalent in meiosis I (MI) and the sister

chromatid interface in meiosis II (MII). The ring complex is comprised of over fifteen known protein components including the Aurora B homolog AIR-2, the kinase BUB-1, the plus-end directed kinesin KLP-19, and the post-translational modification SUMO and its associated enzymes. Ring proteins are required for chromosome congression as well as the loss of sister chromatid cohesion that enables segregation of chromosomes to opposite spindle poles. Despite the clear necessity for the ring complex in *C. elegans* meiosis, how the ring performs its roles in chromosome congression and segregation is poorly understood. Specifically, the relationship between the ring's structural properties and essential functions remains to be explored. Although the ring complex is typically depicted as having a hollow circular shape, our work demonstrates that its structure is more complex. Instead of solely wrapping around the outer surface of the bivalent, super-resolution microscopy revealed that ring components weave through the mid-bivalent region in distinct loop-shaped domains. Notably, these substructures, or "sub-loops," are only present on MI bivalents and not MII chromosomes, suggesting that they associate with the short arm axis that corresponds to the homologous chromosome interface. Many ring components that are found on the outer ring also localize to the sub-loops, including AIR-2, BUB-1, KLP-19, and SUMO. Interestingly, sub-loops appear to undergo structural remodeling as meiosis progresses; while most sub-loop components are offloaded from the sub-loops during metaphase, AIR-2 persists on these structures until anaphase onset. Therefore, we hypothesize that the population of AIR-2 that is in the sub-loops could play a functional role in facilitating homologous chromosome segregation, for example in promoting resolution of the crossover. Ongoing investigation of the sub-loop domains of the ring complex will give us further insight into the relationship between the structure and function of this essential protein complex.

P1148/B274

Failures in Fertility: Elucidating the Function of Gsp-3/4 in *C. Elegans* Meiosis.

B. Meissner; San Francisco State University, San Francisco, CA.

DNA partitioning and segregation during meiosis and mitosis is imperative for cellular proliferation, genetic diversity, and embryonic development. Without such processes, nondisjunction and DNA fragmentation are certain to occur—producing germ cells that are often unable to support life. Meiosis and mitosis are extremely vital to all living organisms and the two systems rely on an extensive network of protein kinases and phosphatases that concertedly activate and deactivate proteins to coordinate these complex pathways. The absence of just one phosphatase belonging to the protein phosphatase 1 (PP1) family has shown to disrupt the products of meiosis and promote DNA fragmentation in mammalian sperm. Other PP1 orthologues have been identified in numerous organisms that, when depleted in germ cells, also disrupt meiosis. It is clear that PP1 phosphatases are necessary for successful meiosis but the mechanism governing this success remains unclear. In this proposal, I aim to elucidate the transient role of two 98% identical sperm-specific PP1 phosphatases, GSP-3 and GSP-4 (further referred to as GSP-3/4) in the context of *Caenorhabditis elegans* meiosis. I plan to accomplish this via co-immunoprecipitation experiments to identify any possible subunits or substrates that interact with each phosphatase as 'key players' in the PP1 phosphatase mechanism. Additionally, I plan to use an auxin-inducible protein degradation system to quantify and compare global phosphorylation levels in both wild-type and GSP-3/4 depleted strains of *C. elegans*. Taken together, these data will both identify novel proteins that associate with GSP-3/4 and quantify the enzymatic activity of each phosphatase to develop a mechanism that describes how GSP-3/4, and other PP1 phosphatases, encourage proper chromosome segregation in meiosis.

Oncogenes and Tumor Suppressors 2

P1149/B276

Sos1 and Sos2 Are Therapeutic Targets That Play Unique Roles in Mutant Egfr-driven Lung Cancer Cells.

P. Theard, E. Sheffels, R. L. Kortum; Uniformed Services University of the Health Sciences, Bethesda, MD.

Lung adenocarcinoma is the leading cause of cancer death. Activating *EGFR* mutations are found in ~15% of lung adenocarcinomas and are the major cause of lung cancer in never smokers. In patients harboring either an *EGFR* L858R point mutation or an exon 19 deletion (85% of cases), the first-generation EGFR-TKIs erlotinib and gefitinib enhance progression-free and overall survival, however, disease progression invariably occurs with secondary *EGFR (T790M)* 'gatekeeper' mutations and 'oncogenic shift' to other RTKs accounting for a majority of cases (60% and 15-30% of cases, respectively). For resistant tumors harboring *EGFR (T790M)* mutations, the 3rd generation EGFR-TKI osimertinib further prolongs survival, however resistance to osimertinib invariably emerges. Here again tertiary EGFR mutations, oncogenic shift to alternative RTKs, and mutations of downstream RTK pathway signaling intermediates have been identified as potentially driving inhibitor resistance and tumorigenic growth. Since a majority of EGFR-TKI resistance mechanisms continue to rely on RTK/RAS signaling to drive oncogenesis, we investigated whether the RasGEFs SOS1 and SOS2 represente tractable therapeutic targets for both primary and EGFR-TKI resistant tumors. We found that *SOS1* deletion reduced oncogenic transformation in NSCLC cells that were sensitive or resistant gefitinib and blunted 'oncogenic shift' to other RTKs. Furthermore, combining EGFR inhibition with the novel SOS1 inhibitor BAY-293 showed marked synergy in inhibiting transforming growth of NSCLC cancer spheroids in 3D culture, suggesting that SOS1 inhibition is a potent primary therapeutic target in EGFR-mutated NSCLC cells. In contrast, while *SOS2* deletion alone did not alter EGFR-driven transformation, combining *SOS2* deletion with low dose EGFR-TKI treatment synergized to inhibit anchorage-independent growth. Finally, in *situ* resistance trials in a 96-well plate format showed that deletion of either *SOS1* or *SOS2* delayed the development of osimertinib resistance and reduced the overall incidence of osimertinib resistance. Overall, these data indicate that the RasGEFs SOS1 and SOS2 are important mediators of mutant EGFR signaling, and therapeutic targeting of SOS in combination with EGFR-TKI therapy may have clinical benefit for patients with EGFR-mutated lung cancer.

Cross-cancer Study with a Special Emphasis on Stomach Cancer Reveals Atad2 as a Diagnostic and Prognostic Biomarker.

A. Nayak[1], S. Kumar[2], A. Bhattacharyya[3], A. Dixit[2], A. Roychowdhury[1]; [1]Indian Institute of Technology, Bhubaneswar, INDIA, [2]Institute of Life Sciences, Nalco Square, Bhubaneswar, INDIA, [3]National Institute of Science Education and Research (NISER), Bhubaneswar, INDIA.

ATAD2, an AAA+ ATPase, has recently been found to be overexpressed in many cancers and correlated with the malignant status of the disease. Therefore, *ATAD2* could be considered as a potential cancer biomarker. By systematic bioinformatics analyses with relevant experimental studies, here we evaluate for the first time the prospect of *ATAD2* as a diagnostic and prognostic biomarker for cancers. Our cross-cancer analyses reveal that *ATAD2* is overexpressed in many cancers (Oncomine and GEPIA (TCGA) databases) and is related to poor survival of the cancer patients (Kaplan-Meier Plotter and SurvExpress

databases). Most interestingly, *ATAD2* appears as the cancer driver *for many cancers* and the potential mutation sites of *ATAD2* (cBioPortal and COSMIC databases) are predicted. All these studies across the cancer types specify ATAD2 as an interesting target particularly for stomach cancer. Therefore, we further focus our study on stomach cancer and indeed find that *ATAD2* is overexpressed in all stages and grades of stomach adenocarcinoma (Oncomine and GEPIA (TCGA) analyses as well as expression analyses with stomach cancer cell lines). Our immunofluorescence microscopy study with adenocarcinoma as well as metastatic stomach tissue samples also shows that *ATAD2* is upregulated in stomach carcinoma; corroborating our finding from cell culture experiments and in *silico* studies. Further survival analysis indicates that high expression of *ATAD2* drastically affects the survival of the stomach cancer patients (Kaplan-Meier analysis). Therefore, we next used cox proportional hazard regression model and receiver operating curve analysis. Our analyses clearly illustrate that high expression of *ATAD2* could be a predictable factor for prognosis of stomach cancer with perfect accuracy. *ATAD2* appears as cancer driver for stomach cancer (iPAC) *and* a total of 40 mutational sites (including the hot spot mutations at ATPase domain) of *ATAD2* have been identified; signifying that many of these mutations could be responsible for stomach oncogenesis. We also show that *ATAD2* directly interact with many transcription factors which could potentially help in ATAD2 mediated cellular proliferation. The top canonical pathways of ATAD2 are identified (ingenuity pathway analysis) indicating the prominent role of ATAD2 in cancer cell proliferation. Therefore, the analysis reported here establishes *ATAD2* as a promising prognostic marker for multiple cancers, and a very promising biomarker and therapeutic target for stomach cancer.

P1151/B278

P53 Amyloid Formation as an Ignition Key for Cellular Transformation: Is Cancer a Prion Disease?

A. Navalkar[1], S. Pandey[1], N. Singh[1], A. Paul[1], S. Jadhav[2], P. Chaudhari[3], S. K. Maji[1]; [1]Indian Institute of Technology Bombay, Mumbai, INDIA, [2]Agarkar Research Institute, Pune, INDIA, [3]Advanced Centre for Treatment, Research and Education in Cancer, Navi Mumbai, INDIA.

p53 gene is mutated in more than 50% of human cancers, leading to loss of its tumor suppressive function.p53 mutation results in its misfolding and/or aggregation leading to its sequestration in cytoplasmic/nuclear inclusions and compromising its native function. Mutational landscape of p53 has been systematically characterized in a large cohort of samples but the link between p53 conformational status and its contribution to cancer is largely unexplored. Our group has shown that native, wild type p53 undergoes amyloid formation and these aggregates possess prion-like properties, thereby spreading the p53 aggregation to neighboring cells. Here, we propose that wild type p53 protein can aggregate upon specific stimulus, resulting in loss of p53 function driving the cells towards cancer progression. Using an in *cellulo* model, p53 fibril seeds were used to induce p53 amyloid formation. p53 fibril treated cells demonstrated increased survival and resistance to apoptosis. Treated cells displayed tumorigenic potential evident by enhanced migration and increased colony formation propensity. Cells with p53 aggregates showed an over-expression of Epithelial-mesenchymal transition markers and formed tumor-like spheroids in 3D cell culture. Injection of cells with p53 aggregates induced tumor formation in xenograft mice model whereas no tumors were detected in mice injected with untreated cells. Furthermore, by using immunohistochemistry, these tumors tested positive for p53 amyloid aggregates. Global gene expression and proteomic profiling revealed p53 amyloid formation in cells significantly influences apoptosis, cell cycle and proliferation, chaperone levels, senescence along with major signaling pathways like MAPK and Wnt pathway. Gene ontology analysis further showed up-regulation

of pro-oncogenic pathways and a loss of tumor suppressive pathways thus contributing towards tumorigenic potential in cells. The present study proposes that native, wild type p53 amyloid formation could act as an ignition key for cancer initiation and the prion-like nature of these amyloid species classifies cancer as a prion-mediated disease.

P1152/B279

P21$^{Waf1/cip1}$ Reduces P53 Protein Stability by Facilitating the Action of Wip1 on P53.

J. Kim, E. Kim, **H. Um**; Korea Institute of Radiological & Medical Sciences, Seoul, KOREA, REPUBLIC OF.

The functions of the p53 tumor suppressor/transcription factor are regulated by cellular components that control the stability of protein p53. ATM, which is activated in response to DNA damage, directly phosphorylates serine-15 (S15) of p53, which stabilizes p53 by preventing its binding to the E3 ubiquitin ligase Mdm2. In contrast, the phosphatase Wip1 dephosphorylates p53-S15, facilitating Mdm2-induced p53 ubiquitination and subsequent proteasomal degradation. As p21$^{WAF1/CIP1}$ binds directly to p53, we investigated whether p21 regulates p53 stability. We found that p21 reduces stability and cellular concentration of protein p53. Such functions of p21 required Mdm2, Wip1, and proteasomal activity. Furthermore, we revealed that Mdm2 requires p21 to induce ubiquitination and proteasomal degradation of p53. Moreover, p21 facilitates dephosphorylation of p53-S15 by Wip1. Thus, p21 may facilitate p53 degradation by facilitating the actions of Wip1 and Mdm2 on p53. Therefore, p21 appears to be a new regulator of p53 stability, which may provide novel insights into the mechanisms underlying tumor progression and DNA damage response.

P1153/B280

Suppression of Human Transposons by P53.

B. Tiwari, 75235-6435, A. E. Jones, C. Calliet, S. R. Kayra, J. M. Abrams; UT Southwestern Medical Center, dallas, TX.

p53 gene mutation is the most common genetic alteration in human cancer. As a transcription factor, p53 regulates important cellular stress response pathways including apoptosis, cell cycle arrest, and senescence. However, compelling studies from several groups have established that these canonical effectors are not adequate to prevent oncogenesis. Recent findings from our lab uncovered an evolutionarily ancient role for p53 in the containment of mobile genetic elements in the germ line of flies and fish. Retrotransposon activity may contribute to destabilized genomes and inflammatory responses that typify human cancers. Therefore, we proposed to determine whether retroelement repressions are conserved p53 function in humans. First, we created p53 knockout in different human cell lines using Crispr-cas9. Importantly, the LINE1 retroelement encoded L1ORF1-p protein was highly expressed in theses p53 knockout lines when compared to their p53 wild type parental lines. Next, we used histone deacetylase inhibitor treatment (HDACi) to artificially induce expression of LINE1 elements in both p53 wt parental and p53 knockout cell lines. Upon withdrawal of HDACi, the p53 knockout cells failed to re-establish repression of the LINE1 elements. Together our data indicates that p53 is required to for both maintenance and de novo silencing of retrotransposons in human somatic cells. These p53 functions may constitute important, and previously unappreciated tumor suppressive mechanisms.

P1154/B281

Identifying the Mechanism and Impact of Hnrnp K Regulation by Keratin 19.

A. Fallatah, 20064; the Catholic University of America, Washington DC, DC.

Breast cancer is the second deadliest type of cancer among women in the United States. One of the biomarkers that physicians use to predict breast cancer patients' overall survival is Keratin 19 (K19). Keratins are critical for maintaining the structural integrity of epithelial tissues but are also involved in other non-mechanical functions including cell growth, proliferation, and apoptosis. In cancer, higher expression levels of K19 correlate with poor survival of breast cancer patients. However, the exact role of K19 in tumorigenesis is not understood. Our data shows there is an interaction between K19 and RNA-binding protein hnRNP K, which can impact all steps of the gene expression. HnRNP K has been found to be overexpressed in many cancers, and its cytoplasmic accumulation has been correlated with tumor cell growth and metastasis. However, the molecular mechanism of how hnRNP K cytoplasmic localization is regulated in K19 dependent manner needs to be studies. We found that cell proliferation and cytoplasmic localization of hnRNP K in MDA-MB-231 breast cancer cells are K19-dependent. To study the effect of K19 on hnRNP K targets on breast cancer cells, we mapped hnRNP K target RNAs in both parental and K19 KO cells using Photoactivatable-Ribonucleoside-Enhanced Crosslinking and Immunoprecipitation (PAR-CLIP). This cutting-edge biochemical technique helps to identify RNA-binding protein target sequences on a transcriptome-wide scale at nucleotide resolution. Using PAR-CLIP to identify hnRNP K targets and RNA-sequencing of parental and K19 knockout (KO) cells, we found hnRNP K targets are downregulated in K19 KO cells, in particular when bound in the 3'UTR, suggesting a cytoplasmic role for hnRNP K in addition to its canonical nuclear role. Then, we used DAVID, a gene ontology tool, to identify functions from a list of top hnRNP K targets deregulated in K19 KO cells. DAVID analysis showed that the endoplasmic reticulum (ER), cell-cell adherent junctions, and the cell cycle are pathways that are most affected among genes that are dysregulated in K19 KO cells. For these pathways, we hypothesize that hnRNP K could impact levels of mRNA targets through K19 by retaining a part of hnRNP K in the cytoplasm, where it is able to bind and regulate a set of targets that are involved in ER, cell-cell adherent junctions, and cell cycle which have been known deregulated in many cancers. In the absence of K19, these targets are then destabilized and the change in gene expression profiles therefore results in the defect in cells proliferation. By characterizing how K19-hnRNP K interaction impacts the transcriptome of breast cancer cells, we hope to ultimately define novel pathways that can be potential therapeutic targets to combat cancer

P1155/B282

Triple Negative Breast Cancer Cell Exposure to Epigallocatechin-3-gallate Increases Expression Levels of Tumor Suppressor Mir-125a-5p.

F. Abdelaal; John Jay College, New York, NY.

Triple negative breast cancer cell exposure to epigallocatechin-3-gallate increases expression levels of tumor suppressor *miR-125a-5p* Authors: Fatma Abdelaal, Toni-Ann Bravo, Kassie Campbell, Lissette Delgado-Cruzata PhD Polyphenols are chemical compounds found in many plant based foods. They offer many health benefits including protection against type 2 diabetes, heart disease, and some types of cancer. They have been shown to target cancer stem cells and to inhibit metastasis and invasion. Studies have proposed that polyphenols act through several mechanisms including regulating the expression of microRNAs (miRNAs), which are small non-coding RNAs that regulate gene expression by sequence

specific binding of mRNA. One important miRNA in breast cancer is *miR-125a-5p*. Overexpression of *miR-125a-5p* showed significant inhibition of breast cancer cell migration and invasion. Research shows that it may inhibit cell proliferation and encourage cell apoptosis by negatively regulating expression of *BAP1*. In clinical settings, lower levels of *miR-125a-5p* have been shown to be an independent predictor of breast cancer suggesting it has an important role in this disease. It is not known whether polyphenols, such as epigallocatechin-3-gallate (EGCG), can modify levels of *miR-125a-5p* in breast cancer cell lines. Here, we investigate the effect of increasing concentrations of EGCG on the growth of the triple negative breast cancer cell line MDA-MB-468 and whether levels of *miR-125a-5p* change after exposure to this chemical. We treated MDA-MB-468 cells with varying concentrations of EGCG for 24 hours, and carried out the MTT proliferation assay. We extracted total RNA, and used miScript reverse transcription and primer assays with quantitative PCR (qPCR) analysis to determine *miR-125a-5p* levels. We found that proliferation significantly decreased in cells exposed to 0.5 mM EGCG in comparison to 1 µ M (44.0 ± 13.0% vs. 85.3 ± 1.9%, respectively (p =0.023)). *miR-125a-5p* levels increased after treatment with 50 µ M EGCG ($miR\text{-}125a\text{-}5p_{50\mu M}$ = 337.1 ± 57.7% (p =0.025) vs. untreated). This work highlights the potential role of polyphenols such as EGCG as an inhibitor of cancer cell growth possibly by modifying the expression of miRNAs such as *miR-125a-5p.*

P1156/B283

Role of RBPMS Splice Variants in Cisplatin Resistance Ovarian Cancer Cells.

R. J. Rabelo-Fernandez[1], G. Santiago[2], P. Vivas-Mejia[2]; [1]University of Puerto Rico, San Juan, PR, [2]University of Puerto Rico Medical Science Campus, San Juan, PR.

RBPMS is a RNA binding protein with multiple splicing encoded by the RBPMS gene located in chromosome eight in humans. RBPMS is capable to bind and process RNA molecules. RBPMS also interact with proteins in the nucleus and it can blocks the formation of c-Jun-c-Fos and/or c-Jun-Smad3 complexes in order to regulate gene expression. Three major RBPMS isoforms has been described RBPMS-A (21.8 kDa), RBPMS-B (22.4 kDa) and RBPMS-C (24.2 kDa). Reports have shown that each RBPMS isoform interact with different proteins and RNAs. Results of our laboratory found that RBPMS is decreased in cisplatin sensitive compared with cisplatin resistant cells. Small-interference RNA (siRNA)-based RBPMS silencing decreased the sensitivity of ovarian cancer cells to cisplatin treatment. However, the specific RBPMS isoform responsible of this biological effects have not been elucidated. We overexpressed separately the isoform a and C of RBPMS in the cisplatin resistant ovarian cancer cells, A2780CP20 cells. We performed cell proliferation, cell viability, cell invasion, and in vivo tumor growth in subcutaneous mouse models. Significant reduction in the number of colonies were observed in both isoform a and isoform C of RBPMS compared with control clones. However, clones of isoform a but not the isoform C were more sensitive to cisplatin treatment. Invasion assay showed that the expression of RBPMS a and C decrease the invasiveness capacity of the cells when compared with controls. Furthermore, in vivo tumor growth showed a significant reduction in tumor growth between RBPMS a and C when compared with the controls. These results suggest that both, isoform a and C regulate transcripts involved in cell proliferation and invasion capacity of ovarian cancer cells. However, only the isoform a contributed to the cisplatin sensitivity of ovarian cancer cells. Ongoing work are identifying the RNA and proteins associated with each RBPMS isoform.

P1157/B284

Pathological Trans-lesion Synthesis (TLS): a Mutagenic Driver and Molecular Vulnerability in Cancer.

C. Vaziri; University of North Carolina, Chapel Hill, NC.

There are fundamental gaps in our understanding of how neoplastic cells tolerate intrinsic DNA replication stress and DNA damage while simultaneously accumulating the mutations that fuel cancer progression. Trans-Lesion Synthesis (TLS) is a specialized mode of DNA replication that employs damage-tolerant and error-prone DNA polymerases. Therefore, TLS provides a potential explanation for how neoplastic cells endure diverse genotoxic stresses while mutating their genomes during multi-step tumorigenesis. We have tested the hypothesis that TLS facilitates carcinogenesis by conferring DNA damage tolerance and mutability. We show that: (1) the TLS pathway is pathologically activated by an aberrantly-expressed germ cell protein (Melanoma antigen A4, or MAGE-A4) in many cancer cells. (2) TLS maintains ongoing DNA synthesis and sustains viability in cells experiencing oncogene-induced DNA replication stress. (3) the TLS pathway promotes tumorigenesis and shapes cancer genomes in *vivo*. Taken together these results show that TLS endows neoplastic cells with two important tumorigenic phenotypes namely DNA damage tolerance and mutability. The DNA damage tolerance and mutability acquired during carcinogenesis also allows cancer cells to resist therapy-induced genotoxicity. The identification of pathological TLS as a cancer-specific DNA damage tolerance pathway provides opportunities for new treatments that selectively sensitize tumors to genotoxic therapies yet are innocuous to normal cells.

3D Culture Conditions Reveal Therapeutic Signaling Vulnerabilities in RAS-mutant Cancer Cells.

E. Sheffels, N. E. Sealover, P. Theard, R. L. Kortum; Uniformed Services University of the Health Sciences, Bethesda, MD.

Signaling from receptor tyrosine kinases (RTKs) to the small G protein RAS through the RAS guanine nucleotide exchange factors (GEFs) SOS1 and SOS2 is critical for normal cellular proliferation. Activating mutations in this pathway can drive tumorigenesis, and RAS family genes (H-, N-, and KRAS) are the most frequently mutated human oncogenes, accounting for ~30% of cancers. These cancers are disproportionately responsible for cancer-related deaths in the US, and therapeutic options to target these cancers are limited, indicating that identifying novel therapeutic vulnerabilities is key to developing successful treatments. Using RAS-mutant cancer cell lines, we demonstrate that three-dimensional (3D) culture methods reveal signaling dependencies in cancer cells that are masked by growth in two-dimensional (2D) culture.Using cancer cell lines expressing mutants of the three RAS isoforms, we found that RAS family members have a hierarchical requirement for SOS2 to drive anchorage-independent (3D) transformation, but not anchorage-dependent (2D) proliferation, with KRAS>NRAS>HRAS. Consistent with the idea that upstream activators of wild-type RAS, including RasGEFs, represent potential novel therapeutic targets in KRAS-mutant tumor cells, wild-type RAS isoforms cooperate with KRAS to promote downstream signaling and transformation in these cancers. We found that SOS2 was necessary for receptor tyrosine kinase (RTK)-dependent, WT RAS-mediated, PI3K activation in RAS-mutant cells regardless of mutant isoform. The differential dependence of cells expressing mutated RAS to SOS2 deletion was due to a hierarchical dependence on PI3K signaling to resist anoikis in anchorage-independent (3D) growth conditions. These results demonstrate the importance of choosing the appropriate culture system to identify and test novel targets in RAS-mutant

tumors, including using anchorage-independent 3D growth screens to supplement current 2D screening efforts.

P1159/B286

Excitability of the Ras-pi3k Network Controls the Dynamic Morphology and Transformation in Epithelial Cells.

D. Zhan[1], S. Bhattacharya[2], H. Cai[3], P. Iglesias[2], C. Huang[1], P. Devreotes[1]; [1]Johns Hopkins University School of Medicine, Baltimore, MD, [2]Johns Hopkins University Whiting School of Engineering, Baltimore, MD, [3]Institute of Biophysics, Chinese Academy of Sciences, Beijing, CHINA.

The Ras-PI3K signaling network is frequently activated in cancer. Studies in Dictyostelium have delineated the role of excitability of this network in cell migration and some parallels have been observed in human cells. Here we show that the activities of the Ras-PI3K signaling network propagate as coordinated waves, biased by epidermal growth factor, which drive actin-based drive protrusions in MDA-MB-231 and MCF10A cells. The signal transduction events display other excitable features including mutual annihilation of oppositely directed waves, full responses to suprathreshold stimuli, and refractoriness. Acute depletion of PI(4,5)P2 or PI(3,4)P2 activated the network by lowering the threshold/setpoint. Activated Ras acts through PIP3 and mTORC2 to drive cytoskeletal activity while ERK provides negative feedback. Importantly, expression of oncogenic H-Ras and K-Ras leads to dramatic increases in coupled signal transduction-cytoskeletal wave activity. These observations suggest that the transformed state can be viewed as a lowering of the threshold of the Ras-PI3K network.

Functional Link of Mir-200a and Elk3 to Regulate Metastatic Nature of Breast Cancer Cells.

H. Kim, J. Park, K. Park; CHA university, Seongnam-si, KOREA, REPUBLIC OF.

ELK3 belongs to the ETS family transcription factor and it has been reported to act as an oncogene to regulate epithelial-mesenchymal transition during metastasis of various cancers including prostate, liver and aggressive triple negative breast cancer cells. Considering that ELK3 is also implicated in the lymphangiogenesis during embryonic development, it is expected that there is a strict window to maintain cellular context dependent proper concentration of intracellular ELK3. Indeed, ELK3 protein level is regulated by multiple steps including transcriptional and post-transcriptional mechanisms.Based on our recent report that ELK3 is highly expressed in aggressive basal type compared to luminal type of breast cancer cells, we questioned what is the underlying mechanism that determines the difference of ELK3 level between basal and luminal breast cancer subtypes. Our analysis showed that the amount of ELK3 in breast cancer cell types is controlled by stepwise regulatory mechanism. Firstly, *ELK3* transcription is controlled by promoter activity and *ELK3* promoter in MCF7 is highly methylated to suppress *ELK3* expression. Then, the expressed *ELK3* transcripts are under second control mechanism by miRNAs targeting to 3'UTR of transcribed *ELK3*. Our result from deletion analysis and mutation analysis demonstrated that miR200a is a primary miRNA to determine the ELK3 level in different breast cancer cell type. We demonstrated that the expression of miR200a and ELK3 is functionally linked to regulate cell migration and invasion of breast cancer cells. These findings provide a previously unknown mechanistic insights into the regulation of ELK3 level in various cancer cell types and it is expected to expand our understanding of ELK3 activity in terms of cancer cell characteristics.

Downregulation of SCAMP3 Suppresses Inflammatory Breast Cancer Progression through EGFR Signaling.

A. C. Acevedo-Diaz[1], J. Reyes-Chea[2], M. M. Martinez-Montemayor[3], I. J. Suárez-Arroyo[3]; [1]University of Puerto Rico, Department of Biology, Bayamon, PUERTO RICO, [2]American University of antigua-College of Medicine, Coolidge, ANTIGUA and BARBUDA, [3]Universidad Central del Caribe-School of Medicine, Department of Biochemistry, Bayamon, PUERTO RICO.

Inflammatory Breast Cancer (IBC) is a rare and aggressive form of breast cancer. It accounts for ~2.5% of all breast cancers in the U.S. IBC is characterized by rapid progression and the ability to invade the lymphatic system by the formation of emboli and subsequent metastasis development. Epidermal Growth Factor Receptor (EGFR) is overexpressed in IBC and contributes to IBC progression and reduced overall survival. Studies associate the endocytosis related protein, Secretory Carrier Membrane Protein 3 (SCAMP3), with the regulation of EGFR recycling and degradation. Recently, we published that SCAMP3 is overexpressed in IBC cells, tumors and emboli. Others have identified SCAMP3 as an indicator of poor prognosis in hepatocellular carcinoma. Therefore, we hypothesize that SCAMP3 promotes trafficking of EGFR, induces EGFR signaling and IBC progression. To evaluate whether SCAMP3 has a direct interaction with EGFR, we treated IBC cells with the EGFR ligand, EGF (100ng/mL) at different time points, then we evaluated the localization of both proteins by immunofluorescence. Results showed that SCAMP3 co-localizes with EGFR at the cytoplasm at early stimulation times and at the perinuclear area after 30 mins. To evaluate if SCAMP3 has a role in IBC progression, we pre-treated IBC cells (WT) and SCAMP3 knockout IBC cells with EGF to assess cell proliferation, tumor emboli formation, and the EGFR signaling cascade. Our results showed that KO of SCAMP3 decreased proliferation and area of formed emboli. The expression of ERK1/2 was also reduced in SCAMP3 KO cells. Taken together, SCAMP3 is involved in the internalization of EGFR, cell proliferation, and tumor emboli formation. We conclude that SCAMP3 has an essential role in EGFR trafficking and IBC progression.

P1162/B289

Functional Role of the Cell-adhesion Molecule Metadherin in Inflammatory Breast Cancer Progression.

G. Ortiz-Soto, I. Suárez-Arroyo, M. Martínez-Montemayor, 00926; Universidad Central del Caribe School of Medicine, Bayamón, PR.

Inflammatory breast cancer (IBC) is one of the most challenging and lethal forms of primary breast cancer with a 5-year survival rate of 43%. The lethality of IBC originates from its nature of invading the vascular and lymphatic systems, absence of a typical tumor mass, and the generation of tumor emboli. Challenges in this disease include the accurate and early diagnosis and the development of effective targeted therapies. Previous studies investigated potential biomarkers involved in tumor spheroid integrity by characterizing IBC's cell surface proteome. Plasma membrane proteins were identified via "stable isotope labeling with amino acids in cell culture" (SILAC) with subsequent mass spectrometry (MS)-based quantitative proteomics analysis using the IBC cell line SUM-149 vs. non- cancerous mammary epithelial cells, MCF10A. SILAC results showed overexpression of Metadherin (MTDH) in SUM-149 cells (>2.0 fold change). Subsequently, we validated the overexpression of MTDH in SUM-149 cells, IBC tissues and emboli. MTDH is a cell adhesion molecule overexpressed in many cancer types, including breast cancer. MTDH promotes cancer progression by modulating various signaling pathways

including NF-kB, which is related to cell survival, proliferation, invasion and metastasis. Therefore, the aim of this study is to assess the functional role of MTDH in IBC progression. To elucidate the mechanism of action of MTDH in colony formation and tumor spheroid we silenced MTDH (CRISPR or shRNA) the SUM-149 and SUM-190 IBC cells. We assessed the expression of MTDH by immunoblotting and we observed a reduction of protein abundance. The number of colonies formed in SUM-149 MTDH silenced cells was ~40% lower when compared to non-silenced cells. Tumor spheroids of SUM-149 and SUM-190 MTDH silenced cells were smaller than non-silenced cells. Aditionally, MTDH silencing results in a decrease in the phosphorylation of the p65 subunit of NF-kB while no changes are observed in total protein abundance in SUM-149 cells. We can conclude from our preliminary results that MTDH serves as a potential IBC target for IBC progression. Radiation Signaling through P53 Modulates Biological Outcome in Normal Adult Human Endothelial Cells Following Radiation.

R. M. Bouten[1], E. A. McCart[1], C. L. Dalgard[2,3], G. Sukumar[2,4], R. M. Day[1]; [1]Department of Pharmacology and Molecular Therapeutics, Uniformed Services University of the Health Sciences, Bethesda, MD, [2]Department of an atomy, Physiology & Genetics, Uniformed Services University of the Health Sciences, Bethesda, MD, [3]The American Genome Center, Uniformed Services University of the Health Sciences, Bethesda, MD, [4]Collaborative Health Initiative Research Program, Henry Jackson Foundation, Bethesda, MD.

Our laboratory determined that the primary response of normal adult endothelial cells to ionizing radiation (IR) is accelerated senescence. We demonstrated that adult human and bovine pulmonary artery endothelial express senescence-associated β-galactosidase (SA- βgal), upregulated cell cycle checkpoint proteins, and increased levels of anti-apoptotic proteins in response to 5-50 Gy (2.4 Gy/min) IR. The signaling differences that result in accelerated senescence vs apoptosis in response to IR are not completely understood. We hypothesized that p53, a protein activated by redox stress and DNA damage, directs early signal transduction following IR, and that specific pathways downstream of p53 determine the biological outcome. We examined the early signaling events of human lung microvascular endothelial cells (HLMVECs) after high dose IR. Similar to other adult endothelial cells, HLMVECs responded to 10 Gy (1.15 Gy/min) IR mainly by undergoing premature senescence as indicated by SA-βgal expression. We also observed upregulation of cell cycle checkpoint protein p21/waf1 by western blotting, a further indication of senescence. Using qPCR, we examined the expression of genes known to be increased in transformed cells in response to IR. We found a significant increase in insulin-like growth factor receptor 1, an anti-apoptotic tyrosine kinase, and a decrease in PIK3CA and PIK3CB, catalytic subunits of an immune response kinase. We also identified transcriptionally independent upregulation of p21, ATM, phospho-ATM, and phosphor-MDM protein levels increased at 4 h post-IR. We investigated p53 binding partners and target genes using co-immunoprecipitation and western blotting. P53 binding of HIPK2, a conserved serine/threonine kinase, increased significantly within 10 minutes of IR. In order to better understand these results and the difference between transformed and HLMEC p53 signaling and gene regulation, we examined total p53 binding partners using co-immunoprecipitation

with mass spectrometry, and RNA-seq. Our data suggest that signaling in HLMVECs differs significantly from cancer cell signaling in response to radiation, which impacts the biological outcome.

Transfer of Lipid from Cancer-associated Fibroblasts Enhances Stemness Properties of Cancer Cells Under Glucose Deficient Condition through Stearoyl-coa Desaturase.

S. Hwang, Y. Kim, Y. Yang, Y. Jeong, J. Jung; Seoul national university, Seoul, KOREA, REPUBLIC OF.

Cancer-associated fibroblast (CAF) plays a crucial role in the tumor progression by interacting with cancer cells. Under tumor microenvironment like glucose deficient condition, lipid metabolism becomes more active for the cancer cell biology. This study investigated the effect of CAF-derived lipids on the cancer cell phenotypes. For xenograft tumor, NCI-H460 (H460) cells were subcutaneously injected into immune deficient mice. Fibroblasts were isolated from the resultant tumor mass and the underarm skin tissue by magnetic-activated cell sorting with anti-FAP and anti-CD90/Thy1 antibodies. Lipid components were measured by a commercial EZ-free fatty acid assay kit and Bodipy staining. Western blot, RT-PCR, immunofluorescence and flow cytometry were performed to assess the expression level of lipid metabolism, cancer and intracellular structure related markers. Mitochondrial function was evaluated using JC-1 assay, Rhod-2AM staining and ATP production assay. Stearoyl-coa desaturase (SCD) expression was manipulated by lentiviral vector and CRISPR/Cas9-based gene editing. Under glucose deficient condition, H460 cells co-cultured with CAFs showed enhanced cell viability and cisplatin resistance compared to those with normal fibroblasts (NFs). The amount of lipid components was higher in CAFs than in NFs. The CAF-derived lipid component was transferred to H460 cells and metabolized by increasing SCD expression under glucose deficient condition. For the lipid supplementation study, oleic acid (OA) was treated to H460 cells. Enhancement of cancer stemness by the supplement of OA to glucose starved cells was significantly mitigated by the treatment with SCD inhibitor. Moreover, cells with upregulated SCD showed significant enhancement of cancer stemness compared to their corresponding controls, but it was remarkably suppressed in SCD-knockout (SCD-KO) cells. Markers of mitochondrial function and intracellular filamentous structure were regulated by SCD expression. Intriguingly, increased F-actin expression in SCD upregulated cells induced the nuclear translocation of YAP, but not in Mock and SCD-KO cells. In xenograft assay, the size of the resultant tumor mass was significantly increased by injection of SCD upregulated cells compared to that by Mock cells. However, SCD-KO cells showed limited tumor development. In conclusion, these results suggested that targeting lipid metabolism in glucose starved cancer cells may be a potential way of anti-cancer therapy, through the suppression of cancer stemness.

Investigation of Nutrient Sharing between Stromal Cells and Cancer Cells in a Mouse Model of Pancreatic Cancer.

J. Hood-DeGrenier, 01602-2861[1], A. Lau[2], M. Vander Heiden[2]; [1]Worcester State University, Worcester, MA, [2]Massachusetts Institute of Technology and Koch Institute for Integrated Cancer Research, Cambridge, MA.

Pancreatic ductal adenocarcinoma (PDAC) is characterized by tumors that contain cancer cells embedded in a vast excess of non-cancerous, stromal cells. Many of the stromal cells in these tumors are a type of fibroblast called pancreatic stellate cells (PSCs). Using a three-dimensional, in *vitro*, mouse organoid model of PDAC, we have developed conditions such that the PDAC cancer cells require the presence of PSCs to proliferate. PSCs secrete large amounts of collagen, which forms the basis of the extensive extracellular matrix in these tumors. It has been shown that the PDAC cells are able to take up collagen produced by the PSCs as a source of amino acids to support proliferation, however dissecting the metabolic relationships between cancer cells and stromal cells in mixed culture is challenging. As a way to study this, we have engineered PSCs to overexpress the RBKS gene, which encodes ribokinase, an enzyme that catalyzes phosphorylation of ribose to ribose-5-phosphate, thus trapping ribose in cells, where it can serve as a precursor for synthesis of nucleotides. Mammalian genomes possess the RBKS gene, but it is not typically expressed at a level that supports detectable ribokinase activity; thus, cells do not incorporate isotope-lableled ribose as assessed by gas chromatography/mass spectrometry analysis of polar metabolites. We are investigating the ability of cells overexpressing RBKS to incorporate labeled ribose as a way to track label from one cell type to another and dissect how nutrients are shared between PDAC cancer cells growing in co-culture with PSCs.

The Nutrient Microenvironment of Tissues and Tumors Affects the Metabolism of Resident Cells.

A. Muir; University of Chicago, Chicago, IL.

The metabolism of mammalian cells is influenced both by cell-intrinsic factors and cell-extrinsic factors. There has been substantial effort towards understanding how cell-intrinsic factors, such as disease causing genetic mutations, alter cellular metabolism. However, much less is known about how physiological microenvironmental conditions alter cell metabolism. Nutrient availability is a cell-extrinsic factor that substantially influences cellular metabolism, yet we have relatively little information regarding nutrient availability in different healthy or diseased tissues. To address this, we developed a quantitative metabolomics approach to measure nutrient levels in the interstitial fluid (IF) of tissues and tumors, providing insight into the metabolic substrates available to cells in their local microenvironment. Profiling IF nutrient levels in different tissues and tumors has provided insight into nutrients that are depleted or accumulate in different anatomical sites in the body. To determine how local nutrient availability alters cellular metabolism, we have developed a cell culture medium based on observed IF nutrient levels in murine pancreatic cancers. Pancreatic cancer cells, as well tumor stromal cells, can be grown in IF-based medium in order to study how cells utilize metabolism to support homeostasis and function when constrained by microenvironmental nutrient levels. In initial experiments, we found that freshly isolated murine pancreatic cancer cells grow robustly in IF-based media, but cancer cells initially cultured in standard media lose the ability to grow in IF-based media, suggesting that the adaptations required by cancer cells to cope with tumor nutrient levels are rapidly

lost by pancreatic cancer cells in standard culture. We are using a multi-omics approach to identify what metabolic adaptations pancreatic cancer cells use to support their growth in their nutrient environment. Collectively, these experiments provide insight into how nutrient availability acts as a cell-extrinsic factor to alter pancreatic cancer cell metabolism, and provide an experimental approach for determining how nutrient availability impacts cellular metabolism in healthy and diseased mammaliantissues.

Breast Cancer Autophagy and Chemoresistance Are Regulated by Substratum Stiffness.

A. An las, 08540, C. Nelson, 08544; Princeton University, Princeton, NJ.

Breast cancer relapse can develop over the course of years due to dormant cancer cells that at one time disseminated to secondary sites. These dormant cells are often resistant to conventional chemotherapy. Although recurrence is the main cause of death from cancer, the microenvironmental factors that determine the duration of dormancy are largely unknown. Considering that breast cancer relapse is often detected in tissues that are softer than the normal mammary gland and the primary breast tumor, such as the bone marrow, the brain and the lung, we explored how the stiffness of the tissue at secondary sites regulates tumor dormancy and the response of breast cancer cells to chemotherapy. We found that substratum stiffness regulates proliferation and apoptosis of MCF7 human breast cancer cells. Soft substrata with compliances reminiscent of those at secondary sites harbor tamoxifen- and paclitaxel-resistant breast cancer cells as determined by EdU incorporation, TUNEL staining, and immunoblotting for p21, p27, and cyclin D1. To determine why cells survive in soft microenvironments, we investigated the effects of tissue stiffness on autophagy, a process that has been implicated in the survival of dormant cancer cells. Immunofluorescence staining for LC3B, immunoblotting for p62, and autophagosome turnover assays demonstrate that autophagy is increased on soft substrata. Additionally, we found that autophagy contributes to tamoxifen resistance and that blocking autophagy sensitizes MCF7 cells to tamoxifen, especially on soft substrata. We also found that increasing the expression of integrin-linked kinase, which transmits mechanical signals received by integrins, leads to a decrease in the number of autophagosomes in cells on soft substrata. Our data suggest that the stiffness of the microenvironment regulates dormancy and autophagy of breast cancer cells, which could facilitate the long-term survival of metastases in the soft microenvironments at secondary sites.

Study of VEGF-A Regulation in Osteosarcoma Spheroids Under Various Cellular Stresses Using Microfluidic Devices.

S. Sarkar[1,2], Y. Tung[2]; [1]National Tsing Hua University, Hsinchu, TAIWAN, [2]Academia Sinica, Taipei, TAIWAN.

Three-dimensional (3-D) cell culture provides a convenient micro-environment to study tumor biology and their survival mechanisms[1]. Cellular stresses like serum starvation and drug therapy often result in aggressive pro-angiogenetic behavior in tumors. Recent drug studies have shown resistance to chemotherapy by hypoxia inducible factor (HIF) regulated pathways, particularly in osteosarcomas, and most studies done on 3-D models have shown different results from conventional 2-D monolayer cell cultures[2, 3]. An approach with statistically significant sample size to observe responses of cancer spheroids under cellular stresses is desired. In our work, vascular endothelial growth factor of type a (VEGF-A) of osteosarcoma MG-63 spheroids cultured using microfluidic devices is studied under normal

growth and stress conditions (serum deprivation and HIF inhibition) to investigate their roles in spheroid growth. The microfluidic device is designed to culture 5000 uniformed sized spheroids, and enzyme-linked immunosorbent assay (ELISA) is used for quantitative characterization of VEGF-A secreted from the spheroids. Cell viability assay is also performed to estimate apoptotic cell ratios based on imaging. The results are compared to conventional 2-D cell culture ones. The results show that the spheroids cultured for a 12-day time period have specific log phase (~6 days) denoted by increase in size by 12-14% and high VEGF-A secretion. This is followed by a stationary phase and decline phase where the VEGF-A concentration lowers gradually and spheroid growth is restricted (3% decrease in size). Our experimental results show that VEGF-A secretion decreases with increase in stress doses (lower serum concentration or higher drug concentration) in 2-D monolayer cell culture. However, in 3-D spheroid cultures, VEGF-A concentration decreases for low stress doses but increases with high stress doses. The VEGF-A regulation in our 3-D models mimics in *vivo* cases of tumor survival and can provide insightful information to investigate tumor angiogenesis. In conclusion, this work provides an efficient, statistically significant method of studying tumor growth kinetics and stress response mechanisms using in *vitro* 3-D cell cultures and cytokine immunoassays. Hence, it also illustrates the significance of 3-D tumor models over conventionally used 2-D models in cancer research. References 1. P. K. Chaudhuri, M. Ebrahimi Warkiani, T. Jing, Kenry and C. T. P1169/B296

Profilin1 Is an Important Intracellular and Extracellular Mediator of Endothelial-Tumor Cell Crosstalk in Tumor Cell Motility and a Novel Prognostic Biomarker in Clear Cell Renal Cell Carcinoma.

A. Allen[1], D. Gau[1], R. Martin[1], Y. Wang[1], A. Duensing[1], S. Duensing[2], M. Lotze[1], W. Storkus[1], P. Roy[1]; [1]University of Pittsburgh, Pittsburgh, PA, [2]Heidelberg School of Medicine, Heidelberg, GERMANY.

Clear cell renal cell carcinoma (ccRCC) is the most common subtype of renal cancer (found in >75% patients) and associated with poor patient prognosis. Additionally, five-year survival of patients with advanced ccRCC is only 10%. The objective of the study is to test if upregulation of the actin-binding protein profilin-1 (Pfn1) promotes ccRCC progression through a pro-angiogenic tumor microenvironment. We performed bioinformatics analyses of TCGA datasets to demonstrate elevated expression of Pfn1 correlated with clinicopathological features of advanced tumors and shorter overall and disease-free survival of ccRCC patients, but not in other histological subtypes of renal cancer. A hallmark of ccRCC is a vascular-rich tumor microenvironment due to genetic inactivation of von Hippel Lindau leading to dramatic upregulation of angiogenic mediators. Immunohistochemistry of human ccRCC tissue microarray revealed that the vast majority of ccRCC tumors exhibit strong Pfn1 expression in stromal (vascular/lymphocytic) cells rather than in tumor cells, a finding further corroborated by single-cell transcriptome studies demonstrating robust transcriptional upregulation of Pfn1 in endothelial cells (EC) of tumor-associated vasculature. Overexpression and knockdown studies provide evidence for endothelial Pfn1-dependent changes in motility of ccRCC cells through a paracrine mechanism that is consistent with alterations in the secreted levels of several cytokine-like molecules. Interestingly, Pfn1 itself is one of the proteins that is released by EC in the extracellular environment, a finding that is further supported by detectable Pfn1 in the serum of ccRCC patients. Furthermore, extracellular Pfn1 stimulates motility of ccRCC motility suggesting that Pfn1 may also have a previously unrecognized extracellular function. Finally, we demonstrated prominent inhibition of ccRCC cell

migration and proliferation, and angiogenesis by novel small molecule antagonist of Pfn1:actin interaction. Collectively, these findings suggest that Pfn1 is an important mediator of endothelial-tumor cell crosstalk, a novel prognostic biomarker and a potential target for intervention in ccRCC.

Neuroblastoma Differentiation in *Vivo* Excludes Cranial Tumors.

R. W. Treffy[1], S. G. Rajan[1], L. M. Nacke[1], U. A. Malkana[1], D. E. Bergey[1], D. Santana[1], V. Rajagopalan[2], J. P. O'Bryan[2], **A. Saxena**[1]; [1]University of Illinois at Chicago, Chicago, IL, [2]Medical University of South Carolina, Charleston, SC.

Neuroblastoma (NB), the most common cancer in the first year of life, is thought to arise from the neural crest (NC)-derived sympathoadrenal lineage and is found almost exclusively in the trunk. To understand why an early-onset cancer would have such a specific localization, we xenotransplanted human NB cells into discrete NC streams in developing zebrafish embryos. We demonstrate quantitatively that human NB cells previously shown to be incapable of differentiation remain undifferentiated when comigrating posteriorly with native NC cells but, upon comigration into the head, readily differentiate into neurons and exhibit decreased survival. Furthermore, we demonstrate that this *in vivo* differentiation requires retinoic acid and brain-derived neurotrophic factor signaling from the microenvironment and cell autonomous intersectin-1-dependent phosphoinositide 3-kinase-mediated signaling, likely via Akt. Our findings suggest a microenvironment-driven explanation for NB's trunk-biased localization in young patients and highlight the potential of differentiation in promoting NB resolution in *vivo*.

P1171/B298

Neuronal Synaptic Proteins Regulate Cancer-associated Fibroblast Pro-tumor Features in Pancreatic Cancer.

J. C. Gardiner, R. A. Francescone, D. B. Vendramini Costa, J. Franco-Barraza, E. Cukierman; Fox Chase Cancer Center, Philadelphia, PA.

Currently, only 9% of pancreatic ductal adenocarcinoma (PDAC) patients live beyond 5 years. These poor outcomes are, in part, driven by a distinct fibrous microenvironment known as desmoplasia that comprises over 70% of the cancer mass. However, desmoplasia is a double edge sword; its highly immunosuppressive behavior is tumorigenic, yet its removal leads to unrestricted tumor growth. Thus, understanding PDAC's desmoplasia is crucial for selectively harnessing its natural tumor suppressive functions. Previous research revealed that the pro-tumorigenic function of desmoplasia relies on two key components; cancer-associated fibroblasts (CAFs) and the desmoplastic extracellular matrix (D-ECM). Notably, D-ECM stimulates CAFs to express a pre- and post-synaptic protein pair that is not expressed under healthy physiological conditions. CRISPR-Cas9-mediated knock out of the pre-synaptic protein in patient-derived CAFs significantly altered CAFs' natural ability to secrete inflammatory cytokines but maintained the ability to create an aligned D-ECM; classically considered a feature of poor patient outcome. Mono-cultured KO CAFs maintained expression of the post-synaptic protein, suggesting that the expression and engagement of these neuronal proteins in CAFs may have important roles in stromal maintenance that can contribute to the pro- and anti-tumorigenic effects. Additionally, RNA sequencing data comparing KO CAFs to controls identified a significant decrease in the expression of a protein tyrosine phosphatase (PTP) involved in synaptic stabilization and focal adhesion formation

that was previously shown to bind these upregulated synaptic proteins in neurons. PTP CRISPR-Cas9-mediated knock out cells similarly altered CAF cytokine secretion but disrupted CAF myofibroblastic features; that is, the ability to maintain an aligned D-ECM. How PTP signaling affects CAF D-ECM organization, cytokine secretion, and whether it is associated with synaptic protein-induced signaling are the current future directions of this project.

Using 3d Spheroids to an alyze the Invasion of Lung Cancer Cells Induced by Fibroblasts Under the Treatment of Cigarette Smoke Extract.

H. Hou[1], H. Pan[2], W. Liao[3,4], C. Yu[3,4], **C. Lee**[2,5]; [1]Graduate Institute of Oral Biology, College of Medicine, National Taiwan University, Taipei, TAIWAN, [2]Research Center for Applied Sciences, Academia Sinica, Taipei, TAIWAN, [3]Department of Internal Medicine, National Taiwan University Hospital, Taipei, TAIWAN, [4]Department of Internal Medicine, College of Medicine, National Taiwan University, Taipei, TAIWAN, [5]Institute of Biophotonics, National Yang-Ming University, Taipei, TAIWAN.

It was reported that cigarette smoke extract (CSE) may participate in the invasion and metastasis of lung tumors through various mechanisms. Using the conditioned medium of the CSE-treated fibroblast (MRC-5) to treat the lung cancer cells (CL1-0), we found that the invasion capability of lung cancer cells was enhanced in the conventional 2D invasion assay. Western blotting assays showed that the CSE enhanced the expressions of the autophagy-relevant microtubule-associated protein 1 light chain 3 β (LC-3B) and decreased the p62 protein. Therefore we suspected that the CSE could induce autophagy in the fibroblast. We further tested this invasion-enhancement capability of the CSE-treated fibroblast using 3D cellular spheroids. We placed Matrigel® mixed with the culture medium into the wells of an ultra-low-attachment 96-well plate. With a 50% volume concentration of the Matrigel®, the cancer cells aggregated to form a spheroid spontaneously after 24 hours. The cancer cells were labelled with the CellTracker dye such that we could use fluorescence microscopy to observe the invasion of individual cells into the gel. For each spheroid, we quantified the cancer cell invasion in 24 hours using the longest invasion distance measured from the spheroid boundary. We observed that the conditioned media of fibroblasts treated by CSE or rapamycin (as a positive control) could enhance the cancer cell invasion in the 3D cellular spheroids. Interestingly, as we co-cultured fibroblasts with the cancer cell spheroid, we observed the fibroblast-led invasion into the Matrigel®. The invasion distances in the co-culture system were longer than those in the mono-culture spheroids. In summary, we demonstrated that the CSE treatment on fibroblast could raise the invasion capability of lung cancer cells using 3D mono-culture and co-culture spheroids. The effect of CSE could be related to the autophagy in fibroblast.

P1173/B300

***RAI14* Is an Actin Cytoskeleton Interacting Protein That Is Upregulated in Pancreatic Cancer and Promotes Src Kinase Stability, Proliferation and Migration.**

F. Runa[1], C. Gonzalez[1], Y. Adamian[1], N. Cox[2], J. Hong[1], K. Bhakta[1], M. Hoover[1], M. Boyce[2], J. A. Kelber[1]; [1]California State University, Northridge, Northridge, CA, [2]Duke University, Durham, NC.

PDAC (pancreatic ductal adenocarcinoma) is one of the most chemoresistant malignances and recognized as the third leading cause of cancer-related deaths. An underlying cause of PDAC's therapy refractory nature is the highly desmoplastic tumor microenvironment that is enriched for extracellular collagen. In this regard, we previously identified integrin alpha one (ITGA1) as a pseudopodium-enriched

protein (PDE) required for protumorigenic collagen signaling in PDAC. Further analysis of PDE proteins co-enriched with collagens and ITGA1 in PDAC led us to the observation that RAI14 (retinoic acid induced fourteen, an kycorbin or NORPEG) is an actin cytoskeleton interacting protein in PDAC cells. We further reasoned that RAI14 expression may be required for the tumorigenic behavior of PDAC as a downstream regulator of collagen/integrin-cytoskeleton signaling. Interestingly, using siRNA-mediated transient silencing, we demonstrate that RAI14 promotes Src kinase protein stability and fibronectin-mediated PDAC cell migration. In light of recent work demonstrating that fibronectin promotes the proper assembly/processing of collagen fibers, our results suggest a potential role for RAI14 as an upstream regulator of collagen trafficking/deposition. Thus, ongoing work is examining the role of RAI14 in collagen processing in and deposition rom PDAC cells using RNAi and CRISPR/Cas9 depletion/deletion methods. These current and prospective findings have potential to illuminate new mechanisms by which PDAC cells foster a malignant microenvironment to supports their expansion and disease progression.

P1174/B301

Extracellular Vesicles Secreted from Pancreatic Cancer Cells Have Bioactive Quiescin Sulfhydryl Oxidase 1 (QSOX1) That Selectively Interacts with the Tumor Microenvironment.

C. Millar-Haskell, C. Thorpe, J. Gleghorn; University of Delaware, Newark, DE.

Pancreatic ductal adenocarcinoma (PDAC) is a solid tumor malignancy that is characterized by a strong desmoplastic reaction. During cancer progression, the extracellular matrix (ECM) becomes increasingly disorganized as cancer-associated fibroblasts deposit dense ECM proteins (collagens, laminins, fibronectin, etc.) which are then modified by matrix-remodeling proteins (MMPs, lysyl oxidase, etc.). In particular, the secreted enzyme QSOX1 is overexpressed in PDAC. QSOX1 is a disulfide bond catalyst that is implicated in cancer invasion, cell migration, and poorer outcomes in cancer patients; however, the specific interactions of QSOX1 with the tumor microenvironment are poorly understood. Because pancreatic cancer is known to release an abundance of extracellular vesicles (EV), we investigated whether QSOX1 was being released into the extracellular matrix via EVs. In this study, we characterized QSOX1-containing EVs and explored how QSOX1 interacted with different ECM protein identities. To analyze the supernatant, PANC-1 cells were cultured in serum free medium for 24 hours and the media was concentrated via spin column centrifugation or differential ultracentrifugation. To characterize EVs, samples were analyzed by nanoparticle tracking analysis and found to be on average 150-200 nm in diameter. EV protein content was then analyzed via Western blot and were positive for QSOX1 along with the exosome proteins Alix and TSG101, while negative for GM-130 and integrin α5. To investigate binding of QSOX1 to various ECM proteins, the concentrated supernatant was resuspended in PBS and allowed to settle on ECM-coated coverslips (laminin, Matrigel, fibronectin, gelatin, and collagen) for 24 hours. Significantly more QSOX1-positive particles were found on the Matrigel, laminin, and fibronectin coating compared to both gelatin and collagen ($p<0.05$). Interestingly, on Matrigel coatings, there was extensive association between QSOX1 and laminin-rich domains, demonstrating further evidence of selective ECM protein localization. Finally, an enzymatic activity assay showed that the supernatant contained 300 nM of functionally active QSOX1, suggesting more than a passive involvement in pancreatic cancer. In summary, we find that QSOX1 containing EVs preferentially associate with laminin(s) and fibronectin through a previously unexplored binding mechanism. Considering how abundant QSOX1 is in the ECM and its ability to rapidly oxidize proteins, these data suggest that QSOX1 plays an important and unappreciated role in ECM remodeling of the tumor microenvironment.

Synergistic Metalloproteinase-based Remodeling of Matrix by Tumor and Stromal Cells during Metastatic Invasion.

H. Cao; Mayo Clinic, Rochester, MN.

The process by which tumor cells mechanically invade through the surrounding stroma into peripheral tissues is an essential component of metastatic dissemination. It is known that matrix metalloproteinase (MMP)-mediated extracellular matrix (ECM) degradation plays an important role in this invasive process, and multiple MMPs have been implicated in metastasis. Defining the contribution and interaction between these MMPs during invasion remains a key interest in the development of targeted anti-metastatic therapies. As both tumor and stromal cells secrete MMPs, the goal of this study was to define the relative contributions between these cell types during matrix remodeling and pancreatic (PDAC) tumor cell invasion. To address this question, we employed multiple different stromal fibroblast populations and cultured PDAC cells and measured the capacity of the tumor cells to degrade a fluorescently-labeled gelatin matrix. Interestingly, co-culture of stromal fibroblasts and PDAC tumor cells results in a marked increase in matrix degradation by tumor cells. Importantly, tumor cells co-cultured with the conditioned medium from stromal fibroblasts exhibited a substantial increase in invadopodial-based matrix degradation, indicating that the fibroblast-mediated increase in matrix degradation is due to a secreted protein. This increase in matrix remodeling also potentiated the capacity of cells to invade through transwell chambers by 30%. Western blot analysis and zymography indicated that stromal fibroblasts, but not PDAC cells, express high levels of pro-MMP2. To test if stromal secretion of MMP2 was acting to stimulate matrix degradation by PDAC cells, MMP2 expression was depleted in stromal fibroblasts using siRNA, and the conditioned media was added to PDAC cells. Loss of MMP2 in the stromal cells prevented the increase in tumor-cell based matrix degradation. MMP2 is known to be activated by MT1-MMP. We hypothesized that the MMP2 secreted by fibroblasts was being activated by MT1-MMP on tumor cells. Indeed, depletion of MT1-MMP in tumor cells by siRNA largely blocked matrix remodeling, even in the presence of stromal cell medium. Consistent with this model, zymography revealed that the pro-MMP2 from the stromal fibroblasts is cleaved and activated following incubation with PDAC tumor cells. In Summary**,** these findings implicate an important interplay between MT1-MMP from tumor cells and MMP2 from fibroblasts as a key component for ECM remodeling and invasion.

Mapping in *Vitro* Cellular Interactions between Cancer and Normal Cells Via Synthetic Notch Ligand-Receptor Pairs.

B. Avsaroglu, A. Hyrenius Wittsten, D. Superville, K. Roybal, A. Goga; UCSF, San Francisco, CA.

Understanding how cells move within an organism and what other cells they come into contact with is critical for elucidating fundamental mechanisms of development, organogenesis as well as pathologic processes such as metastasis. Here we show, in *vitro*, a synthetic-Notch ligand/receptor pair (synNotch - Morsut et al. Cell 2016) based approach can be used to detect physical interactions between immortalized human retinal pigment epithelial (hTERT RPE-1) cells and patient derived Adenoid Cystic Carcinoma (ACC) cells or mouse mammary epithelium derived cells that overexpress human c-Myc oncogene in the presence of doxycycline (MTB/TOM). hTERT RPE-1 or ACC or c-Myc overexpressing

MTB/TOM cells, expressing synthetic ligand (outer plasma membrane localized GFP), were co-cultured with hTERT RPE-1 cells, expressing transgenic (i) LoxP-tagBFP-STOP-LoxP-DsRed, (ii) synthetic Notch receptor/transcriptional activator (outer plasma membrane anti-GFP nanobody combined with internal Gal4 transcription factor through a transmembrane domain) and (iii) CRE-recombinase fused to Estrogen receptor (ER-T2). By combining FACS and fluorescence microscopy facilitated scratch assays, we find that cells carrying the receptor component of synNotch system can switch their fluorescent reporter expression from tagBFP to DsRed more than 10 times when co-cultured with ligand carrying cells in the presence of estrogen receptor modulator, 4-Hydroxytamoxifen (4-OHT) in comparison to mock control. We also find that it takes about one cell division to switch the fluorescent reporter color of a single, receptor carrying cell after its attachment with a ligand carrying one is achieved. Surprisingly, we observed that ligands are not fixed in position between two interacting cells but also are taken in by the receptor carrying cells via a trogocytosis-like process. Our findings suggest that dynamic physical interactions between cells can be mapped using cell surface localized synthetic Notch ligand/receptor pairs in a highly specific manner. Ultimately, we seek to integrate our system into mice to study how an individual cancer cell metastasizes and identify all of the nontumor host cells with which it comes into contact during the metastatic process. We envision the same sensor mice will be valuable to study other processes, such as neurogenesis or development of the immune system.

P1177/B304

Secretome of Human Breast Cancer Cells Induces Changes in Gene Expression Profile but It Is Not Involved Transformation of Mesenchymal Stem Cells from Wharton´s Jelly.

A. L. Sánchez-Corrales, 11340[1], C. M. Mejía-Barradas[1], C. C. Calzada-Mendoza[2], A. Parra-Barrera[1], G. Gutiérrez-Iglesias[1]; [1]Lab. Regenerative Medicine. Instituto Politécnico Nacional, Mexico City, MEXICO, [2]Lab 107. Cell Signalling. Instituto Politécnico Nacional, Mexico City, MEXICO.

Mesenchymal cells are cells that have great potential for differentiation, proliferation and self-renewal, they are present in all tissues. Mesenchymal stem/stromal cells (MSCs) are commonly used as a source of cellular therapy due to their strong immunosuppressive and regenerative effects. Despite the relevance and potential impact of WJ-MSCs on regenerative medicine and tissue remodeling, there is a posibility that the use of these cells in a non-diagnostic procarcinigenic environment on patients with cell therapy this will be considered a risk to tumour transformation, which remains in controversy still. Therefore, a study model is needed to investigate whether tumoral secretome influences on the molecular profile of WJ-MSCs indicating tumour transformation. So the above was investigated in an in *vitro* model. Methods: Secretome was obtained at 24 and 48 h from MCF-7 cultures and it was added on WJ-MSCs and incubated during 48 h. Epifluorescence Microscopy was used to observe changes in cell morphology and citoskeleton organization using phaloidin staining. Finally gene expression was evaluated by RT-PCR for different genes involved in proliferation, immunologic profile as well as mesenchymal markers. Results showed that umbilical cord-derived WJ-MSCs accomplished the criteria proposed by International Society for Cell Therapy (ISCT). Secretome from MCF-7 induced atypical proliferative but not exacerbated behavior of WJ-MSCs in comparison with cells without stimuli. In addition, we observed that cytoskeleton of mesenchymal stem cells changed when the cultures were in presence of secretome of cancer cells. Gene expression of molecules involved in immunological regulation also changed, but genes related to tumoral transformation or excessive proliferation were not affected when WJ-MSCs were incubated with secretome. We concluded that WJ-MSCs are not capable to present characteristics of malignant cells in presence of tumoral environment. It is necessary

to continue with more investigations for ensure that MSCs does not change to tumoral form; nevertheless this work show evidence that cell therapy with MSCs administration be sure and no represent risk for tumoral transformation.

P1178/B305

High-throughput Microfluidic Platform for in Vitro Vascularization of Human Organoids and Tissue Explants - Cell Cultures' Missing Component?

D. Kurek[1], S. Previdi[1], F. Bonanini[1], S. De Ruiter[1], S. J. Trietsch[1], A. Nicolas[1], D. Hendriks[2], D. Dutta[2], H. Hu[2], H. Clevers[2], H. Lanz[1], P. Vulto[1], J. Joore[1]; [1]MIMETAS B.V., Leiden, NETHERLANDS, [2]Hubrecht Institute, Utrecht, NETHERLANDS.

Vasculature is a crucial ingredient of human organs and tissues. In addition to being a vehicle for blood circulation, exchange of angiocrine factors contribute to tissue function and development. The challenge in creating better biomimetic models lies in capturing the 3D morphology, heterogeneity and boundary aspects of tissues. Microtissues such as spheroids or organoids show often limited growth potential and an immature phenotype due to the lack of circulation. One way to improve vascularization of organoids or explants is by transplanting them into a host (*i.e.* mouse). However, the low predictivity of animal models, boost the development of in *vitro* alternative strategies. Microfluidic techniques are increasingly recognized as an important toolbox able to add physiologically relevant cues to traditional cell culture models. Here, we introduce a microfluidic platform that is capable of vascularization of tissues such as organoids, spheroids and tissue fragments. The platform comprises 64 independent microfluidic chips arranged in a microtiter plate format. Each chip comprises an extracellular matrix gel that is patterned by means of a surface tension technique called PhaseGuiding. In each chip two blood vessels are grown on lateral side of the free-standing ECM gel. A gradient of angiogenic factors is applied to induce vascular bed formation. Tissues are grafted onto the vascular bed by placing it on top of the ECM gel, containing the vascular bed. Tissue dependent vessels remodeling and stabilization can be monitored overtime by real time imaging and barrier integrity. When liver spheroids or organoids are used, vessels became stabilized and fully leaktight in the system. Moreover, the expression of $CD31^+$ cells around and in within the spheroids proves that endothelial cells migration and tissue envelopment occurred during co-culture. The high number of units (up to 64 chips in 384 well format) enables functionality studies and compound screening in a robust and automated way. We propose the use of the Organoplate® Graft as a vessels grafting platform for multiple 3D tissues allowing drug discovery and disease modeling in a more physiological environment. The method provides an in vitro alternative to current xenograft techniques and may fill up a crucial gap in current day cell culture.

Characterization of Reprogrammed Human Cancer Cells Contributing to Tumor-free Chimeric Mammary Gland Outgrowths.

L. E. Ragle, E. C. Erickson, M. C. Kelly, C. A. Boulanger, G. H. Smith; National Cancer Institute, Bethesda, MD.

Cellular behavior can be influenced by local tissue microenvironment. When transplanted on their own, human embryonal carcinoma (Ntera2) cells form tumors. However, the tumorigenic phenotype is lost upon mixing and co-inoculation with normal mouse mammary epithelium into epithelium-divested mammary fat pads of Athymic nude mice. Despite loss of tumorigenic phenotype, we have shown that

tumor cells persist throughout at least four transplant generations, indicating that the human cells are self-renewing and respond to in *vivo* signals during mouse mammary gland redevelopment. This phenotypic shift from tumorigenic to non-tumorigenic shows the normal mammary epithelium and microenvironment are able to reprogram the human carcinoma cells. It is predicted that these differences in phenotype can be explained via altered gene expression patterns. Magnetic cell sorting revealed the reprogrammed cells are tightly associated with mammary epithelium because there was contamination of the cell populations. In order to study the reprogrammed human cells individually, single cell RNA sequencing was used. Transcriptional differences between the normal human and mouse chimeras versus tumorigenic human cells were compared. Identifying changes in gene expression will narrow down important contributors to the normal phenotype, thereby gaining greater insight into the prevention of cancer.

Extracellular Vesicles from Breast Cancer Cells Stimulated with Linoleic Acid Promote an giogenesis in Human Endothelial Cells.

A. García Hernández[1,2], P. Cortes-Reynosa[2], E. Perez Salazar[2]; [1]CINVESTAV-IPN, CINVESTAV-IPN, MEXICO, [2]CINVESTAV-IPN, Mexico City, MEXICO.

Breast cancer is the leading cause of death for women worldwide maintaining upward trends in incidence and mortality. Several studies have established a clear association between obesity, a high-fat diet and the development of breast cancer. One of the most abundant fatty acids in the diet is linoleic acid (LA), that can be used as an energy source and it is the ligand for two G protein coupled receptors (FFAR1 and FFAR4) and their activation induces several biological processes including proliferation, migration and invasion. On the other hand, during cellular progression, cellular communication is a key event, one mechanism of communication is mediated by small spherical fragments of membranes called extracellular vesicles (EVs). The EVs are secreted by normal and malignant cells, their function is variable and depends on the type of charge that they carry on, as well as the cell type from which they originated. A variety of reports demonstrates that EVs mediate various biological processes associated with cancer progression, including tumor angiogenesis. In this study, we demonstrate that EVs isolated from supernatants of MDA-MB-231 cells stimulated with LA increase the number of secreted EVs. In addition, the EVs from MDA-MB-231 cells stimulated with LA induce migration, proliferation, invasion, secretion of MMP-2 and MMP-9 and angiogenesis in HUVEC cells. Analysis of Early Cellular and Sub-cellular Changes during Tumor Initiation and Progression in Live an imals.

W. Wang, 20892, K. Rechache, R. Weigert; National Institutes of Health, Bethesda, MD.

Head and neck squamous cell carcinoma (HNSCC), most of which arise in the oral cavity, is one of the most common cancers with a 65 % 5-year survival rate. It accounts for more than 650,000 cases and 330,000 deaths worldwide annually. In 2019, it is estimated to have more than 53,000 new cases of HNSCC in the United States, which consists of 3% of all new cancer cases. Understanding the mechanisms that control initiation, progression, and spreading of the tumor to distal sites is of

paramount importance to develop effective therapies. To this end, we have used a well-established carcinogen model in live mice that mimics the progression of HNSCC observed in patients. Here, we show, for the first time, the visualization within the same animal of the onset and progression of cancerous and pre-cancerous lesions that were followed for 22 weeks. By using intravital subcellular microscopy (ISMic), we acquired information on cellular and subcellular changes in the tumors cell and the microenvironment (blood vessels, ECM, an immune cells), and specifically, we focused on changes in the architecture of the actomyosin cytoskeleton, mitochondrial metabolism, and autophagy. This powerful approach allows for the first time to investigate the cell biology of tumor initiation and progression in a live animal.

Stromal Matrix Metalloproteinase 3 (mmp3) Inhibits Breast Cancer but Is Required for Metastasis from the Primary Tumor.

M. Miranda Vergara, E. I. Hartland, C. Q. Jang, M. Lipa, A. Nataranjan, W. Kaliney, L. E. Littlepage; University of Notre Dame, Notre Dame, IN.

Matrix metalloproteinases (MMPs) are zinc-dependent endopeptidases that regulate the tissue microenvironment. MMP3 regulates both breast development and cancer progression and localizes to both mammary epithelial and stromal cells in normal and tumor mouse mammary tissues. Epithelial MMP3 overexpression promotes mammary tumor development. However, the functions of stromal and epithelial MMP3 have not been distinguished. We investigated the requirements for stromal MMP3 during breast cancer. We transplanted PyMT cancer cells, which express MMP3, into mammary glands of mice expressing (MMP3 Het) or not expressing (MMP3 KO) MMP3. Surprisingly, tumor burden increased in MMP3 KO mice, suggesting an inhibitory role for stromal MMP3. We next analyzed proliferation, apoptosis, and immune cell infiltration by immunohistochemistry to identify stromal MMP3's contribution to tumor progression. Tumors from KO recipient tumors had decreased cell proliferation marker phospho-histone H3 and neutrophil recruitment but increased $CD4^+$ and $CD8^+$ T cell infiltration compared to Het tumors. Apoptosis was not significantly different. Subsequent bone marrow transplantation experiments confirmed an inhibitory role for a stromal MMP3, but MMP3-deficient bone marrow, $CD11b^+$ cells, and CAFs were insufficient to increase tumor burden, and bone marrow-derived MMP3 even had a tumor promoting role. We next investigated stromal MMP3's role during lung metastasis. In contrast to the inhibitory role for stromal MMP3 in the primary tumors, stromal MMP3 was required for lung metastasis by orthotopic transplantation of breast cancer cells. Interestingly, stromal MMP3 inhibited lung metastasis by tail vein injections of breast cancer cells, suggesting that MMP3 impacts metastasis by effects at the primary tumor site. Together, this study suggests that stromal MMP3 has both protective and tumor promoting roles during breast cancer and highlights the context-specific functions of MMP3 during breast cancer.

P1183/B310

Anti-inflammatory and Antiangiogenic Therapies Inhibit Endothelial-to-mesenchymal Transition in TRAMP Mice Prostate.

F. Montico[1,2], I. M. U. Rossetto[1], A. M. Baseggio[1], L. A. Kido[1], V. H. A. Cagnon[1]; [1]University of Campinas, Campinas, BRAZIL, [2]University of Western São Paulo, Jaú, BRAZIL.

Prostate cancer is the most frequently diagnosed cancer among men in about half of the countries worldwide. Reactive stroma comprises a set of changes in the stromal compartment, including stimulated angiogenesis and inflammatory cell influx, which lead to prostate cancer progression and metastasis. Although it is well known that cells in reactive stroma have a mesenchymal secretory phenotype, their originating mechanisms from adjacent tissue are still poorly understood. Thus, the aim herewith is to investigate whether reactive stroma cells can derive from resident endothelial cells and the influence of inflammatory and angiogenic inhibitors on this endothelial-to-mesenchymal transition (EndMT). Male Transgenic Adenocarcinoma of Mouse Prostate (TRAMP) mice (12 week-old) were divided into the groups: Control (TRCON): received the vehicles used for drug dilution; Celecoxib (TRCEL): received celecoxib (15 mg/kg), an anti-inflammatory drug; Nintedanib (TRNTB), received nintedanib (10 mg/kg), a triple angiokinase inhibitor; Nintedanib + Celecoxib (TRNTCEL): received the combination of treatments. After 6 weeks, dorsolateral prostate samples were collected for morphological, immunohistochemical and Western Blotting analyses. Nintedanib treatment resulted in decreased incidence of well-differentiated adenocarcinoma (PC) foci in relation to control group, regardless of celecoxib co-administration. This finding was concomitant with reduced percentage of PCNA immunolabeling in both TRNTB and TRNTCEL groups. TGF-β1 and TGF-β2, which have recognized roles in driving reactive stroma development and EndMT, respectively, showed lower protein levels following combined treatment, whereas vimentin, a well-known mesenchymal cell marker, had reduced expression in all treated groups. Microvessel density (MVD) was significantly decreased in the TRNTCEL group, as demonstrated by CD31-positive vessel count, as well as the protein levels of Snail, a transcription factor that mediates EndMT. Nintedanib is an effective antitumor agent against prostate cancer progression in TRAMP mice. Moreover, its association with the anti-inflammatory drug celecoxib results in additional beneficial effects towards glandular balance and tumorigenesis delay, such as lowered MVD and TGF-β1 protein levels. At the same time, decreased vimentin, TGF-β2 and Snail protein expressions in the TRNTCEL group suggest that EndMT is indeed a source of activated stromal cells in prostate cancer and that inhibiting angiogenesis and inflammation in this stromal milieu may be a promising strategy to restrict this cellular recruitment. Financial support: State of São Paulo Research Foundation (2018/16299-9).

Evix Elisa Tools Reveal Differences in Cd3, Cd4, Cd8 and Mhc Class 2 Positive Extracellular Vesicles (evs) Derived from the Colon Cancer Cell Lines Sw480 and Sw620.

M. L. Wolf, S. A. Cohen, P. C. Everson, J. W. Orf; InCepix, St. Paul, MN.

SW480 and SW620 are paired cell lines established from a primary tumor and its metastatic counterpart obtained from the same patient and have a shared genetic background. These cell lines are considered to be a useful model for the changes which may take place during progression of colon cancer. Thus, the SW480 and SW620 cell pairing provides insight into metastatic and malignant behavior of human colon cancer. We report that using EVix Elisa tools we can identify differences between extracellular vesicles (EVs) released by these respective cell lines. EVs from SW480 cells are distinct from EVs from SW620 cells. While both SW480 and SW620 have similar tetraspan expression patterns on their respective EV populations, a marked difference exists in immune associated molecules. We have found that EVs from SW480 cells can be captured with antibodies against CD3, CD4, CD8, MHC Class 1 and 2 and TCR CB1. These captured EVs were detected by anti-tetraspan (CD9, CD63, CD81) antibodies. In contrast EVs from SW620 cells were not captured using the same antibodies against CD3, CD8, TCR CB1 and MHC Class 2.

EVs from SW620 were positive for CD4 and MHC Class 1 antigens similar to EVs from SW480. Comparable amounts of starting EVs from the SW480 and SW620 cell lines were evaluated as determined by Cholera Toxin B capture and human tetraspan (CD9, CD63, CD81) detection. The presence of immune associated molecules in EVs isolated from human SW480 and SW620 colon cancer cell lines is of interest. The differences in the EV populations positive or negative for immune associated molecules suggest differences in respective tumor cell interaction with the host immune system.

Analysis of Oncogenic Exosomal Micro-RNAs Released from Triple Negative Breast Cancer and Cancer Stem Cells.

A. Choudhary, B. Das; Amity University, NOIDA, INDIA.

IntroductionTriple-negative breast cancers (TNBCs) are defined by lack of estrogen receptor, progesterone receptor and human epidermal growth factor receptor type 2 (HER). TNBC comprise 15% of all breast carcinomas and have high rates of recurrences and mortality. TNBC is characterized by an abundance of treatment-resistant breast cancer stem cells (CSCs) and very poor prognosis. Since targeting these CSCs may improve treatment outcome of TNBC, it is imperative to investigate new therapeutic approaches. Exosomes have emerged as critical mediators of intercellular communication in tumor microenvironment. Exosome-secreted miRNAs have been shown to induce a number of biological functions including tumorigenesis. Cancer cells modify their microenvironment by transferring miRNAs that are suitable for tumor growth and progression through exosomes. MicroRNAs are specific to various physiological and pathological conditions thus exosomal miRNAs offer great hope for the diagnosis, prognosis and possibly prediction of cancer progression. This study was sought to analyze oncogenic exosomal miRNAs secreted by TNBC and TNBC stem cells and their possible role in tumor diagnosis/ prognosis. **Methods** Exosomes were isolated from TNBC and TNBC stem cells' serum depleted conditioned media. Exosomes were characterized by structural analysis (TEM, AFM), protein markers (CD63, CD81), Immunofluorescence and quantitative real time PCR. TNBC and TNBCSC secreted exosomal miRNAs were isolated and subsequently evaluated by RT-qPCR. **Results**Our results indicate significant upregulation of target exosomal miRNAs in TNBC cell lines (MDA MB 231, MDA MB 468) in comparison to normal breast epithelial cells (MCF10A). In addition, some previously unreported exosomal miRNAs were found to be highly expressed in TNBC stem cells. **Conclusion** These preliminary results demonstrate a significantly higher expression of exosomal miRNAs in TNBC stem cells which may serve as novel diagnostic/ prognostic biomarkers.

Evaluation of Anticancer Drugs on Human Lung 3D Spheroids.

A. Madabushi, A. Jackson, L. Jackson, W. Timothy, C. Weaver; Baltimore City Community College, Baltimore, MD.

Non-small cell lung cancer (NSCLC) represents 85% of all lung cancers. A549 is the one of the most common NSCLC cell line used for modelling alveolar region of lung cells. The goal of this study is to grow A549 lung cancer cells in 3-dimensional spheroid form in *vitro to* mimic tumor like conditions in lung cancer. The main features of spheroids that are similar to tumors include their structure, assembly, hypoxic conditions, and nutrient gradients. Anti-cancer drugs, Crizotinib and Erlotinib were added to determine cellular response of lung cells in 3D spheroid conditions. Both the drugs have been approved

by the FDA in USA as First-Line lung cancer therapy for specific patients. We aim to utilize this model to compare the efficacy of these chemotherapeutic agents on A549 cells in 2D monolayer versus 3D spheroid models.

P1187/B314

Microenvironmental Stress and the Cell Nucleus: an Essential Conversation for Breast Cancer Progression.

R. A. Stucky, S. Chittiboyina, S. A. Leliévre; Purdue University, West Lafayette, IN.

Oxidative stress (OS) in the tumor microenvironment resulting from an imbalance in reactive oxygen species is involved in cancer progression; yet its impact on chromatin and the epigenome known to drive cancer phenotypes remains obscure. We have identified that the nuclear mitotic apparatus protein (NuMA), a chromatin organizer, interacts with transcriptional coactivator, lens epithelium derived growth factor (LEDGF) and remodeling and spacing factor (RSF-1) protein that under OS is overexpressed and is associated with H3K9me2, a known suppressor of LEDGF. **Our central hypothesis is that NuMA-LEDGF-RSF1 interaction controls cancer progression under stress by influencing transcriptional regulation.** We use the HMT-3522 model of triple negative breast cancer progression that in 3D cell culture mimics the phenotypically ductal carcinoma in-situ (S2 cells) and invasive ductal carcinoma (T4-2 cells). Acute OS has been induced with exposure to 250 µM H_2O_2 for four hours. NuMA, LEDGF and RSF-1 show lower expression in T4-2 cells compared to S2 cells. However, prolonged exposure to ROS (25 µM H_20_2 for four weeks) results in a loss of NuMA and LEDGF and increased RSF1 expression in S2 cells, hence mimicking the changes observed in *vivo*. In addition, the size of the nucleus increases in NuMA silenced S2 cells but not in those silenced for LEDGF under OS with no observable changes in nuclear circularity. These results highlight the need to investigate the role of NuMA and LEDGF in response to oxidative stress in cancer progression. To further understand the role of NuMA under chronic OS in influencing cancer cell phenotype, we will explore NuMA silencing using CRISPR in S2 cells. Findings from this study will provide insight to investigate possible therapeutic targets for triple negative breast cancer.

P1188/B315

Nos2 Modulates Hypoxic Gradients in an in *Vitro* Model of the Tumor Microenvironment Based on Restricted Diffusive Exchange.

S. J. Flaherty[1,2], A. C. Gilmore[1,2], V. Somasundaram[3], D. A. Scheiblin[2], S. J. Lockett[2], D. A. Wink[3], W. F. Heinz[2]; [1]Optical Microscopy and an alysis Laboratory, Office of Science and Technology Resources, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Frederick, MD, [2]Optical Microscopy and an alysis Laboratory, Cancer Research Technology Program, Frederick National Laboratory for Cancer Research, Frederick, MD, [3]Cancer and Inflammation Program, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Frederick, MD.

The solid tumor microenvironment (TME) is heterogenous, and cellular phenotypic variation within it both drives and arises in response to varying concentrations of soluble molecules. In tumors, cellular consumption of soluble molecules (such as $O_{2\ and}$ nutrients) diffusing from capillaries generates concentration gradients of these molecules. As a tumor grows, the tumor core becomes hypoxic, nutrient deprived, and eventually necrotic. The spatial distribution of phenotypic variation within the TME is poorly understood and is difficult to study with standard 2D cell culture (which lacks physiological

complexity) or spheroids (which are highly variable structures with interiors not easily accessible to live-cell optical microscopy). We utilized a radially symmetric 2D chamber system which restricts the exchange of soluble molecules to model the cell-generated $O_2$and nutrient gradients within the TME in *vitro to* investigate the role these gradients on tumor and immune cell phenotypes, using mouse mammary tumor cells (4T1) and mouse macrophages (ANA-1) individually and in coculture. 4T1 syngeneic mouse tumors model human triple negative breast cancer (TNBC). Macrophages are the most abundant nonneoplastic cell in the TME, have been shown to localize to hypoxic/necrotic regions within tumors, and play an immunosuppressive role in tumorigenesis. We demonstrated that 4T1 cells cultured in this system form O_2 gradients within 2 hours using spatially resolved, ratiometric measurements of dissolved O_2 concentration. Gradients of intracellular hypoxia were verified through immunofluorescence imaging of reduced pimonidazole and nuclear localization of hypoxia-inducible factor 1α (Hif1α). Within 60 hours, 4T1 cells in the chambers migrated away from hypoxic regions and formed stable disks ~1 mm in diameter around the O_2 source. Beyond the disk, cells either detach from the surface or die, analogous to necrotic zones in tumor tissue. We applied this system to investigate the organization of nitric oxide synthase 2 (Nos2) and cyclooxygenase-2 (Cox2) expression within the TME. Nos2 and Cos2 interact in a proinflammatory feed-forward loop, and in TNBC their co-expression is a very strong predictor of poor prognosis. Using multiplexed immunofluorescence labeling, we showed that Nos2 and Cox2 were expressed in spatially distinct environments, with Nos2 expression localized in hypoxic regions. These results were analogous to those observed in spheroids and xenograft tissue sections, and they suggest that the Nos2 / Cox2 feed-forward loop occurs through an paracrine mechanism. We further showed that ANA1 macrophages generated hypoxic gradients and that ANA1s stimulated with inflammatory cytokines (IFNg+LPS) modulated the magnitude and extent of the hypoxic gradient.

P1189/B316

Exploring the Role of Stroma in Breast Cancer Using a Microfluidic 3D Mammary Duct Platform.

O. Lloyd[1], C. Kowalski[1], A. Miquel[1], D. Cojocaru[1], C. Marks[1], S. Ross[1], M. Kutys[2], K. Gagnon[2], C. Chen[2], R. Bellin[1]; [1]College of the Holy Cross, Worcester, MA, [2]Boston University, Boston, MA.

It has been shown that cross-talk occurring between the epithelial cells and fibroblasts of mammaliantissue can play a role in the development of breast cancer. The purpose of our research is to understand the role this communication plays in the formation and proliferation of mammary carcinomas with respect to the transmembrane heparan-sulfate proteoglycan, syndecan-1 (sdc-1). In clinical studies of tissue biopsies from breast cancer patients, it has been shown that sdc-1 is actively expressed and shed in tumor-associated fibroblasts. In addition, published studies indicate that sdc-1 ectodomain molecules can play an important role as a co-receptor for FGF receptor. Based upon this information, we are exploring the role that sdc-1 ectodomain-based cross-talk between epithelial cells and fibroblasts may play in promoting epithelial cell tumorigenesis by increasing FGF-based cell proliferation. In previous work, we have shown that NIH-3T3 fibroblast cells actively express and shed sdc-1 ectodomain in culture, and have demonstrated an increase in proliferation of mammary epithelial cells co-cultured with NIH-3T3 cells. We are now expanding these studies to a more physiologically-relevant system by adapting our existing microfluidic 3D mammary duct platform to allow the inclusion of stromal fibroblasts. 3D culturing of fibroblasts in the presence of epithelial ductal structures in the chip has been successful, and we are now initiating experiments utilizing modified fibroblasts to directly test the role of shed sdc-1 molecules in the initiation of epithelial tumor formation.

P1190/B317

Cancer-associated Mutations That Inhibit Phosphofructokinase-1 Activity Confer Increased Resistance to Reactive Oxygen Species Stress.

J. Miller, M. Glass, A. Robart, **B. Webb**; West Virginia University, Morgantown, WV.

Cancer cells have an altered metabolic program, termed aerobic glycolysis or the Warburg effect, to provide energy and building blocks required to support rapid proliferation. The glycolytic "gatekeeper" enzyme phosphofructokinase-1 (PFK1), which catalyzes the step committing glucose to breakdown, is dysregulated in cancers. While increased expression and activity of PFK1 has been demonstrated in cancers, how somatic mutations affect metabolic adaptation is incompletely understood. We have previously mapped 44 cancer-associated somatic mutations in the platelet isoform of PFK1 (PFKP) and found that the majority were predicted to inhibit enzymatic activity. We characterized one of these mutations, PFKP-D564N, to gain insight into how inhibitory PFK1 mutations can contribute to cancer cell metabolism. Purified, recombinant PFKP-D564N had decreased affinity for the sugar substrate fructose 6-phosphate and decreased maximal catalytic activity compared to the wild type enzyme. We determined the crystal structure of PFKP-D564N to 3.4Å resolution to determine how the mutation inhibited enzymatic activity. Only small changes in structure were observed compared to wild type PFKP. However, the mutation was predicted to disrupt a salt bridge between aspartic acid 564 and arginine 319, which are evolutionarily conserved from bacteria to human. Cancer-associated mutations of this Asp-Arg pair were also identified in the liver isoform PFKL. Recombinant PFKL-R310Q and PFKL-D553N had decreased affinity for fructose 6-phosphate and decreased maximal catalytic activity, consistent with our observation on PFKP activity. PFKP-D564N was stably expressed in MTLn3 rat mammary adenocarcinoma cells to determine if expression alters cancer cell metabolism. Cells expressing PFKP-D564N displayed decreased flux of glucose to lactate compared to control cells or cells expressing wild type PFKP. Inhibition of glycolytic flux by loss of function mutations may confer a selective advantage for cancer cell growth and metastasis by redirecting carbon flow through the pentose phosphate pathway. To test this hypothesis, we assessed survival after a reactive oxygen species (ROS) stress. Cells expressing PFKP-D564N were resistant to ROS-induced death, as they showed a significant increase in the number of live cells after treated with 1µM paraquat for twenty-four hours compared to control cells and cells expressing wild type PFKP. Taken together, our results suggest inhibitory PFK1 mutations can alter cancer cell metabolism and provide resistance to ROS.

A Fatty Acid Oxidation-dependent Metabolic Shift Regulates the Adaptation of *BRAF*-mutated Melanoma to MAPK Inhibitors.

A. Aloia[1], D. Müllhaupt[1], C. D. Chabbert[1], T. Eberhart[1], S. Flückiger-Mangual[1], A. Vukolic[1], O. Eichhoff[2], A. Irmisch[2], L. T. Alexander[1], E. Scibona[1], D. T. Frederick[3], B. Miao[3], T. Tian[4], C. Cheng[4], L. N. Kwong[5], Z. Wei[4], R. J. Sullivan[3], G. M. Boland[3], M. Herlyn[6], K. T. Flaherty[3], N. Zamboni[1], R. Dummer[2], G. Zhang[6], M. P. Levesque[2], **W. J. Kovacs**[1]; [1]ETH Zurich, Zurich, SWITZERLAND, [2]University Hospital Zurich, Zurich, SWITZERLAND, [3]Massachusetts General Hospital Cancer Center, Boston, MA, [4]New Jersey Institute of Technology, Newark, NJ, [5]The University of Texas MD an derson Cancer Center, Houston, TX, [6]The Wistar Institute, Philadelphia, PA.

Treatment of *BRAF*^{V600E}-mutant melanomas with mitogen-activated protein kinase inhibitors (MAPKi) results in significant tumor regression, but acquired resistance is pervasive. To understand non-mutational mechanisms underlying the adaptation to MAPKi and to identify novel vulnerabilities of melanomas treated with MAPKi, we focused on the initial response phase during treatment with MAPKi. By screening proteins expressed on the cell surface of melanoma cells, we identified the fatty acid transporter CD36 as the most consistently upregulated protein upon short-term treatment with MAPKi. We further investigated the effects of MAPKi on fatty acid metabolism using in vitro and in vivo models and analyzing patients' pre- and on-treatment tumor specimens. Melanoma cells treated with MAPKi displayed increased levels of CD36 and of peroxisome proliferator-activated receptor α (PPARα)-mediated and carnitine palmitoyltransferase 1A (CPT1A)-dependent fatty acid oxidation (FAO). While CD36 is a useful marker of melanoma cells during adaptation and drug-tolerant phases, the upregulation of CD36 is not functionally involved in FAO changes that characterize MAPKi-treated cells. Increased FAO is required for *BRAF*^{V600E}-mutant melanoma cells to survive under the MAPKi-induced metabolic stress prior to acquiring drug resistance. The upfront and concomitant inhibition of FAO, glycolysis and MAPK synergistically inhibits tumor cell growth in *vitro* and in *vivo*. Thus, we identified a clinically relevant therapeutic approach that has the potential to improve initial responses and to delay acquired drug resistance of BRAF^{V600E}-mutant melanoma.

Comparative Proteome an alysis of Breast Cancer Tissues to Investigate Breast Cancer Metabolism.

K. KARAOSMANOGLU YONETEN[1], M. KASAP[1], G. AKPINAR[1], A. GUNES[2], B. GUREL[1], N. UTKAN[1]; [1]Kocaeli University, Kocaeli, TURKEY, [2]Derince Training and Research Hospital, Kocaeli, TURKEY.

Breast cancer (BC)-associated deaths among women are dramatically increasing. One of the reasons for the increase is the absence of an easy to perform early-diagnosis test, which would allow physicians to take timely precautions to prevent the growth of the tumor tissue. Unfortunately, however, there is no easy to use, affordable, specific and sensitive laboratory test for BC diagnosis. In this study, we aimed to discover potential diagnostic or prognostic biomarkers by investigating the global changes occurring in protein profiles of BC tissues. For this purpose, BC tumor tissues and their corresponding healthy counterparts were collected, subtyped, and subjected to comparative proteomics analyses using two-dimensional gel electrophoresis (2-DE) and difference gel electrophoresis (DIGE) coupled to matrix-assisted laser desorption/ionisation-time of flight mass spectrometry (MALDI-TOF/TOF). Western blot analysis was used to verify changes occurring at the protein levels. Bioinformatics analyses performed with differentially regulated proteins highlighted the changes occurring in proteins, namely glycerol-3-phosphate dehydrogenase 1 (GPD1) and monoacylglycerol lipase (MAGL) and directed our attention to triacylglyceride (TAG) metabolism. These proteins were down-regulated in tumor groups in comparison to the control group. GPD1 and MAGL might be promising tissue-based protein biomarkers with a predictive potential for BC.

This work was supported by the Scientific and Technological Research Council of Turkey (TUBITAK) under the grant number of 117S218 and Kocaeli University Scientific Research Unit under the grant number of 2018/123.

P1193/B320

Targeting Cancer Metabolism in BRCA Deficient Breast Cancer.

T. Collins, E. Efimova, J. Lutze, J. Brinkman, S. J. Kron; University of Chicago, Chicago, IL.

Women carrying a single defective copy of BRCA1 or BRCA2 are at dramatically increased risk of developing breast and ovarian cancer. Specifically, BRCA-deficient ($BRCA^{def}$) breast cancer is associated with early onset, high grade, rapid growth, recurrence and metastasis. There is a pressing need for new approaches to prevent, detect, and treat breast and other cancers in women carrying BRCA mutations. The role for the BRCA1 and 2 gene products in homologous recombination (HR)-mediated double strand break (DSB) repair provides a rationale for the well-known "synthetic lethality" strategy of blocking other forms of DNA repair such as non-homologous end-joining (NHEJ) DSB repair as a means to differentially sensitize $BRCA^{def}$ breast cancer cells to DNA damage. Recent studies from the Kron Lab describing how cancer metabolic reprogramming can modulate the hexasomine biosynthetic pathway (HBP) to enhance NHEJ repair suggest a mechanism for how $BRCA^{def}$ cancer cells may compensate for their HR repair deficiency, offering a new opportunity for synthetic lethal targeting. The HBP generates the activated sugar UDP-GlcNAc, allowing transfer of GlcNAc moieties to protein serine and threonine residues by the enzyme O-GlcNAc transferase (OGT). Subsequent removal of O-linked GlcNAc from proteins is mediated by O-GlcNAcase (OGA). As proof-of-principle, the Kron Lab has examined the impact of modulating O-GlcNAcylation on response to genotoxic therapy in breast cancer. Using xenograft tumors formed from the MCF-7 breast cancer cell lines, we found that blocking O-GlcNAcylation via knockdown of OGT or treatment with the OGT inhibitor alloxan conferred radiation sensitivity. In turn, knockdown of OGA or treatment with the OGA inhibitor PUGNAc to promote O-GlcNAcylation conferred radiation resistance. To explore the hypothesis that O-GlcNAcylation might be critical for cells to survive genomic stress in cells lacking BRCA genes, we examined transient knockdown of OGT or OGA in the $BRCA^{def}$ breast cancer cell line MD-MBA-436 using inducible shRNA miRs. When $BRCA^{def}$ cells were irradiated after knockdown of OGT, cells displayed persistent yH2AX foci, indicating an enhanced DNA repair defect. Similarly, in mice bearing MD-MBA-436 tumors exposed to radiation while being treated with alloxan to block OGT, the tissue displayed persistent yH2AX immunoreactivity and decreased Ki67 levels, indicating a prolonged DNA damage response. Our data to date confirm that targeting the HBP sensitizes $BRCA^{def}$ cells to radiation in *vitro* and in *vivo*, suggesting potential as a target for synthetic lethality and/or sensitization to genotoxic cancer therapy in patients.

AMPK Activators Suppress Cancer Cell Metabolism and Growth Both in *Vitro* and in *Vivo* Providing a Novel Therapy.

B. Nag, T. Ray, S. Roy, 94545; Invitek Inc., Hayward, CA.

AMP-activated protein kinase (AMPK) plays an important role in the regulation of cellular energy homeostasis. Metformin (biguanide) is a known AMPK activator used as a therapeutic agent for the treatment of Type-II diabetes. In the present study, Metformin, and AICAR (5-Aminoimidazole-4-carboxamide ribonucleotide) were used as AMPK activators to monitor tumorigenesis and suppression of cancer cells. The cytotoxicity of Metformin and AICAR were determined in both human pancreatic (PANC-1) and human mammary carcinoma cells (MDA-MB 231), respectively. The results showed that both Metformin and AICAR significantly inhibit cell proliferation in a dose and time-dependent manner. However, the IC-50 of Metformin was slightly higher as compared to AICAR. Furthermore, *in-vivo*

models were established through xenograft tumor models in athymic nude mice by injecting PANC-1 and MDA-MB 231 cells subcutaneously (5x 10^6) suspended in matrigel into the right flank. When tumor size was between 500-1000 mm^3, mice were treated with Metformin and AICAR intraperitoneally at three different doses (100, 200, 400 mg/kg). The tumor size and weight were measured. Metformin and AICAR showed to significantly inhibit tumor growth (size and weight) after 21 days of treatment. However, no significant differences were observed with the low dose. This study demonstrates that AMPK activators, Metformin and AICAR, possess anti-tumor activity on human pancreatic (PANC-1) and breast cancer (MDA-MB 231) cell lines. These results strongly suggest that the activation of AMPK can be a novel anti-cancer therapy.

Defective Glycan Branching Compromises the Activity of the Novel Immunotherapy Target CD73 in Human Liver Cancer.

K. P. Alcedo[1], A. Guerrero[2], V. Basrur[3], D. Fu[1], M. L. Richardson[1], J. S. McLane[1], C. Tsou[3], A. I. Nesvizhskii[3], T. H. Welling[4], C. B. Lebrilla[2], C. A. Otey[1], M. B. Omary[3], H. J. Kim[1], N. T. Snider[1]; [1]University of North Carolina, Chapel Hill, NC, [2]University of California, Davis, Davis, CA, [3]University of Michigan, an n Arbor, MI, [4]NYU Langone Health, New York, NY.

CD73 is a ubiquitous ecto-enzyme that converts adenosine 5'-monophosphate (AMP) to adenosine. Several anti-CD73 therapeutic antibodies are undergoing clinical development because extracellular adenosine promotes tumor growth and metastasis via its immunosuppressive activity. On the other hand, CD73-generated adenosine is critical for protecting the epithelial barrier, thereby functioning in an anti-tumor fashion. Understanding how CD73 activity is regulated in normal versus tumor cells can yield novel insights into the functional complexity of this important cancer target. The objective of this study was to characterize CD73 regulation in normal liver and hepatocellular carcinoma (HCC), the most common form of primary liver cancer. CD73 is a complex molecule that undergoes *N*-linked glycosylation, disulfide bond-mediated homo-dimerization, and membrane association via a glycosylphosphatidylinositol (GPI) anchor. Previously we identified a novel splice variant isoform of CD73 (CD73S) that is catalytically inactive and selectively expressed in HCC, alongside canonical CD73. In this study, we examined canonical CD73 expression, sub-cellular localization, and enzymatic activity using molecular, biochemical, and cellular analyses on human HCC surgical specimens (N=23 adjacent liver-tumor pairs), coupled with mechanistic studies in HCC cells. We analyzed site-specific CD73 glycan signatures in normal liver and HCC tumor tissue via mass spectrometry glycomics analysis. CD73 was primarily expressed on tumor hepatocytes, where it exhibited cytoplasmic distribution and abnormal *N*-linked glycosylation, independent of HCC etiology, tumor stage, or fibrosis presence. Aberrant glycosylation of tumor-associated CD73 resulted in a 3-fold decrease in 5´-nucleotidase activity ($p<0.0001$). Biochemically, tumor-associated CD73 was enriched in high mannose, but deficient in hybrid and complex glycans specifically on residues N311 and N333, located in the C-terminal catalytic domain. Blocking N311/N333 glycosylation via site-directed mutagenesis produced CD73 with significantly decreased 5´-nucleotidase activity in *vitro*, similar to the primary tumors. Glycosylation-impaired CD73 partially co-localized with the Golgi structural protein GM130, which was strongly induced in HCC tumors. In conclusion, we provide the first detailed characterization of CD73 glycosylation in normal and tumor cells, revealing a novel mechanism leading to the functional suppression of CD73 in human HCC tumors. The present findings have translational implications for therapeutic candidate antibodies

targeting cell-surface CD73 in solid tumors and small molecule adenosine receptor agonists that are currently in clinical development for HCC patients.

P1196/B323

High Throughput CAR-T Cell Potency Assay with Single Cell Resolution.

M. Balles[1], A. Fischbeck[1], **J. Schwarz**[1], D. Drell[2], E. Noessner[3], R. Zantl[1]; [1]ibidi GmbH, Gräfelfing, GERMANY, [2]MetaVi Labs, Austin, TX, [3]Helmholtz Zentrum München, Immunoanalytics Core Facility & Reserch Group Tissue Control of Immunocytes, Munich, GERMANY.

Adoptive cellular cancer therapies, especially the usage of autologous T cells expressing engineered antigen receptors (CAR-T cells) represent a promising new cancer therapy tool. The evaluation of quality, specificity and killing efficiency (potency) of CAR-T cell populations is crucial for the development of potent and safe patient specific CAR-T cell products. Potency usually is evaluated on the population level by measurement of Interferon-gamma secretion or Cytotoxic T-cell assays, such as ^{51}Chromium Assays. The evaluation on population scale, however, lacks sensitivity and fails to identify surviving cancer cell populations. We used “in channel micropatterning” to generate arrays of homogenously distributed single cancer cells, or cancer cell aggregates (spheroids) to evaluate cytotoxic T cell activity on a single cell level. By optical analysis combined with advanced image processing of cell / spheroid arrays we obtained efficient label free analysis of each cancer cell – T cell interaction over time. Additionally, using matrix embedded arrays, highly physiological three dimensional T-cell migration conditions could be mimicked.

Glutamate Receptor Signaling Improves Anti-tumor T Cell Immune Responses.

M. Prudente De Aquino[1], T. W. Hodo[1], R. Uzhachenko[1], A. Shanker[1,2]; [1]Meharry Medical College, Nashville, TN, [2]Vanderbilt University, Nashville, TN.

The interaction between the nervous system and immune system has sparked interest in recent years. Emerging evidence shows an intricate neuro-immune network. We were intrigued by the expression of various neurotransmitter receptors on mouse T lymphocytes. Specifically, following TCR stimulation, glutamate receptors (GluR) were significantly upregulated on both $CD4^+$and $CD8^+$T cells, with a peak at 48 h. Concomitant with the upregulation of activation molecules CD69, CD25 and CD44, proliferating $CD8^+$ T cells presented higher levels of GluA3 and mGluR1 when compared with non-proliferating cells, as well as a higher production of IFN-γand granzyme B. By blocking group I metabotropic glutamate receptors and AMPA receptors through antagonists, we show that $CD8^+$T cells have a delayed activation but their viability is not altered. Activation markers as CD25, CD69 and CD44 were downregulated on $CD8^+$T cells but were not completely decreased. However, GluR blockade affected $CD8^+$T cells proliferation and their ability to kill tumor cells in *vivo*or target cells in *vitro*. While the frequency of $GluR^+$ $CD8^+$T cells ranges around 30% of total $CD8^+$T population, the effect of blocking glutamate signaling through receptor antagonists is major and it is mediated by transient reduction in protein phosphorylation of TCR mediated pathways as well as calcium modulation. Overall, data suggest that glutamate receptors may have a stimulatory effect on T cell activation and glutamate agonists may boost T cell response in an immunosuppressive setting such as cancer.

P1198/B325

Studying CAR T Cells in a Solid Tumor Model.

K. L. Robinson, Gen Z[1], M. Z. Madden[2], J. Rathmell[2]; [1]Tennessee State University, Nashville, TN, [2]Vanderbilt University, Nashville, TN.

T cells orchestrate immune responses when their receptors bind specific antigen of a pathogen or cancer. Cancer immunotherapy eliminates cancer cells primarily by enabling anti-tumor T cell activity. Chimeric antigen receptor (CAR) T cells are a revolutionary form of cellular immunotherapy. CARs are genetically engineered antigen- binding receptors that permit CAR T cells to recognize and eliminate cancer cells. While CAR T cells recognizing CD19 have proven efficacious against B cell leukemias and lymphomas, navigating the more complicated microenvironment of solid epithelial tumors is a challenge for CAR T cell therapies. Optimizing CAR T cell metabolism may permit enhanced anti-tumor function in the nutrient-deprived tumor microenvironment. To study CAR T cells in a solid tumor microenvironment, we endeavored to develop murine B16 melanoma and MC38 colorectal carcinoma cell lines that ectopically express CD19. Transduction experiments proved unsuccessful, but we will next attempt to generate CD19-expressing cell lines with a transposon system. Previous work in the Rathmell lab has demonstrated that inhibition of Glutaminase, an enzyme that converts glutamine to glutamate, alters T cell differentiation which may enhance anti-tumor immunity. We hypothesized that Glutaminase inhibition by small molecule CB-839 would alter mitochondrial metabolism, which has been associated with improved CAR T cell functions. CB-839 treatment of CD8 T cells increased mitochondrial mass without increasing mitochondrial membrane potential, suggesting enhanced mitochondrial fitness. Our results suggest that glutaminase inhibition may be a promising approach to enhance CAR T cell function in solid tumors.

P1199/B326

Macrophage Checkpoint Disruption Enhances in *Vitro* Phagocytosis and in *Vivo* Repression of Opsonized, Syngeneic Tumors in Immunocompetent Mice.

L. J. Dooling, J. C. An drechak, S. Kadu, B. H. Hayes, D. E. Discher; University of Pennsylvania, Philadelphia, PA.

Macrophages possess an inhibitory receptor SIRPα that binds ‘marker of self’ protein CD47 on all cells, including cancer cells, to impede their engulfment. However, C57 mice with CD47 knockout are nearly normal, and anti-CD47 is likewise ineffective in monotherapy against cancer in clinical trials whereas combination with a tumor-opsonizing monoclonal is effective in some patients. A syngeneic, immunocompetent mouse model is thus needed, and so we first deleted CD47 in B16 murine melanoma cells. B16’s are weakly immunogenic in C57 mice and are often studied for immunotherapies. Phagocytosis of knockout cells by primary mouse macrophages is enhanced more than two-fold relative to B16’s with wildtype-levels of CD47 – but only when cells are opsonized with a mouse monoclonal against melanoma antigen Tyrp1. Similar effects are seen in combinations with monoclonals against either CD47 on B16’s or SIRPα on macrophages. CD47 knockout tumors grow similar in C57 mice to wildtype tumors – which are mechanically soft and fragmentable, but growth of knockout tumors is repressed by systemic injections of anti-Tyrp1 that has no effect on wildtype tumors. In a more therapeutic approach, marrow-derived monocytes treated *ex vivo* with anti-SIRPα are co-injected with anti-Tyrp1, extending survival while avoiding anemias caused by anti-CD47 infusions. Efficacy with macrophage checkpoint blockade thus requires a simultaneous activation of macrophages.

P1200/B327

Ex Vivo Phenotyping and Potency Monitoring of CD19 Car T Cells with a Combined Flow Cytometry and Impedance-based Real Time Cell an alysis Workflow.

L. Jachimowicz[1], P. Ye[2], M. Lei[2], Y. Lu[2], G. Guenther[1]; [1]Agilent Technologies, San Diego, CA, [2]Agilent Technologies, Hangzhou, CHINA.

Immunotherapy harnesses the immune system to attack cancer cells. While immunotherapy holds tremendous promise for cancer treatment, significant challenges remain in clinical translation. Further development is still required to expand treatment to more cancers and minimize adverse effects. T-cell differentiation and exhaustion influence the establishment and persistence of CAR-expressing T cells. Evaluation of the potency of CAR T cells is essential for effective immunotherapies. Here, we study the potency of CAR-T cells using of a combined impendence-based Real Time Cell an alysis (RTCA) and flow cytometry cell analysis workflow for *ex vivo* cytolytic potency monitoring of CD19 CAR T cells (CART19). CART19 cell killing of CD19 expressing HEK-293 cells with different E:T (Effector to Target) ratio was monitored by the xCELLigience RTCA system. Concurrently, T cell cytokine production was measured on the NovoCyte Quanteon. This workflow provides a thorough examination of CART cell function, RTCA data demonstrates that CART19 killing is highly potent as well as being antigen specific and dose dependent. In conjunction, more cytokine was produced with higher numbers of effector CART19 cells. It was also observed that CART19 cells express stem memory cell (T_{SCM}) markers, expressing activation and exhaustion markers after expansion. Co-culture with HEK-293-CD19 also results in increased expression of CD25, decreased expression of CD127 and upregulation of exhaustion markers, PD-1, TIM-3, and LAG-3. In summary, this study demonstrates the combination of RTCA and flow cytometry cell analysis is a powerful workflow for immunotherapy research and can be employed for QC in CAR T cell manufacturing.

P1201/B328

***Ganoderma Lucidum* Compounds: Effects on Inflammatory and Triple-Negative Breast Cancer Cell Viability.**

K. M. Garcia-Ortiz[1], T. Ling[2], F. Rivas[2], M. M. Martínez-Montemayor[1]; [1]Department of Biochemistry and Cancer Research Unit, Universidad Central Del Caribe, Bayamon, PUERTO RICO, [2]Department of Chemical Biology and Therapeutics, St. Jude Children's Research Hospital, Memphis, TN.

Breast cancer is one of the leading causes of death in the United States and in Puerto Rico. Among the different types of breast cancers, the inflammatory breast cancer (IBC) and the triple-negative breast cancer (TNBC) subtypes are two of the ones with the worst prognosis, presenting with low survival rates, early recurrence and resistance to treatment. These subtypes are also seen more frequently in younger populations. TNBC is recognized by the absence of estrogen, progesterone, and human epidermal growth factor 2 receptors (ER, PR and HER2, respectively). IBC may present with different molecular subtypes, including TNBC, ER-/PR-/ HER2+, or ER+/PR+/HER2+. *Ganoderma lucidum* extract (GLE) has proven to have anti-cancer properties against IBC and TNBC, but individual compounds in GLE are yet being studied. This experiment studied one of the active compounds in GLE, ergosterol peroxide (EP) and the synthesized cholesterol peroxide (CPO), both part of the steroid family and of cholesterol core. Three cell lines, SUM-159 (TNBC), SKBR3 (HER2+ non-IBC) and SUM-190 (HER2+ IBC), were treated with increasing concentrations of EP or CPO for 72h to evaluate the capacity of these compounds to reduce cell viability in each of these lines. Our results showed a concentration dependent decrease in cell

viability in all three cell lines, with a higher anti-viability capacity for CPO (IC_{50} of 8.90µM for SUM-190, 13.84µM for SKBR3, and 30.84µM for SUM159) compared to EP (IC_{50} of 22.41µM for SUM-190, 45.14µM for SKBR3, and 31.80µM for SUM159). Also, SUM-190 IBC cells were found to be more sensitive to both compounds compared to SUM-159 and SKBR3 cell lines. These findings suggest that CPO might affect HER2 signaling, especially in IBC cells. However future studies need to be conducted in order to confirm these findings.

P1202/B329

Targeting Triple Negative Breast Cancer: a New Molecular Target and Agent.

J. Evans, 14623, H. F. Schmitthenner, I. M. Evans, 14623; Rochester Inst Technol, Rochester, NY.

Triple-negative breast cancer (TNBC) is a form of breast cancer that does not express any of the three main markers for breast cancer. To better detect and treat breast cancers including TNBC, it is vital that new methods be developed. The use of targeted molecular imaging agents (TMIAs) is a promising method which can be applied to effective diagnosis of primary and metastatic tumors by locating and illuminating metastatic cell types of interest. Initial studies suggested that targeting peptides, including deca-peptide 18-4, discovered by Dr. Kaur at Chapman University, bound to keratin 1 of breast cancer (BrCa) cells. We evaluated the utility of a TMIA based on 18-4, produced by the Molecular Imaging Lab at RIT. This new TMIA was tested on MDA-MB-231 breast cancer cells and on other cancer cell lines grown in vitro and visualized with confocal fluorescence microscopy (CFM). The results show that the 18-4 based TMIA (which we have named M2) binds to breast cancer cells and is endocytosed into the cytoplasm. Developing agents that are able to effectively and accurately target and detect metastatic tumors should allow better clinical treatment and enhance cancer survival.

P1203/B330

Cytotoxic Mechanism of Palladium Complex Aj-5 in Three-dimensional Breast Cancer Culture T47-d Cell Culture.

E. Santos, L. Luvisotto Oliveira, G. M. Machado-Santelli; University of São Paulo, São Paulo, BRAZIL.

Metallic compounds, such as palladium exhibits significant anti-cancer activity accompanied by improved bioavailability, efficacy, and toxicity characteristics that limit the use of platinum analogues in antineoplastic chemotherapy. Despite that, new palladium complexes are being developed, but, the descriptions of cytotoxic effects in culture techniques that better mimic the tumor environment in *vivo*, such as multicellular spheroids, is still insufficient. In this context, the present study aimed to evaluate the cytotoxic response of palladium complex AJ-5 in multicellular T47-D breast tumor cell spheroids. The T47-D multicellular spheroids were cultured for 7 days by liquid overlay technique, treated for 24h with AJ-5 palladium complex at 1.6 µM, and 3.2 µM concentrations. The parameters of spheroid size, cell cycle (acquire by flow cytometry), expression of apoptosis, autophagy and adhesion proteins (caspase-3, LC3a/b, E-cadherin, respectively) by Western blot were evaluated as well as their intracellular localizations by immunofluorescence. The results showed increase in spheroids diameter treated with AJ-5, mainly at highest concentration, with mean values of 753 µm compared to control (644.9 µm), which seems to be associated with loss of cell-cell adhesion corroborated with reduction of e-cadherin protein expression. In addition, AJ-5 complex seemed to induce apoptosis and autophagy at the highest concentration by increase caspase-3 and LC3-II protein expression. In conclusion, AJ-5 palladium complex induced reduction of spheroid cell adhesion associated with increase of apoptotic and

autophagic process, corroborating previous monolayer studies. However, further studies will be needed to better characterize that cytotoxic effects in multicellular spheroids.

P1204/B331

Mechanistic Insight of Ergosterol Peroxide Against Triple-negative Breast Cancer Models.

D. M. Rivera Rodríguez[1], T. Ling[2], W. Lang[2], F. Rivas[2], M. Martinez[3]; [1]University of Puerto Rico, Bayamón Campus, Bayamón, PR, [2]St. Jude Children's Research Hospital, Memphis, TN, [3]Universidad Central del Caribe, Bayamón, PR.

Triple-negative breast cancer (TNBC) accounts for approximately 10-20% of the breast cancer population and is often associated with poor patient outcome. This poor prognosis is increased due to the lack of targeted therapies available for TNBC. Former studies have identified anti-cancer effects of *Ganoderma lucidum*extract (GLE) against breast cancer models, and have attributed some of its effects to Ergosterol Peroxide (EP). This oxidized sterol possesses a therapeutic index, and has been proven to be the main cytotoxic constituent of GLE. EP has proven to affect signaling that maintains mitochondrial integrity and plays a role in cellular response to peroxides. By doing so, EP can compromise the mitochondria and induce reactive oxygen species (ROS), causing apoptosis. Although inhibitory effects of EP have been documented, mechanism of action is still unknown. Thus, the main objective of this study is to investigate EP's mechanism of action against TNBC cell models (SUM-149 and MDA-MB-231) to further develop EP as a naturally derived TNBC therapeutic. To assess our objective, the following cellular-molecular biology assays are conducted: mammalian cell culture protocols, apoptosis and cell cycle assays for CRISPR clones, migration assays, immunoprecipitation assays, and western blotting. Our results suggest that EP reduces cell migration in TNBC clones, induces apoptosis more readily, and exhibits a more potent cytotoxic effect. In conclusion, our studies will further validate EP's therapeutic potency in TNBC cell models by providing preliminary insight to its mechanism of action. This work was supported by NIH NIGMS #SC3GM111171 (MMM), and NIMHD #MD007583 (MMM).

P1205/B332

Mirna Expression Changes After Decarbomoyl Mitomycin C (dmc) Exposure in the Mcf7 Breast Cancer Cell Line.

N. Almodovar, E. Champeil, L. Delgado-Cruzata; City University of New York, New york, NY.

MicroRNAs (miRNA) are non-coding RNAs that post-transcriptionally regulate gene expression by binding functional mRNA. Altered miRNA expression has been found to be important in different tumorigenic events in breast cancer. It is currently known that mitomycins such as decarbamoylmitomycin C (DMC) are able to alkylate DNA upon reductive activation to generate monoadducts and Interstrand Crosslinks (ICLs) affecting important pathways and triggering cell death in cancer cells. However, whether cellular mitomycin effects are mediated by deregulating RNA molecules and more specifically miRNAs, has not been investigated to date. Here, we explore whether DMC has the potential to alkylate miRNA molecules and affect miRNA levels leading to changes of expression in specific mRNA targets. The identification of RNA adducts in DMC treated miRNA was performed at the nucleoside level following digestion with phosphodiesterases and phosphatases. The digest was analyzed by liquid chromatography-photo diode array detector-mass spectrometry (LC-PDA-MS). In a parallel in vitro experiment MCF7 breast cancer cells were treated with 50uM DMC for 24 hours to determine possible changes in miRNA and mRNA expression levels. The change in expression of 800

miRNAs and 770 cancer-related mRNA was determined using Nanostring RNA panels, and the miRNA Target Prediction Database (miRDB) was used to identify gene targets for each differentially expressed miRNA. We identified a DMC miRNA adduct based on its precursor mass (m/z 543.2) and UV spectra. These data were identical to those of an authentic standard synthesized independently by direct reaction between guanosine and reduced DMC. In in vitro experiments, we found that miRNAs miR-1260a, miR-125a-5p, and miR-503-5p were underexpressed after DMC exposure, and that its respective target mRNAs, THEM4, EIF4EBP1, and CCNE1 were overexpressed in the same samples. These mRNA encode for proteins known to inhibit cancer cell growth and metastasis by interfering in translation, promoting chromosome instability, or inhibiting the RET signaling pathway, respectively. Our work suggests that one potential biological mechanism of action of mitomycins is through direct interaction and deregulation of miRNA levels. Further studies will have to be conducted to confirm the presence of miRNA-DMC adducts in vivo and to determine whether their presence directly leads to changes in miRNA expression.

P1206/B333

The Flavonoids Acacetin and Pinostrobin Selectively Inhibit Cell Migration and Adhesion in Cell Models of Breast Cancer.

A. A. Jones, N. Staton, **S. Gehler, 61201-2210**; Augustana College, Rock Island, IL.

Cancer cell metastasis, the process by which cancer cells migrate and form new tumors elsewhere in the body, accounts for approximately 90% of cancer-related deaths worldwide. Consequently, finding new therapies that target cancer cell metastasis is crucial for the effective treatment of late-stage cancer patients. For the last several decades, the majority of anticancer drugs have originated in some form from natural compounds. These compounds continue to be the main source of disease treatment. Naturally occurring flavonoids have been found to have anticancer effects in various cancer types. However, the effects of flavonoids have not been extensively studied on breast cancer cells. Here, we tested the effects of the flavonoids acacetin and pinostrobin on malignant MDA-MB-231 and T47D breast epithelial cells and non-tumorigenic MCF10A breast epithelial cells. Using scratch and transwell assays, both acacetin and pinostrobin selectively inhibited the migration of both MDA-MB-231 and T47D breast cancer cells in a dose-dependent manner while exhibiting blunted effects on non-tumorigenic MCF10A cells. However, neither compound had an effect on cell proliferation in any of the three cell lines when tested over a wide range of concentrations. Furthermore, both acacetin and pinostrobin reduced MDA-MB-231 and T47D cell adhesion by approximately 35-50%, but had no significant effect on MCF10A cell adhesion. Moreover, both compounds inhibited cell spreading and focal adhesion formation in the malignant but not the non-tumorigenic breast cell lines. Taken together, these results suggest that both acacetin and pinostrobin mediate their effects on motility by inhibiting adhesion in malignant breast epithelial cells. These findings position acacetin and pinostrobin to be potential drug treatments for breast cancer metastasis during late-stage tumor progression.

The Covalent Cdk7 Inhibitor Enhances Temsirolimus-induced Cytotoxicity Via Autophagy Suppression in Human Renal Cell Carcinoma.

Y. Chang[1,2], K. Kuo[1,2,3], W. Lin[4], K. Huang[1,2], P. Chow[1,2,3]; [1]Department of Urology, College of Medicine, National Taiwan University, Taipei, TAIWAN, [2]Department of Urology, National Taiwan University Hospital, Taipei, TAIWAN, [3]Graduate Institute of Toxicology, College of Medicine, National Taiwan University, Taipei, TAIWAN, [4]Department of Pathology, National Taiwan University Hospital, Taipei, TAIWAN.

Renal cell carcinoma (RCC) is the major cancer of the kidney. The 5-year survival rate is 74% overall and only 8% for Stage 4 diseases. In the past 10 years, several agents including tyrosine kinase inhibitors (TKIs), mTOR inhibitors and immune checkpoint inhibitors are available as first- or second-line therapy for metastatic RCC. However, the survival benefits are limited. Recently, THZ1 was identified as a CDK7 inhibitor interfering the transcriptional machinery. Although it has been shown effective in various pre-clinical models of different cancers, the data for RCC has never been reported. In our study, we performed in *vitro* and in *vivo* experiments to investigate the effect of THZ1 in RCC. We also analyzed the significance of CDK7 in our clinical cohort. Our result showed that THZ1 induced apoptosis and cell cycle arrest in RCC cells, thus reducing cell viability in *vitro*. In addition, THZ1 in combination with temsirolimus had synergistic effects in *vitro*, probably through the inhibition of autophagy. Compared with monotherapy with either THZ1 or temsirolimus, the combination treatment further suppressed tumor growth in our mice xenograft models. Finally, the impact of CDK7 expression on tumor progression and patient survival was demonstrated in our clinical cohort. These results indicated that CDK7 is associated with the progression and the prognosis of RCC, and THZ1 might potentially serve as a therapeutic agent to conquer drug resistance in RCC.

P1208/B335

Glutamine Deficiency Induces Apoptosis by Enhancing Ros and Pp2a in Lymphoma.

Y. Kim, H. Yang, M. Yeo, K. Lee; Department of Convergence Medicine, Asan Institute for Life Sciences, University of Ulsan College of Medicine, Asan Medical Center, Seoul 05505, Republic of Korea, Seoul, KOREA, REPUBLIC OF.

Altered glutamine metabolism is emerging target of cancer therapy. Glutamine deprivation has been proposed to induce apoptosis in multiple cancers. Dependency on glutamine metabolism of skw 6.4 lymphoma cell was investigated in vitro and in vivo. Glutamine deprivation induces apoptosis of skw 6.4 cell. Intracellular concentration of metabolites in tricarboxylic acid cycle and glutathione concentration were reduced and concentration of reactive oxygen species (ROS) and expression of PP2A were increased in glutamine-deprived skw6.4 cell. Reduction of ROS by antioxidants and knockdown of PP2A inhibited apoptosis induced by glutamine deprivation. Glutamine antagonist reduces skw6.4 tumor size in mouse xenograft model in PP2A-dependent manner. Overall, these results suggest survival of skw6.4 cells depends on the supply of glutamine in PP2A-dependent manner.

P1209/B336

Increased ROS Enhanced Photosensitizer Accumulation and PDT-cytotoxicity in Highly Metastatic Breast Cancer.

A. Terasaki[1], H. Ito[2], H. Kurokawa[3], H. P. Indo[4], H. Bando[3], H. Hara[3], H. J. Majima[2], H. Matsui[3]; [1]Graduate School of Comprehensive Human Sciences, University of Tsukuba,, Tsukuba, Ibaraki, JAPAN, [2]Graduate School of Medical and Dental Sciences, Kagoshima University, Sakuragaoka, Kagoshima, JAPAN, [3]Faculty of Medicine, University of Tsukuba, Tsukuba, Ibaraki, JAPAN, [4]Graduate School of Medical and Dental Sciences, Kagoshima University, Sakuragaoka, Kagoshima,, JAPAN.

Breast cancer is one of the most common types of cancers prevalent in women. Several types of breast cancers can easily metastasize to bone and cause disease complications, such as hypercalcemia and pathologic fracture, thus compromising the quality of life of people affected by it. Bisphosphonate drugs are often used for the treatment of bone metastasis to suppress osteoclastic bone resorption. However, bisphosphonate has adverse effects on the gastrointestinal tract and kidney and also induces osteonecrosis of the jaw. Photodynamic therapy (PDT) is an alternative cancer treatment approach with minimal invasiveness. It is a combination treatment that uses photosensitizers, which accumulate in tumor cells, followed by laser irradiation. We previously reported that the cellular incorporation of protoporphyrin IX (PPIX), the 5-aminolevulinic acid (5-ALA) precursor, was regulated by reactive oxygen species derived from mitochondria (mitROS). In this study, we investigated the incorporation of 5-ALA, accumulation of PPIX, and subsequent effects on cell viability after laser irradiation of two different breast cancer cell lines with different metastaticity. The highly metastatic breast cancer cell line 4T1E/M3 showed a significant increase in ROS production after treatment with indomethacin (IND). In addition, IND treatment enhanced the cellular uptake of 5-ALA via PEPT1 upregulation in 4T1E/M3, but not in the non-metastatic cell line. Overall, metastatic breast cancer is likely to be sensitive to ROS and activate signaling pathways associated with 5-ALA transportation, suggesting that ALA-PDT could be an effective treatment for metastatic breast cancer with low invasiveness.

P1210/B337

Crotamine Reduces Migration and Invasion of Breast Cancer Cells Via the Mmp-9 Activation.

H. Yang, Y. Kim, M. Yeo, K. Lee; University of Ulsan college of medicine, Seoul, Seoul, KOREA, REPUBLIC OF.

Breast cancer is leading cause of death by cancer in women in world. Development of therapeutic modalities targeting the key molecules in cancer progression is crucial to improve the survival rates of breast cancer patients. Crotamine, a peptide toxin isolated from snake venom, has cytotoxicity effects on cells and anti-microbial activities. However, effects of crotamine on cancer has not been extensively studied. Crotamine treatment showed the no significant cytotoxicity on highly metastatic breast cancer cell line, MDA-MB231 at 30 μM and lower concentrations. At 10 μM and 20 μM, the crotamine significantly reduced the migration and invasion of EGF-stimulated MDA-MB231. Crotamine treatment reduces the activity and expression of MMP-9 and expression of active forms of AKT, ERK, c-JUN, and p65 in EGF-stimulated cells. Reporter assays showed crotamine attenuated the induction of NF-κB and AP-1-depenedent promoter activities and proximal MMP-9 promoter activity. Crotamine repressed the invasion, migration, and activation of signal pathways in primary triple negative breast cancer cells in the same way of MDA-MB231. Overall, these results suggest the anti-breast cancer effects of crotamine and

provide the support for the further application of crotamine and its derivatives in anti-cancer treatments.

Parthenolide Exerts a Cytotoxic Effect in Triple Negative Breast Cancer Cells through Interrupting Interferon-alpha Signaling.

O. Provance[1], E. S. Geanes[1], A. Lui[1], A. Roy[2], J. Lewis-Wambi[1]; [1]University of Kansas Medical Center, Kansas City, KS, [2]University of Kansas, Lawrence, KS.

Triple negative breast tumors (TNBC) lack the estrogen receptor, progesterone receptor and the human epidermal growth factor receptor and are responsible for approximately 10-25% total breast cancer diagnoses. Heterogeneity is inherent in TNBC as delineated by the identification of multiple subtypes based on gene expression analysis including basal, mesenchymal, immune-enriched and luminal androgen receptor (AR) subtype. The tumoral diversity and lack of molecular targets hinder the development of FDA approved specific targets, perhaps resulting in the lower 5 year overall survival rate compared to receptor positive breast tumors due to metastatic recurrence. Therefore, identification of novel targets and therapeutic agents is necessary to further enhance therapy as well as to understand TNBC biology. Our investigations identified that an interferon-alpha (IFN-alpha) regulated gene, interferon inducible transmembrane protein-1 (IFITM1), is overexpressed in TNBC cell lines. IFITM1 regulates the aggressive phenotype of TNBC cells in *vitro and* in *vivo*. To date, the only known drug to target IFITM1 is the JAK inhibitor Ruxolitinib, which has had poor clinical outcomes in patients with TNBC. Therefore, we used a high-throughput FDA approved drug screen to identify agents which are both toxic to TNBC cells as well as target IFITM1. Parthenolide (PN), a NF-kappaB inhibitor, was identified as a drug of particular interest. In this study, we investigated the functional role of targeting IFITM1 and subsequent PN sensitivity on multiple TNBC cell lines. We aimed to define the mechanism of PN and its effects in TNBC cell lines that have yet to be studied. Our data suggest that both the basal-like subtype of TNBC (SUM149 and MDA-MB-468) and the mesenchymal subtype of TNBC (MDA-MB-157) are sensitive to PN. Phenotypically, it was identified that both inhibition of IFITM1 and treatment with the IC50 of PN significantly decreases migration, growth and clonogenicity in all three TNBC cell lines. Notably, we identified that PN regulates IFITM1 expression on both the mRNA and protein level. Lastly, we identified a novel mechanism of PN such that it inhibits IFN-alpha signaling through inhibiting IFN-alpha gene expression and by interrupting its downstream signaling and subsequent activation of IFITM1, thus resulting in increased apoptosis. These results suggest that the IFN-alpha signaling pathway and subsequent IFITM1 expression has pro-survival mechanisms, that there is intracellular crosstalk regulated by IFN-alpha in TNBC, and that PN is a potential therapeutic agent for TNBC regardless of clinical subtype.

P1212/B339

Inhibition of Mcf-7 Breast Cancer Cell Proliferation and Cell Cycle Progression by the Dietary Polyphenols Ellagic Acid and Luteolin.

J. Rivosecchi-Fulton, **K. Baker**; University of Indianapolis, Indianapolis, IN.

Normal 0 false false false EN-US X-NONE X-NONE /* Style Definitions */ table.MsoNormalTable {mso-style-name:"Table Normal"; mso-tstyle-rowband-size:0; mso-tstyle-colband-size:0; mso-style-noshow:yes; mso-style-priority:99; mso-style-parent:""; mso-padding-alt:0in 5.4pt 0in 5.4pt; mso-para-

Epidemiological studies have demonstrated a positive correlation between the consumption of polyphenolic compounds and cancer prevention. Ellagic acid and luteolin, dietary polyphenols found in a variety of fruits and vegetables, have been shown to inhibit cancer cell proliferation and motility and induce apoptosis in *vitro*. In this study, we evaluated the antiproliferative effects of ellagic acid and luteolin, individually and in combination, using MCF-7 breast cancer cells. We found that both ellagic acid and luteolin inhibited MCF-7 cell proliferation in a dose dependent manner. Furthermore, we found that co-administration of ellagic acid and luteolin led to a greater inhibition of cell proliferation than either agent alone at the same dose and indicate an additive effect. These results suggest that combinatorial treatments using ellagic acid and luteolin may be an effective chemotherapeutic strategy against breast cancer.

P1213/B340

Agents That Decluster Centrosomes Are Effective Against an euploid B-Cell Precursor ALL Cells.

M. Guo, J. Jiang, S. Jo, G. Reid, C. Maxwell; UBC, Vancouver, BC, CANADA.

Background: Acute lymphoblastic leukemia (ALL) is the most common malignancy in children. Some ALL subtypes are defined by aneuploidy, which is likely caused by a defective cell division that also bestows an abnormal number or size of centrosomes. Cancer cells, but not normal cells, must cluster these organelles during cell division. Thus, centrosome clustering (CC) inhibitors may specifically kill B-ALL cells. Tumor cells generally respond to targeted therapies but often a population of cells becomes refractory. We hypothesized that pediatric ALL may frequently contain centrosome amplification and be sensitive to CC inhibitors; as CC inhibitors are likely to induce genome instability, B-ALL cells refractory to CC inhibitors may activate innate immunity via cyclic GMP-AMP synthase - stimulator of interferon genes (cGAS-STING) pathway. **Methods**: Twelve potential CC inhibitors were screened against a panel of four immortal B-ALL cell lines. Four CC inhibitors were selected for further study based upon correlation between IC50 dose and frequency of centrosome amplification. Primary B-ALL cells, both patient samples and cells isolated from a transgenic Emu-ret mouse that spontaneously develops leukemia, were grown as co-culture with feeders and screened for centrosome amplification and responses to CC inhibitors; primary human normal stem cells were also counter-screened. Immortal 289 mouse cells (Emu-ret+ B-ALL) that resist CC inhibitors were derived over a period of four months. Centrosome phenotype, spindle morphology, cGAS colocalization, gamma-H2AX and micronuclei were determined using immunofluorescence. Colorimetric assay and high content screening were performed to measure drug efficacy. **Results**: Centrosome amplification (CA) is a common feature of human diagnostic and relapsed B-ALL samples. CC inhibitors induced multipolar spindles, and CA levels correlated with sensitivity to CC inhibitors in primary patient B-ALL samples and normal stem cell control samples. The refractory B-ALL cells (termed 289r) showed increased level of gamma-H2AX and micronuclei. cGAS was found to colocalize to micronuclei. Primary B-ALL cells also showed increased levels of cGAS- MN after treatment with CC inhibitors. **Conclusion**: IC50 doses for CC inhibitors are 10 - 100 X lower for primary human pediatric B-ALL than normal control stem cell samples. Immortal refractory B-ALL cells have increased levels of genetic instability, as measured by gamma-H2AX, and genomic instability, as measured by micronuclei, which elevates the level of cGAS-bound micronuclei and may activate

TBK1/NF-$_K$B and pro-inflammatory signals. The combination of CC inhibitors, such as PARP inhibitors, and immune checkpoint inhibitors may be effective against relapsed pediatric B-ALL samples.

Developing a Single-Cell, Imaging Assay to Characterize CAR-T Functional Heterogeneity.

E. Kwee[1], A. Peskin[2], J. Chalfoun[1], J. Jiang[3], A. Mullan[3], C. Grigoriadou[3], S. Sarkar[1], J. Elliott[1]; [1]National Institute of Standards and Technology, Gaithersburg, MD, [2]National Institute of Standards and Technology, Boulder, CO, [3]AstraZeneca, Gaithersburg, MD.

Chimeric antigen receptor (CAR) T cells are genetically modified T cells designed for antigen specific killing of cancer cells. CAR-T populations are typically composed of both transduced and un-transduced cells. Heterogeneity in the donor cells and transduction process contribute to variability to CAR-T function and viability. There is a need to understand the subpopulation of cells which comprise a CAR-T population. This information could provide insight into the effectiveness of a CAR-T therapy. We developed a large field of view, live cell imaging workflow using phase contrast microscopy, fluorescence surface marker staining, and machine learning to perform single cell characterization of CAR-T cells by imaging in microgrids. This approach is similar to the TIMING assay (Vadarajan lab, University of Houston) to identify dynamic cytotoxicity characteristics determined from live cell imaging. Using a model CAR-T cell system targeting human epidermal growth factor receptor 2 (HER2), we were able to identify subpopulations in CAR-T and un-transduced T cells based on differences in viability and proliferation rates. Single cell analysis of CAR-T cells revealed subpopulations where 8.5% were apoptotic and 65% were proliferative with a doubling time of 52.0 ± 34.9 hours (mean ± standard deviation). Single cell analysis of un-transduced T cells showed subpopulations where 17% were apoptotic and 36% were proliferative with a doubling time of 56.4 ± 32.7 hours. Future work includes staining surface markers to differentiate the phenotype of the apoptotic and proliferative CAR-T subpopulations. Moreover, quantification of cytotoxic CAR-T heterogeneity is being evaluated by co-culturing CAR-T with target cells in microgrids and quantifying single cell interactions. This approach can be applied to other CAR-T populations to understand what subpopulations exist in a heterogeneous cell population and potentially enable enrichment of subpopulations with desirable dynamic characteristics determined from live cell imaging.

P1215/B342

Appetizers & Entrees: Phagocytosis of Microbeads Or Red Blood Cells (RBCs) and Then 'Self'-Inhibited Cancer Cells.

J. C. An drechak, L. J. Dooling, D. E. Discher; University of Pennsylvania, Philadelphia, PA.

CD47 is a ubiquitous membrane protein that functions as a marker of 'self' to enable immune recognition of healthy cells by SIRPα on macrophages. Combining blockade of this inhibitory interaction with pro-phagocytic cues on cancer cells is already emerging in clinical therapy, but many challenges remain including control over the amount of eating. Here, depletion of CD47 via CRISPR knockout (KO) in B16 melanoma cells is combined with B16 opsonization by anti-Tyrp1, which results in more eating of cancer cells in *vitro* by mouse bone marrow-derived macrophages (BMDMs) relative to wild-type (WT) and relative to un-opsonized B16s. Pre-feeding BMDMs with ~2 μm polystyrene microbeads 24 hours prior to feeding KO's leads to slightly greater eating of the cancer cells, whereas pre-feeding of RBCs eliminates such phagocytosis. In *vivo*, intravenous injection of these same KO cells into C57 mice results

in lung tumor nodules that model metastasis and that are indistinguishable from WT tumors. However, we find anti-Tyrp1 injections suppress the growth of CD47 KO tumors but not WT tumors - which reinforces the need for combining pro-phagocytic signals and blockade of CD47. For a more therapeutically relevant approach, we make antibody Primed & Phagocytosis Blocked macrophages (A'PBs) by antibody-treatment of donor marrow monocytes to block SIRPα and also to target B16s via anti-Tyrp1. WT lung tumor nodules are significantly reduced in size and number by A'PBs, and studies of A'PB that have pre-eaten microbeads or RBCs before being infused are now testing the hypothesis that such 'appetizers' affect the trafficking and cancer-engulfment capacity of these immune cells.

P1216/B343

Enhancing Cytotoxicity of Natural Killer Cells by Exogenous Mitochondrial Transfer.

J. Hwang[1], Y. Chun[2], Y. Park[2], J. Lee[1], J. Kim[1], Y. Choi[1], Y. Choi[2]; [1]CHA University, Seongnam-si, KOREA, REPUBLIC OF, [2]CHA University, Pocheon-si, KOREA, REPUBLIC OF.

Natural killer (NK) cells have been concentrated as a source of anti-cancer cell therapies as a major component of the innate immune system, contributing to the first line of defense against cancer and viral infections. Mitochondria are organelles responsible for cellular function, including energy metabolism, free radical production, cell survival and death. Recently, we have developed a simple and easy mitochondrial delivery protocol using centrifugation, in which mitochondria can be delivered directly to target cells. Here, we delivered mitochondria directly to NK cells to enhance NK cell cytotoxicity. Mitochondria-enriched NK cells have shown a potent therapeutic effect in myeloid leukemia models in *vitro*. As a result, our findings showed a new strategy for NK activation methods that could be used clinically.

P1217/B344

Characterization of Coumestrol as an Anticancer Therapy Against Triple-Negative Inflammatory Breast Cancer.

K. M. Rodriguez-Martir, D. Negron Figueroa, I. Jimenez, X. S. Bittman, E. A. Peterson PhD; University of Puerto Rico - Rio Piedras Campus, San Juan, PR.

Breast cancer is the second leading cause of death in females in the United States, being Inflammatory Breast Cancer (IBC) one of the most aggressive subtypes. The poor prognosis for patients with IBC emphasizes the need to better understand the molecular signature. To this date, there is no effective targeted therapeutics, especially for those patients that account for approximately 20-40% of IBC cases with triple-negative breast cancer (TNBC) classification. Importantly, several studies have shown that estrogen can exert non-genomic effects in IBC and non-IBC TNBC, mediated by the expression of a shorter isoform of the canonical estrogen receptor alpha (ER), named estrogen receptor alpha-36 (ERα-36), and a G protein-coupled receptor, GPR30, that can also be activated by estrogens. In this context, estrogen can activate rapid non-genomic signaling pathways involved in the acquisition of oncogenic phenotypes such as increased motility and invasion in IBC cells. Phytoestrogens, like coumestrol (Cou), are natural compounds found in plants, specifically soybeans. Also, it is a polyphenolic compound that is structurally similar to estradiol (E2), and several studies have shown that coumestrol inhibits cell proliferation and migration in TNBCs. We hypothesize that (1) estrogen non-genomic signaling has an active role in the aggressive metastatic phenotype of IBC, and (2) Cou has anticancer activity by inhibiting estrogen non-genomic signaling in IBC. To test these hypotheses, IBC cells, SUM 149, were

treated with E2 and activation of downstream kinases (ERK and AKT) was analyzed by Western blot. Immunofluorescence in SUM149 cells and Western Blot showed expression of both, ERα-36 and GPR30. Besides, preliminary observations treatment using previously reported IC50 (50μM) of Cou caused a decrease in cell viability in ER-positive breast cancer cell lines and TNBC, including IBC cells. Also, in comparison to E2, Cou decrease migration in IBC cells. In summary, IBC cells are responsive to E2 treatment making this signaling pathway attractive for the development of innovative therapeutic strategies. Importantly, preliminary studies show a potential anticancer activity of coumestrol in IBC cell lines by either decreasing migration and/or cell viability.

P1218/B345

Protect Or Potentiate: the Role of Common Medications in Modulating Response to Radiation Exposure.

S. An des[1], J. B. Davis[2], D. Pinto[2], F. Kashanchi[2], **V. Espina**[2]; [1]College of William and Mary, Williamsburg, VA, [2]George Mason University, Manassas, VA.

Objective: to investigate the effects of common medications on protein signal transduction and metabolic activity in response to radiation in a lung cancer cell line model. Drugs and drug metabolites are known to modulate cellular signaling cascades, either intentionally or unintentionally as off-target effects. For example, calcium channel blockers and angiotensin converting enzyme inhibitors are known to confer cellular protection from radiation. Radiation also modulates cell signaling pathways in both target cells and distant cells (by-stander effect). We examined cell viability and protein signaling pathways following escalating radiation doses, with or without drug treatment. Methods: NCI-H2228 non-small cell lung cancer cells were x-ray irradiated at various doses with and without *a priori* drug treatment. We evaluated medications used for the treatment of cardiovascular ailments, high cholesterol, epilepsy, and diabetes. Treatment consisted of physiologic doses of a calcium channel blocker, an angiotensin converting enzyme (ACE) inhibitor, a HMG CoA reductase inhibitor, a beta-adrenergic antagonist, an anti-epileptic drug, and 1,1-dimethylbiguanide hydrochloride. Cell viability/metabolic activity was measured by quantifying the reduction of 10% resazurin in cell culture. Signal transduction pathways were quantified by reverse phase protein array. Immunohistochemistry of cytospin preps was used to assess apoptosis. Results: Untreated cells were irradiated with doses ranging from 0.1 Gy to 20 Gy. Effects became pronounced by Day 6. Maximal effects were observed with 20 Gy of radiation, with half maximal effects observed at 2.5 Gy. A time course of 2.5 Gy post exposure toxicity shows persistent decline of viability over 2 weeks. Leviteracetam and metformin alone increased sensitivity to low dose radiation. We identified propranolol and an ACE inhibitor + metformin regimen as agents that provide temporary resistance against low-dose (2.5 Gy) radiation. Cleaved PARP was present in Metformin+ACE treated cells 20 days post-irradiation. Conclusion: Medications used for the treatment of cardiovascular ailments, high cholesterol, epilepsy, and diabetes can protect lung cancer cells, or potentiate the effects, of low dose radiation. The effects of common medications were reduced when high doses of radiation were applied.

Creating an Integrated Landscape of Human iPSC Nuclear States.

S. M. Rafelski,.Allen Institute for Cell Science; Allen Institute for Cell Science, Seattle, WA.

The Allen Institute for Cell Science is developing a state space of stem cell structural signatures to understand the principles by which cells reorganize as they traverse the cell cycle and differentiate. To do this, we have developed a pipeline that generates high-replicate, dynamic image data of cell organization and activities in human induced pluripotent stem cell (hiPSC) lines (the Allen Cell Collection at www.allencell.org). Each of the ~35 lines expresses an endogenous monoallelic EGFP-tagged protein that represents a particular cellular organelle or structure. For each line, we develop image-based assays and segmentation algorithms for quantitative analyses, taking advantage of the thousands of replicate high resolution 3D images for each structure. This image database is used for data and machine learning analyses and computational modeling. We are applying these same approaches to creating an integrated state space of nuclear signatures. We have endogenously EGFP-tagged an initial set of 17 nuclear proteins representing key nuclear organizational landmarks at multiple spatial scales including at the level of the nucleus and nucleoplasm as a whole (nuclear lamina, nuclear pores, several nucleolar subcompartments, and nuclear speckles), chromatin structure (histone H2B, HP1-beta, and EZH2), key proteins in chromatin looping (CTCF, SMC1A), two types of chromatin loci (telomeres and DNA replication sites), RNA polymerase, and two pluripotency transcription factors. We have imaged the sub-nuclear localization of these structures as the cells progress through the cell cycle and differentiate into cardiomyocytes. We are developing assays to image and quantify the protein localization patterns of these proteins at different spatial scales and creating machine learning transfer functions to enhance the resolution capabilities for live-cell imaging of nuclear structures. We are also developing methods to track and quantify specific loci within the genome relative to these protein landmarks. The cell lines, image data and analyses are being integrated with genome-wide assays of chromatin architecture together with the 4D Nucleome Project NOFIC centers, and once fully characterized, will be distributed publicly. For example, to provide realistic spatial constraints within the nucleus for more accurate modeling of chromatin organization basd on genomic assays, we are applying deep-learning based “label-free” technology to generate integrated models of key nuclear landmarks, beginning with the nuclear envelope, nucleolus, and nuclear speckles.

P1220/B348

The Biological Role of an Endogenous Epigenetic Metabolic Small Molecule, O-acetyl-ADP-ribose, on Yeast Silent Heterochromatin.

S. Tung[1], S. Wang[2], S. Lee[1], M. Tsai[3], **G. Liou**[1]; [1]Academia Sinica, Taipei, TAIWAN, [2]Chung Shan Medical University, Taichung, TAIWAN, [3]Da-Yeh University, Changhua, TAIWAN.

The biological role of an endogenous epigenetic metabolic small molecule, O-acetyl-ADP-ribose, on yeast silent heterochromatin Shu-Yun Tung[1,#], Sue-Hong Wang[2,#], Sue-Ping Lee[1,#], Ming-Shiun Tsai[3], Gunn-Guang Liou[1,4,5,*] [1] Institute of Molecular Biology, Academia Sinica, Taipei 115, Taiwan, ROC. [2]Department of Biomedical Sciences, Chung Shan Medical University, & Department of Medical Research, Chung Shan Medical University Hospital, Taichung 402, Taiwan, ROC. [3]Department of Food Science and Biotechnology, Da-Yeh University, Changhua 515, Taiwan, ROC. [4]Institute of Biological

Chemistry, Academia Sinica, Taipei 115, Taiwan, ROC. [5]Guang EM Laboratory, New Taipei 242, Taiwan, ROC. [#]These authors contributed equally to this work Budding yeast heterochromatin is a major model to study the epigenetic gene silencing. The formation of yeast heterochromatin combines an NAD-dependent histone deacetylation and the generation of an epigenetic metabolic small molecule, *O*-acetyl-ADP-ribose (AAR) by Sir2 with SIR complexes conformational change, and follows by the repeated recruitment cycle of SIR complexes along the adjoin chromatin, and additional processing of maturation and maintenance. In our study, we show that AAR is able to enhance the silencing effect and able to promote the Sir3 spreading alone the telomeres. We also demonstrate that AAR physical associates with the Sir3 and importantly, we find that AAR is able to stabilize the association of Sir3 BAH domain with Sir3 C-terminal region. This AAR-dependent association of artificially separated Sir3 BAH domain with the rest C-terminal region that might be the key answer why the structure rearrangement of SIR complex happens when Sir2 deacetylates histone, generates AAR and interacts with Sir3. Furthermore, we also demonstrate that PolySir3-AAR plays a specific and essential role in modulating the formation of SIR-nucleosome pre-heterochromatin filaments *in vitro*. Our data suggests that for the assembly of SIR-nucleosome pre-heterochromatin filament, the structural rearrangement of SIR complexes is important and result in creating more stable interactions of Sir3, such as the inter-molecule Sir3-Sir3 interaction, and the Sir3-nucleosome interaction within the filaments. In summary, AAR, an endogenous metabolic small molecule, mediates a conformational change of protein complex that is involved in the epigenetic gene silencing.

Toward a Mechanistic Characterization of Promoter Progression for Glucocorticoid Receptor Responsive Genes.

G. FETTWEIS[1], M. Puglia[2], A. McGowan[1], S. Fujiwara[1], T. Johnson[1], S. Kim[1], G. Pegoraro[3], D. Stavreva[1], B. Blagoev[2], G. Hager[1]; [1]Laboratory of Receptor Biology and Gene Expression, CCR, NCI, NIH, Bethesda, MD, [2]Center for Experimental Bioinformatics, Department of Biochemistry and Molecular Biology, University of Southern Denmark, Odense, DENMARK, [3]NCI High-Throughput Imaging Facility, Bethesda, MD.

After hormone activation, the Glucocorticoid Receptor (GR), translocates to the nucleus and binds to GR Responsive Elements (GREs) to regulate target genes. Although GR can either up or down-regulate transcripts, it has also been demonstrated that responsive genes are subjected to complex regulation profiles early after hormone treatment, with a gene specific alternance of activation and repression phases. To understand the mechanisms behind these different expression profiles, we performed a quantitative proteomic study of GR partners present on the chromatin (Chip-SICAP) at varying times after GR induction. These experiments provide a list of interactants differentially recruited to GR at the chromatin level. We alsodeveloped an RNA-Hybridization Chain Reaction (RNA-HCR) fish protocol to examine the different expression profiles of various GR responsive genes (Mt2, Ccl2, Tsc22d3) on a High-Throughput platform (HiTIF). iRNA screens against the differentially GR recruited partners will identify key players in the GR regulated expressions patterns. These approaches will form the basis for a comprehensive understanding of regulatory mechanisms active in these complex induction/repression schemes.

Cohesin Impedes Heterochromatin Assembly in Fission Yeast Cells Lacking Pds5.

H. Folco; National Institutes of Health, Bethesda, MD.

The fission yeast *Schizosaccharomyces pombe* is a powerful genetic model system for uncovering fundamental principles of heterochromatin assembly and epigenetic inheritance of chromatin states. Heterochromatin defined by histone H3 lysine 9 methylation and HP1 proteins coats large chromosomal domains at the centromeres, telomeres and the mating type (*mat*) locus. Although genetic and biochemical studies have provided valuable insights into heterochromatin assembly, many key mechanistic details remain unclear. Here we use a sensitized reporter system at the *mat*locus to screen the gene deletion library to identify additional factors affecting heterochromatic silencing. In addition to known components of heterochromatin assembly pathways, our screen identified eight new factors including the cohesin-associated protein Pds5. We find that Pds5 enriched throughout heterochromatin domains is required for proper maintenance of heterochromatin. This function of Pds5 requires its associated Eso1 acetyltransferase implicated in acetylation of cohesin. Indeed, introducing an acetylation-mimicking mutation in a cohesin subunit can suppress defects in heterochromatin assembly in *pds5Δ and eso1Δ* cells. Our results show that in cells lacking Pds5, cohesin interferes with heterochromatin assembly. Supporting this, eliminating cohesin from the *mat* locus in *pds5Δ* mutant restores both heterochromatin assembly and gene silencing. These analyses highlight an unexpected requirement for Pds5 in ensuring proper coordination between cohesin and heterochromatin factors to effectively maintain gene silencing.

Sumoylation-induced Liquid Condensation Clusters Telomeres.

H. Zhang, J. Tones; Carnegie Mellon University, Pittsburgh, PA.

Telomerase-free cancer cells rely on an alternative lengthening of telomeres (ALT) pathway that employs homologous recombination (HR) to maintain telomere length for immortality. One of the unique features of ALT is the sumoylation of proteins on telomeres, which is required for telomere maintenance but the underlying mechanism remains unknown. We hypothesize that sumoylation induces liquid condensation at telomeres for ALT, based on the observations that sumoylated proteins interact with proteins containing SIM (SUMO interaction motif) and multivalent interactions between SUMO and SIM drive liquid-liquid phase separation in vitro. The induced SUMO-SIM condensates can potentially coalesce to cluster telomeres together so one can use another as a template for recombination. To test this hypothesis, we recruited SUMO ligase to telomeres with chemical dimerizers, which induced sumoylation and liquid condensation at telomeres and led to telomere clustering. To confirm that the underlying driving force is SUMO-SIM interaction, we bypassed the sumoylation process and recruited SUMO or SIM directly to telomeres and drove condensation and telomere clustering. Our work shows that sumoylation contributes to HR-based ALT by inducing liquid condensation to aid homology search, suggesting a similar mechanism may at play during normal HR.

Investigating the Role of Dsk1 and Kic1 Protein Kinases in Heterochromatin Formation.

A. Vyas[1], M. Wu[2], X. Liu[2], X. Yang[3], C. Tang[3], P. Zhang[1], B. Alhoch[1], Z. Tang[1]; [1]W. M. Keck Science Center, the Claremont Colleges, Claremont, CA, [2]College of Chemistry and Molecular Engineering, Peking University, Beijing, CHINA, [3]Center for Quantitative Biology, Peking University, Beijing, CHINA.

Dis1- suppressing protein kinase (Dsk1) in *Schizosaccharomyces pombe* is a highly evolutionarily conserved serine-threonine protein kinase, implicated in important cellular functions such as mitotic cell cycle regulation, cell proliferation and differentiation. While the significance of Dsk1 on these cellular events has been well documented, the targets through which Dsk1 mediates these events is still not well understood. To investigate the potential targets of Dsk1, we used a proteomics based approach to determine the differential protein phosphorylation between wild type and dsk1-deletion mutant strains. This resulted in a list of potential Dsk1 phosphoprotein substrates that were found to be significantly associated with 10 Gene Ontology processes such as cytoskeletal and mitotic spindle organization, chromosome localization and cell cycle regulation. Physical interaction networks generated for proteins involved in these GO processes, suggest potential central nodes through which Dsk1 may affect such processes as cell growth polarity, mitotic phase transition, sister-chromatid segregation and cytokinesis. We then performed genome-wide epistasis analysis, which helped us identify a strong genetic interaction between Dsk1 and components of an integral kinetochore associated DASH complex. These results suggest that Dsk1 is likely involved either functionally or organizationally with centromeric heterochromatin. We further investigated the effect of Dsk1 as well as another LAMMER-related kinase Kic1, on centromeric gene expression in *S. pombe*. The results imply that both Dsk1 and Kic1 kinases are required for gene silencing at centromeres. Additionally, we looked at the change in phosphorylation status of a heterochromatin binding protein, Swi6 (*S. pombe* homolog of human HP1) in Dsk1 and Kic1 deletion backgrounds. The results indicate that both Dsk1 and Kic1 kinases, either directly or indirectly through a phosphorylation cascade, are involved in regulating Swi6 activity to ultimately affect heterochromatin formation/function. We also performed immunofluorescence analysis on WT cells, and observed a strong co-localization of GFP-Kic1 with Swi6 associated heterochromatic regions within the *S. pombe* nucleus. Collectively, our results provide evidence for Dsk1 and Kic1 kinases affecting chromatin structure and gene expression at the centromeric heterochromatin regions in S. *pombe* cells.

P1225/B353

Investigation of the Mechanism of Set1-mediated Telomere Silencing and Maintenance in *Saccharomyces Cerevisiae*.

M. Jezek, E. Green; University of Maryland Baltimore County, Baltimore, MD.

Telomeres, the nucleoprotein structures found at the ends of linear chromosomes, provide a protective function for the genome. Alteration to the chromatin structure at or adjacent to these protective caps leads to dysfunctional telomeres, which are associated with genomic instability and implicated in cellular aging and many types of cancer. In *Saccharomyces cerevisiae*, the H3K4 methyltransferase Set1 has been linked to both transcriptional activation at gene promoters and silencing at telomeres. However, while we have some insight regarding the role for Set1 in silencing, the mechanism is still largely unclear. Previously, we investigated the role of Set1 in the regulation of gene repression at native telomeres in Saccharomyces cerevisiae and found that gene derepression in the absence of Set1 is largely through a Sir protein-independent mechanism. Additionally, we have analyzed the transcriptomes from cells lacking Set1 and have found them to show a strong correlation with transcriptomes belonging to mutants that display defects in telomere maintenance, revealing a specific

role for Set1 in pathways required for telomere integrity, rather than just gene silencing. In order to further dissect the role of Set1 at telomeres, we have generated a number of Set1 mutants to determine the contributions of both its catalytic and non-catalytic activity and have characterized the role of Set1's catalytic and non-catalytic functions in telomere silencing, telomere length, and the response to DNA damage. We have determined that these phenotypes are largely dependent on Set1's methyltransferase activity. We also have preliminary data suggesting that the expression and localization of some of the protein machinery required to protect telomeres, including the telomere -binding proteins Rap1 and Cdc13, may be altered in the absence of Set1. Overall, our data provides support for a role for Set1 and H3K4 methylation in the promotion of telomere integrity through the regulation of telomere-binding proteins.

P1226/B354

Phase-separated Heterochromatin Domains Impart Mechanical Stiffness to the Nucleus.

M. C. King[1], J. F. Williams[1], I. V. Surovtsev[1], A. Nguyen[2], S. G. J. Mochrie[3]; [1]Yale School of Medicine, New Haven, CT, [2]Pomona College, Claremont, CA, [3]Yale University, New Haven, CT.

The association of heterochromatin with the nuclear periphery has long been suggested to reflect its transcriptional repression. However, our prior work revealed that chromatin, particularly regions of the genome associated with the inner nuclear membrane, also play an integral role in supporting the mechanical robustness of the nucleus through mechanisms that remain poorly understood. In light of new insights into the potential for heterochromatin to form a distinct liquid-like phase, we sought to define the underlying basis for the biophysical contribution of heterochromatin to nuclear mechanics. Our approach employs an image reconstruction software we developed to quantitatively measure dynamic nuclear envelope fluctuations, a novel force spectroscopy assay that employs optical tweezers to directly measure the viscoelastic properties of isolated nuclei, and microscopy approaches to monitor the dynamics of heterochromatin foci in living cells. We find that loss of the histone H3K9me2/3 binding protein Swi6, an HP1 orthologue found to undergo liquid-liquid phase separation in *vitro*, results in increased nuclear deformability in *vivo* and a 50 percent drop in the nuclear spring constant in *vitro*. Accordingly, deletion of the histone H3K9 demethylase Epe1, which drives heterochromatin spreading, results in stiffer nuclei. As cytoplasmic microtubules are coupled to the centromeres in fission yeast, we characterized the deformation of the centromeric heterochromatin in response to force, which reinforces the liquid-like behavior of heterochromatic foci. This behavior is altered in cells harboring an allele of Swi6 with a mutation in the critical "hinge" domain; this mutated protein associates normally with H3K9me2/3-rich chromatin domains but fails to induce silencing, suggesting that this allele may uncouple the phase separation behavior of Swi6 from its other biochemical activities. Accordingly, both this allele and cells lacking Swi6 demonstrate defects in the coalescence of heterochromatic foci. Taken together, these results suggest that liquid-liquid phase separation can contribute to cellular mechanics, in this case by contributing to nuclear stiffness.

P1227/B355

Phase Separation of YAP Reorganizes Genome Topology for Long-term Yap Target Gene Expression.

D. Cai[1,2], D. Feliciano[1], P. Dong[2], N. Porat-Shliom[1], Z. Liu[2], J. Lippincott-Schwartz[2]; [1]National Institutes of Health, Bethesda, MD, [2]Janelia Research Campus, Howard Hughes Medical Institute, Ashburn, VA.

Yes-associated Protein (YAP) is a transcriptional co-activator that regulates cell proliferation and survival by binding to a selective set of enhancers for potent target gene activation, but how YAP coordinates these transcriptional responses is unknown. Here, we demonstrate that YAP forms liquid-like condensates in the nucleus in response to macromolecular crowding. Formed within seconds of hyperosmotic stress, YAP condensates compartmentalized YAP's transcription factor TEAD1 along with other YAP-related transcription co-activators, including TAZ, and subsequently induced transcription of YAP-specific proliferation genes. Super-resolution imaging using Assay for Transposase Accessible Chromatin with photoactivated localization microscopy (ATAC-PALM) revealed that YAP nuclear condensates were areas enriched in accessible chromatin domains organized as super-enhancers. Initially devoid of RNA Polymerase II (Pol II), the accessible chromatin domains later acquired RNA Pol II, producing newly transcribed RNA. Removal of YAP's intrinsically-disordered transcription activation domain (TAD) prevented YAP condensate formation and diminished downstream YAP signaling. Thus, dynamic changes in genome organization and gene activation during YAP reprogramming is mediated by liquid-liquid phase separation.

P1228/B356

Impact of 3D-Genome Organization on Regenerative Ability.

A. S. Ahsan, 20057-0001, E. Silva; Georgetown University, Washington, DC.

Although the field of regenerative medicine has made several advances, the molecular mechanisms driving the remarkable processes of wound healing and tissue replacement are yet to be fully uncovered. We aim to determine why new neurons do not form after spinal cord injury in higher vertebrates, by taking a closer look at the spatial organization of DNA in neural stem cells (NSCs), which differentiate into neurons during early development. DNA is arranged non-randomly within a cell nucleus, and its intricate packaging into topological domains plays a critical role in a critical role in gene regulation and thus, cell fate determination. The African-clawed frog, *Xenopus laevis*, which has high regenerative potential during its larval or tadpole stages, but loses it after metamorphosis, will serve as an excellent model organism to understand how the three-dimensional (3D) genome organization of NSCs varies in regenerative versus non-regenerative environments. We hypothesize that the 3D genome organization of NSCs alters unfavorably as *X. laevis* transitions from larval to adult stages, limiting NSC proliferative capacity and resulting in loss of neuron regeneration. To test this hypothesis, a Sox2-GFP transgenic *X. laevis* line will be created to fluorescently label NSCs. Spinal cord transections will be performed on tadpoles (staged 50) and post-metamorphosis froglets (staged 66), as representatives of regenerative and non-regenerative phases respectively. NSCs will be isolated by FACS (fluorescence activated cell sorting), and their 3D genome organization will be analyzed by the chromosome conformation technique, Hi-C. If the Hi-C data confirms our hypothesis, we will modulate specific architectural proteins, such as CTCF and cohesin, in adult *X. laevis* NSCs to test whether these modifications can restore regenerative capacity in the metamorphosed frog.

P1229/B357

Distinct Roles of the H2A.Z Variants in Chromatin Organisation and Mitosis.

R. Sales Gil, H. Amin, V. Vinciotti, **P. Vagnarelli**; Brunel University London, Uxbridge, UNITED KINGDOM.

Gene silencing through heterochromatin is an important mechanism to ensure establishment of cell type-specific gene expression patterns and dysregulation of heterochromatin can result in severe developmental defects. While H3K9me3 is important for HP1 recruitment to heterochromatin, it is becoming apparent that it is not solely sufficient, thus suggesting that additional factors also contribute to direct the chromatin-binding activity and function of HP1. Some reports suggest that specific histone variants could be involved in promoting HP1 association to chromatin. One candidate is the histone variant H2A.Z. Using a proteogenomic approach to identify histone variants specifically enriched in the chromatin fraction able to bind HP1α, we have identified the H3.3 and the H2A.Z variants. In vertebrates, H2A.Z exists in two different isoforms H2A.Z-1 and H2A.Z-2 coded by two non-allelic genes, H2AFZ and H2AFV, respectively. These seem to have no redundant functions and it is not known which one is important for the establishment of heterochromatin. Moreover, compelling in *vivo* data that supports a mechanism linking these variants to H3K9me3, HP1 and heterochromatin establishment is still elusive. The analyses of DNA sequencing recovered from the proteogenomic study revealed that 50% of the HP1α bound chromatin is also bound by H3K9me3 and that 25% of the HP1α bound regions are bound by H2A.Z but only 17% of those regions contain both H2A.Z and H3K9me3. This suggests that these regions may represent different chromatin states to which HP1α can potentially bind. Moreover, we could successfully deplete each isoform in HeLa cells and demonstrate that only the H2A.Z-2 variant has an effect on HP1α localization, while H2A.Z-1 presented a strong phenotype affecting nuclear shape. Finally, the RNA seq analyses of cells depleted of each isoform and the associated mitotic phenotypes indicate a distinct and non-redundant role for the two H2A.Z isoforms in chromatin organization in human cells.

A New Hi-C Method Reveals the Conformation of Sister Chromatids.

M. Mitter[1], C. Gasser[2], Z. Takacs[1], R. Stocsits[3], W. Tang[3], S. L. Ameres[1], J. Peters[3], A. Goloborodko[4], R. Micura[2], D. W. Gerlich[1]; [1]Institute of Molecular Biotechnology of the Austrian Academy of Sciences, Vienna BioCenter, Vienna, AUSTRIA, [2]Institute of Organic Chemistry and Center for Molecular Biosciences (CMBI), Leopold-Franzens University, Innsbruck, AUSTRIA, [3]Research Institute of Molecular Pathology, Vienna BioCenter, Vienna, AUSTRIA, [4]Department of Physics, Massachusetts Institute of Technology, Cambridge, MA.

The three-dimensional organization of chromosomal DNA is key for proper gene regulation, DNA recombination and repair, and chromosome segregation. Throughout interphase, cohesin forms DNA loops to shape topologically associated domains (TADs). Moreover, a subset of cohesin complexes links replicated sister chromatids from S-phase until mitosis to enable DNA damage repair and faithful chromosome segregation. The genomic landscape of chromatin loops and TADs has been studied in great detail by chromosome conformation capture techniques (Hi-C), but available methods cannot distinguish between identical DNA copies of replicated chromosomes. The distribution of sister chromatid linkages has hence remained unclear. We have developed a sister-chromatid-sensitive Hi-C method based on in vivo DNA labeling with nucleotide analogues. Using this methodology, we have generated genome-wide conformation maps of replicated chromosomes from interphase and mitotic

cells. We discovered four-way junctions where loops from both sister chromatids are linked at their base, as well as unlinked loop structures on individual sister chromatids. We have also applied our methodology to study reorganization of sister chromatids during cell cycle progression and will discuss the implications for chromosome segregation.

P1231/B359

Reconstitution of Cohesin and Condensin-mediated Dna Loop Extrusion in Xenopus Egg Extracts.

S. Golfier, T. Quail, **J. Brugues**; Max Planck Institute, Dresden, GERMANY.

The structural maintenance of chromosomes (SMC) complexes, cohesin and condensin, organize chromatin in metaphase and interphase. Condensin can extrude DNA loops *in vitro*, which may be responsible for folding chromatin into condensed chromatids during metaphase. Cohesin has been hypothesized to organize interphase chromatin into topological associating domains also via a loop extrusion mechanism. However, direct imaging of loop extrusion in cellular contexts is lacking, and consequently whether loop extrusion is a general mechanism that organizes chromosomes both in interphase and metaphase is unknown. Here we used *Xenopus* egg extract to reconstitute and image loop extrusion in single DNA molecules. We show that loops form in both metaphase and interphase, but with distinct symmetry and processivity. Condensin extrudes non-symmetric loops in metaphase, whereas cohesin extrudes symmetric loops in interphase. This work shows that loop extrusion is a general mechanism for chromosome organization, with dynamical and structural properties that are molecularly regulated to achieve different levels of chromatin organization during the cell cycle.

P1232/B360

Connecting Chromosome Structure and Dynamics through High-precision Microscopy, Genetic Perturbations and Stochastic Simulations.

I. V. Surovtsev[1], J. F. Williams[1], M. L. Bailey[2], H. Yan[2], S. G. J. Mochrie[2], M. C. King[1]; [1]Yale School of Medicine, New Haven, CT, [2]Yale University, New Haven, CT.

Inside cells, the DNA polymers are compacted into a spatially ordered, yet dynamic, 3D-structure. Recent genome-wide chromatin conformation capture (Hi-C) experiments reveal a hierarchical organization of the DNA structure, with DNA domains nested within bigger domains (or compartments). This structure underlies chromosomal dynamics, e.g. The probability that distant loci encounter each other, with a higher probability for intra-domain contacts relative to inter-domain contacts. To gain insight into the structure-dynamics relationship of chromatin, we combine high-precision microscopy in living *Schizosaccharomyces pombe* cells with systematic genetic perturbations and stochastic modeling of DNA looping. First, we investigate the model that the activity of SMC proteins, which play crucial roles in chromosome structure, drive chromatin dynamics by loop extrusion. Surprisingly, inhibiting the activity of SMC complexes (either condensin or cohesin) using temperature-sensitive alleles increases chromatin mobility. These results suggest that SMC complexes normally constrain rather than agitate chromatin motion. Next, we interrogate how other DNA-organizing protein complexes, including RNAP, nucleosome remodelers or histone modifiers, impact chromosome dynamics. Interestingly, we found that perturbation of the INO80 nucleosome remodeling complex, but not the SWI/SNF, RSC or FFT complexes, reduces the mobility of chromosomal loci. Taken together with prior studies in budding yeast, we suggest that INO80 uniquely couples the act of transcription and chromatin motion. Stimulated by these experimental data, we built and simulated minimalistic stochastic models that

include transcription- and nucleosome-dependent dynamics of SMC proteins and compare it to models of CTCF-dependent or random (diffusion-capture) SMC dynamics. As modeling outputs strongly depend on the parameter values, we developed a polymer-physics-inspired metric that allows a quantitative comparison of the model outputs to experimental Hi-C data. Surprisingly, a simple transcription-nucleosome-dependent model can reproduce the major features of Hi-C maps in mammalian cells without invoking positions of CTCF binding. Our work suggests that the underlying architecture of transcriptional units plays a foundational role in establishing DNA structure that is further influenced by sequence-specific factors.

P1233/B361

HP1α Is a Chromatin Crosslinker That Dictates Nuclear Mechanics and Morphology.

A. Stephens[1], E. Banigan[2], R. Biggs[3], C. Herman[3], J. Collado[3], J. Ritland[4], L. Tait[4], D. Scalzo[4], M. Groudine[4], J. Marko[3]; [1]University of Massachusetts Amherst, Amherst, MA, [2]Massachusetts Institute of Technology, Boston, MA, [3]Northwestern University, Evanston, IL, [4]Fred Hutchinson Cancer Research Center, Seattle, WA.

The cell nucleus houses, organizes, and protects the genome. Previous findings reveal that chromatin, DNA and associated proteins, provide mechanical resistance to maintain the proper organization of the genome and shape of the nucleus to facilitate its proper function. HP1α is a known dimer that can act as a heterochromatin crosslinker, but its contribution to nuclear mechanics and morphology has been elusive. We used a novel HP1α -EGFP-AID, auxin inducible degron, cell line generated by the 4D Nucleome to degrade HP1α in 4 hours and determine its role in nuclear mechanics. Single nucleus isolation and micromanipulation force measurements reveal that HP1α is an essential mechanical component to chromatin-based short-extension nuclear force response, while not contributing to lamin A-based strain stiffening at longer extensions. As with other perturbations that decrease chromatin-based nuclear rigidity, degradation of HP1α results in abnormal nuclear morphology. Simulations of nuclear mechanics suggest HP1α could be acting either as a chromatin component or a chromatin-chromatin crosslinker but not as a lamin-chromatin crosslinker. Thus, we modulated heterochromatin levels to determine if HP1α dictates heterochromatin's mechanical rigidity to the cell nucleus. Increased heterochromatin, via the histone demethylase inhibitor methylstat, is not dependent on HP1α as it rescued both nuclear rigidity and nuclear shape in HP1α degraded nuclei. These findings suggest that even though HP1α is a heterochromatin crosslinker, HP1α crosslinking and heterochromatin provided differing contributions to nuclear rigidity and thus nucleus shape and function.

P1234/B362

DNA Methylation Status Is Sensed in the Nucleosome Self-assembly.

C. Gong, H. Ito, T. Ohyama; Dept. Biol., Waseda University, Tokyo, JAPAN.

We previously reported that dsDNA molecules can sense homology and those with identical sequences selectively assemble with one another. We named this phenomenon "DNA self-assembly" (1). Furthermore, we also reported that nucleosomes also have homology sensing ability and those with identical DNAs preferentially associate with one another. This phenomenon was named "nucleosome self-assembly" (2). These phenomena are facilitated or enabled by physiological concentrations of Mg^{2+} ions (1, 2). The next question to be answered is whether DNA methylation influences DNA self-assembly and/or nucleosome self-assembly. In this study, we examined the effect of DNA methylation on the

nucleosome self-assembly. Briefly, using the 601 sequence and histone octamers purified from chicken erythrocytes, homomeric or heteromeric tetranucleosomal arrays were reconstituted in *vitro. The* arrays had the 'AAAA', 'BBBB', 'AABB' and 'ABAB' structures, in which 'A' and 'B' indicate the nucleosome with unmethylated 601 and that with methylated 601, respectively. Then, using low concentrations of $MgCl_2$, these nucleosomal arrays were weakly induced to form intra-condensates with the conformation in which two nucleosomes associated and the remaining two were still free. Interestingly, in the intra-condensates, the association between the same nucleosome species was predominant, as compared to that between different species, strongly indicating that the status of nucleosomal DNA methylation is sensed in the nucleosome self-assembly. This phenomenon seems implicated in various chromatin-based biological phenomena. In this meeting, we will discuss the phenomenon we observed.

Post-Transcription Gene Regulation

P1235/B363

Linking RNA Condensation to Translational Regulation.

H. Glauninger[1], **J. A. M. Bard**[1], C. D. Katanski[1], E. M. Airoldi[2], E. W. J. Wallace[3], D. A. Drummond[1]; [1]University of Chicago, Chicago, IL, [2]Harvard University, Cambridge, MA, [3]The University of Edinburgh, Edinburgh, UNITED KINGDOM.

Post-transcriptional regulation of protein production helps maintain carefully balanced protein levels under normal growth conditions. It also allows for rapid adaptation to new environments such as the dramatic changes in the translational program associated with cellular stress responses. One means of post-transcriptional control is to change the localization or availability of mRNAs. For instance, in response to a variety of stresses, such as energy depletion or heat shock, RNA and protein are localized to biomolecular condensates termed RNA granules which are thought to be involved in translational regulation. However, the mechanisms of translational regulation during stress and the functional consequences of RNA granule formation remain unclear. In order to better understand the roles these granules and other RNA condensates play in translational regulation, we sought to determine which transcripts enter condensates in response to stress. To do so, we used ultra-centrifugation and RNA-seq to identify the transcripts which multimerize in response to heat shock in budding yeast. We find that the majority of transcripts aggregate in response to stress, while certain transcripts, such as those encoding heat shock proteins, remain soluble. Interestingly, we also observe that highly transcribed genes are more soluble than expected even under normal growth conditions. This suggests that RNA aggregation is tied to translational control at all times, not just during stress. To further investigate this phenomenon, we have designed a series of artificial reporters whose translation is regulated through a variety of mechanisms. We have used these transcripts to further explore the underlying mechanisms of RNA aggregation and its role in controlling protein production.

P1236/B364

The SUMO E3 Ligases Siz1 and Mms21 Are Required for DNA-protein Crosslink Repair.

D. K. Sam[1], E. M. Tulowetzke[1], Q. A. Simonson[1], D. D'Amours[2], J. Lopez-Mosqueda[1]; [1]Biology and Microbiology, South Dakota State University, Brookings, SD, [2]Ottawa Institute of Systems Biology, Cellular and Molecular Medicine, University of Ottawa, Ottawa, ON, CANADA.

Accurate duplication of chromosomes and their faithful transmission to daughter cells is essential to all eukaryotic organisms. This essential process can be interrupted by DNA damage lesions including DNA-protein crosslinks (DPCs). DPCs are the covalent attachment of proteins to DNA and are physical impediments to DNA replication and transcription machinery. Failure to repair DPCs results in genomic instability, which is a hallmark of cancer. Wss1, Mre11 and Tdp1 are three DNA repair enzymes that are important for DPC repair. However, how the protease Wss1 targets DPCs for repair remains unknown. We hypothesized that for a DPC to be repaired, it must first be marked for Wss1-dependent removal. Here, we made use of an inducible Flp-step mutant to model DPC repair at a defined locus in the budding yeast *Saccharomyces cerevisiae*. Wildtype cells can tolerate expression of a single unrepairable site-specific Flp-DPC but cells deficient in Mre11 cannot. Using this approach, we screened for factors that are important for tolerance to Flp-DPC induction. We found two SUMO E3 ligases, Siz1 and Mms21, as important for tolerance to our model DPC as well as for Topoisomerase1 covalent complexes induced with Camptothecin. Mms21 functions as part of the SMC5/6 complex that is recruited to DNA double strand breaks. Our data show that mutations in the SMC5/6 complex impairs DPC repair, suggesting that DPCs are modified by Mms21 when they are converted to DNA double strand breaks. Our results provide molecular insight to how Wss1 targets DNA-protein crosslinks for removal.

P1237/B365

Mapping the Rbfox2 Interactome in Mouse Myoblasts Using a Proximity Proteomics Approach.

T. Govindarajan, R. S. Adelstein, S. Kawamoto; National Institutes of Health, Bethesda, MD.

Myogenesis is regulated by the coordinated expression of muscle regulatory factors that includes Mbln1, Ptbp1, Cugbp1, Cugbp2 and Rbfox2. Rbfox2 is a UGCAUG sequence-specific RNA binding protein and plays an important role in regulating alternative splicing transitions during skeletal muscle differentiation. We and others have previously reported that the Rbfox2 gene undergoes tissue-specific alternative splicing and produce multiple isoforms specific to brain, heart and skeletal muscle. However, the function of Rbfox2 isoforms and their associated protein interaction and signaling pathways in skeletal muscle differentiation are largely unknown. Thus, we used a live cell proximity-labeling proteomics approach (BioID) to identify a spectrum of new protein interactions to Rbfox2 in C2C12 myoblast cells. This technique is particularly useful in identifying weak or transient interactions in living cells that are not detected by co-immunoprecipitation or yeast two-hybrid systems. In this study, we used three different Rbfox2 isoforms either containing ubiquitously expressed (B40) or a muscle specific (M43) exon or lacking an RNA recognition motif. The BioID fusion Rbfox2 isoforms are predominantly localized to the nucleus of the cell, and regulates the alternative splicing of an exogenously expressed Non-muscle Myosin Heavy Chain IIB mini-gene, reflecting native Rbfox2 function and subcellular distribution. To identify Rbfox2-proximal proteins in living cells, biotin was added to the cells expressing myc-BirA*Rbfox2 or myc-BirA*control followed by streptavidin pull-down and mass spectrometry analysis. Following mass spectrometry analysis, we filtered the data for a minimum fold change of >3 over control. This analysis identified 453 proteins proximal to at least one Rbfox2 isoform and also

identified known interactors of Rbfox2 such as Ataxin2. Of the 453 total proteins identified, 94 were common to all three Rbfox2 isoforms. This common set of 94 proteins was highly enriched for gene ontology terms related to the spliceosomal complex assembly, N6-methyladenosine-containing RNA binding and histone deacetylase binding that suggests a novel physiological role for Rbfox2.

P1238/B366

Terminal Uridyltransferase 7 Regulates Toll-like Receptor 4-driven Inflammatory Response by Controlling Messenger RNA Stability.

C. Lin[1,2], S. Guo[1], Y. Shen[1], C. Chang[1], Y. Young[1], L. Hsu[1]; [1]Institute of Molecular Medicine, National Taiwan University, Taipei, TAIWAN, [2]Genomics Research Center, Academia Sinica, Taipai, TAIWAN.

Innate immune responses are the first line of host defense to effectively clear pathogens and repair damaged tissues, however, dysregulation of inflammatory responses has been associated with numerous illnesses, such as cancer, sepsis, and metabolic disorders. Therefore, the innate immune responses must be tightly regulated. Toll-like receptors (TLRs) play a major role in the innate immune-mediated responses by sensing pathogen-associated molecular patterns from pathogens or damage-associated molecular patterns released from stressed or damaged cells. Various mechanisms have been reported to regulate TLRs-driven immune responses, including phosphorylation, ubiquitination/deubiquitination, and transcription/post-transcriptional control. Among them, post-transcriptional regulation is a rapid and flexible mechanism to modulate the expression of inflammatory-related genes. However, the molecular mechanism of post-transcriptional regulation still remains largely unknown. We previously studied the regulation of TLRs-mediated immune responses, and found a terminal uridyltransferase (TUT), TUT7, which was induced after TLR ligands treatment, including Pam_3CSK_4 (TLR1/2), poly(I:C) (TLR3), LPS (TLR4) and CpG-1826 (TLR9). TUTs are known to have the ability to uridylate or adenylate small RNAs and mRNAs, thereby modulating the stability of the target RNAs. Nevertheless, the function of TUT7 in TLRs-induced immune response remains to be discovered. Here, we demonstrate that depletion of TUT7 in both bone marrow-derived macrophages (BMDMs) and RAW264.7 macrophage cells results in dysregulated TLR4-triggered cytokine expression, including decreased the production of pro-inflammatory cytokines IL-1β, IL-6, and IL-12. Downregulation of IL-6 mRNA expression is also observed in TUT7-deleted BMDMs treated with various TLR agonists. We further reveal that TUT7 associates with and uridylates the endonuclease Regnase-1 mRNA, resulting in destabilization of Regnase-1 mRNA, which leads to upregulated expression of its target gene IL-6. Collectively, our findings indicate that TUT7 is involved in the regulation of TLR4-triggered immune responses by modulating mRNA stability of distinct inflammatory mediators.

Hypoxia-inducible Factors Repress Translation Via Alkbh5-mediated M^{6}A RNA Demethylation in Hypoxic Breast Cancer Cells.

C. Vissers, D. Samanta, T. Huang, G. Semenza; Johns Hopkins University, Baltimore, MD.

Hypoxia-inducible factors repress translation via ALKBH5-mediated m^{6}A mRNA demethylation in hypoxic breast cancer cells *N*^{6}-methyladenosine (m^{6}A) is a post-transcriptional modification of mRNA that alters mRNA and protein expression with emerging roles in cancer. Intratumoral hypoxia is a driving force for cancer progression, and expression of the m^{6}A demethylase ALKBH5 is strongly induced by hypoxia-inducible factors (HIFs), leading to global changes to the m^{6}A landscape in hypoxic cancer cells.

However, the relationship between transcriptional and post-transcriptional regulation by HIFs and ALKBH5, respectively, and downstream functional consequences of global changes in m^6A have not been examined. In this study we used total RNA-sequencing, m^6A sequencing, and mass spectrometry proteomic analysis to elucidate the shared and distinct roles of HIF and ALKBH5 in mediating breast cancer cell response to hypoxia, and how this is mechanistically accomplished through m^6A. We report that in hypoxic MCF7 breast cancer cells the majority of HIF-dependent genes are also ALKBH5 dependent at both the mRNA and protein levels. Additionally, the repression of cell cycle-promoting genes is both HIF- and ALKBH5- dependent, and knockdown of HIF-1α/HIF-2α or ALKBH5 causes increased levels of cancer cell proliferation in hypoxia. Loss of either HIF-1α/HIF-2α or ALKBH5 expression also causes increased levels of m^6A^+ RNA. Through m^6A-RNA sequencing we found that transcripts that promote translation initiation are consistently methylated in control cells, while transcripts encoding proteins mediating oxidative metabolism are dynamically demethylated in response to hypoxia. Loss of HIF-1α/HIF-2α or ALKBH5 broadly alters m^6A coverage patterns on mRNA, and specifically prevents demethylation of oxidative metabolism gene transcripts, which impairs the switch from aerobic to glycolytic metabolism in hypoxia. We also found that the most highly expressed m^6A reader protein in MCF7 cells is YTHDF1, which promotes translation of m^6A-modified mRNA. Indeed, m^6A^+ mRNAs produce significantly more protein in response to hypoxia than do m^6A^- mRNAs. Therefore, HIFs and ALKBH5 work in concert to limit translation, restrict cancer cell proliferation, and upregulate glycolytic metabolism in response to hypoxia.

A Genome-wide Crispr-cas9 Knockout Screen in Human Cells to Identify New NMD Factors and Regulators.

A. Cheruiyot, S. Li, Z. You; Washington University School of Medicine, Saint Louis, MO.

Nonsense mediated RNA decay (NMD) is a highly conserved RNA surveillance and gene regulation mechanism in eukaryotes. NMD degrades nonsense RNA transcripts containing premature translation termination codons (PTCs), and down-regulates other non-mutant RNAs containing other features on the RNA, such as upstream open reading frames, inclusion of PTCs-containing exons, introns in 3' untranslated region (UTR), and long 3' UTRs. Therefore, NMD is important for normal physiology and in diseases, where it modifies the phenotypic outcomes of many genetic disorders and cancers caused by nonsense mutations. The known core NMD factors, including UP-Frameshift (UPF) proteins and suppressors with morphogenetic defects in genitalia (SMG) proteins were identified in *S.cerevisiae and C. elegans.* While the NMD pathway is conserved in eukaryotes, there are significant differences in the mechanisms of NMD across species. Strikingly, several branches of NMD have been observed in humans, where NMD can occur in the absence of some core NMD factors, such as UPF2, or UPF3B, or in the absence of exon junction complexes that are known to strongly promote NMD in humans. Therefore, to fully dissect the mechanisms of NMD in humans, an unbiased approach is required to identify factors involved in NMD. We have developed a novel NMD reporter system to effectively measure NMD in human cells and used it to performed a genome-wide CRISPR/Cas9 knockout screen to identify genes important for NMD. Among our top validated hits, we have identified 9 novel genes that promote NMD in human cells. Our screen also identified SF3B complex of the spliceosome as one of the most enriched complexes, and additional experiments uncovered a previously unrecognized role of SF3B in NMD. Uncovering how the novel genes and protein complexes function in NMD will provide us with a better understanding of NMD in humans.

Translational Regulation of the Antiapoptotic Protein Survivin by Control Elements in the 5' Untranslated Region.

C. Palavecino[1], N. Carrasco-Véliz[1], M. Garrido[2], V. Contreras[1], A. Quest[2], **M. A. Valenzuela, 8330546**[1]; [1]Universidad Central De Chile, Santiago, CHILE, [2]Universidad de Chile, Santiago, CHILE.

Survivin is an anti-apoptotic protein that is ubiquitously expressed during embryonic development but is absent in most adult tissues, with exceptions, including the gastrointestinal epithelium. Despite its relevance in physiological processes, Survivin is re- or over-expressed in most cancer types correlating inversely with patient survival. The most important mechanisms studied related to the control of Survivin expression include transcriptional regulation, protein stability, and post-translational modifications, however to date, translational control has been poorly studied. Thus, we focused particularly on the translational control elements present in Survivin 5' untranslated region (5'UTR). Bioinformatic analysis of ribosome occupancy on Survivin 5'UTR (GWIPS online server) showed the presence of elongating ribosomes upstream the canonical initiator AUG, opening the possibility of the presence of an alternative upstream initiator AUG (uAUG). As expected, this uAUG was found at position -71, however, its impact on Survivin translation has not been determined. This study employed mainly human gastric (AGS and Ges-1), embryonic (HEK293T) and cervical (Hela) cell lines. The activity of the putative uAUG was assessed by Renilla reporter assay, qRT-PCR, Western blot, *in vitro* transcription/translation and DNA recombinant techniques (DNA cloning and point mutations). Results: Transfection of Renilla reporter plasmids under the control of CMV promoter, showed that when the Survivin 5'UTR was cloned upstream of the Renilla gene, the expression of the reporter gene was decreased without changes in its mRNA levels; however, when the uAUG was mutated to AUU, the inhibitory effect was abolished. Since this uAUG was not positioned in frame with the Survivin initiator AUG, we inserted nucleotides in two different positions between both AUGs (In-Frame reporter constructs), which also increased reporter activity. Moreover, immunodetection of Renilla (35 kDa) by Western blot revealed the presence of a second band (38 kDa approximately) in cells transfected with these In-frame reporter constructs, indicating that the uAUG was actually functional in all cell lines tested. In conclusion, our experimental data demonstrate the presence of an alternative and inhibitory initiator uAUG in the Survivin 5' UTR. This inhibitory uAUG could help to understand how Survivin expression is downregulated under stress conditions. Funding: This work was supported by the grants Fondecyt 11711715 and CIP16020 (MAVV).

Engineering Combinatorial and Dynamic Decoders Using Synthetic Immediate-early Genes.

P. Ravindran[1], M. Wilson[2,1], S. Jena[1], J. Toettcher[1]; [1]Princeton University, Princeton, NJ, [2]University of California- Santa Barbara, Santa Barbara, CA.

Mammalian cells use signaling pathways to process information about the outside world, and then decode pathway activity into downstream gene expression. Some hallmarks of this decoding process are dynamic control, where only certain time-varying signals trigger a response, and combinatorial control, where two signals are interpreted together through a logic gate. While these hallmarks are known, their application to the process of gene expression remains unclear. One hypothesis for how cells apply these principles stems from a common design principle of gene expression, which is regulation throughout

multiple steps of the central dogma. In addition to transcriptional activation, signaling pathways can modulate mRNA stability, protein translation, or protein stability. However, the signal-processing properties of this multi-step regulation are still poorly understood. Here, we have developed a flexible platform to produce synthetic immediate-early genes (synIEGs) that contain user-defined transcriptional and post-transcriptional regulation, as well as live-cell biosensors throughout the central dogma. First we found that synIEGs can be randomly integrated into the genome and transcribe on the same timescale as endogenous immediate-early genes, suggesting that, for this class of genes, the specific location in which we integrate the genes may not matter. We next demonstrate the utility of this approach to study the signaling pathway to gene expression interface by engineering synIEGs that implement dynamic or combinatorial control in mammalian cells. Our synIEGs demonstrate that regulation at multiple nodes through the central dogma, along with the modular plasticity of mRNA/protein domains, can be used to decode both dynamic and combinatorial information. We believe that, in the future, this approach will allow us to better understand how genes interpret signaling pathway activity as well as engineer genes that respond to user-defined inputs.

Meiotic Production of N-terminally Truncated Proteins in *S. Cerevisiae*.

A. L. Higdon, A. R. Eisenberg, I. Hollerer, G. A. Brar; University of California Berkeley, Berkeley, CA.

Budding yeast meiosis is an intricate developmental program that requires highly dynamic and coordinated gene expression regulation. We used start-site ribosome profiling to identify translation start-sites genome-wide across meiosis, providing a view of translation across a unperturbed developmental process. These data are particularly useful for identifying ORFs originating from within canonical full-length proteins, including those that initiate from downstream start sites that are in-frame with the canonical proteins and end at the same stop codon (N-terminal truncations). We have identified hundreds of cases of these truncated proteins, many of which are dynamically regulated across meiosis. In addition, we have begun molecular characterization of examples of truncated proteins to determine functional relevance during both meiosis and vegetative growth. Our work points towards potential functional roles for previously uncharacterized truncated proteins and suggests a greater diversity of gene products produced even within compact genomes.

P1244/B372

Tumor Regulator PICT1 Interacts with MTR4/exosome and Is Involved in the Pre-rRNA Processing.

S. Miyao[1], K. Saito[1], R. Oshima[1], Y. Kanbayashi[1], K. Kawahara[2], **M. Nagahama**[1]; [1]Meiji Pharmaceutical University, Tokyo, JAPAN, [2]Kagoshima University, Kagoshima, JAPAN.

RNA exosome is a 3’-5’ exonuclease complex, which is involved in processing and degradation of a wide variety of nuclear RNAs by collaborating with an RNA helicase MTR4. During ribosome biogenesis, MTR4/exosome plays critical roles in the processing of pre-RNAs. In *Saccharomyces cerevisiae*, Nop53 has been identified as an adaptor that recruits Mtr4 to the 3’-processing site of 5.8S rRNA. Intriguingly, PICT1, a putative mammalian ortholog of Nop53, has been characterized as a nucleolar localized tumor-regulating protein, which controls cell proliferation through MDM2-p53 axis. To examine a possible role of PICT1 in the connection between ribosome biogenesis and cell proliferation process, we explored the function of human PICT1 in the pre-rRNA processing during ribosome biogenesis. Physical interaction between PICT1 and MTR4/exosome was confirmed by co-immunoprecipitation, which depends on the

integrity of conserved arch interacting motif (AIM) in PICT1. Knockdown of PICT1 led to a defect in pre-rRNA cleavage as shown by accumulation of the 32S processing intermediate. On the contrary, overexpression of AIM-defective mutants of PICT1 led to an accumulation of 12S processing intermediate, showing inhibition of MTR4/exosome-mediated processing step of 12S rRNA. These results suggest that PICT1 functions at the two distinct steps during pre-rRNA processing. Furthermore, knockdown of either PICT1 or MTR4 led to upregulation of p53 in cells, although knockdown of DIS3 or RRP6, catalytic subunits of the nuclear exosome, did not affect the p53 levels. Thus, these results suggest that interaction between MTR4 and PICT1, but not 12S pre-rRNA processing, might be important for transmitting the nucleolar stress to the p53 regulation.

Autoregulation of Hoxa1 during Mouse Es Cell Differentiation.

U. Emelogu, 70180, E. Martinez-Ceballos; Southern University and A&M College, Baton Rouge, LA.

Autoregulation of Hoxa1 during Mouse ES Cell Differentiation Emelogu Ugochi and Eduardo Martinez-Ceballos, Southern University and a & M College Baton Rouge, LA Hoxa1, a member of the homeobox (Hox) family of transcription factors, is an important regulator of embryonic patterning and organogenesis. Inactivation of both alleles of the *Hoxa1* gene in mice results in numerous developmental defects, including hindbrain deficiencies and abnormal skull ossification, and ultimately, in neonatal death. In humans, mutations in the *HOXA1* gene have been described in association with various CNS disorders. However, in spite of the recognized importance of Hoxa1 during vertebrate development, little is known about its molecular mechanism of action in cells and tissues. The goal of this work is to shed light on the molecular mechanisms of Hoxa1 transcriptional gene regulation and function. By performing preliminary ChIP-on-chip analyses, we have identified a putative Hoxa1 binding site in the *Hoxa1* coding region. As overexpression of Hoxa1 in mouse ES cells was found to inversely correlate with the endogenous expression of *Hoxa1*, we hypothesize that the Hoxa1 protein can repress its own gene expression by directly binding to the *Hoxa1* coding region. Preliminary in vitro DNA binding/EMSA assays using biotinylated DNA probes, that correspond to different regions of the *Hoxa1* coding region, resulted in bound DNA observed when nuclear extracts from Retinoic Acid-treated J1 ES cells were used but not with extracts from untreated J1 ES cells. This band was not observed when 200-fold excess unlabeled DNA (specific competitor) was added. All together, our studies identified a putative Hoxa1 binding site in the *Hoxa1* coding region, which suggests the presence of a novel autoregulatory mechanism for this transcription factor. The results from this project will lead to the elucidation of the specific roles played by Hoxa1 on the differentiation of ES cells, which will represent a significant contribution to the area of stem cell biology.

P1246/B374

Brct Domains Contain an Intrinsic Post-translational Modification (ptm) Recognition Code That Affects It Stability.

J. Davis; Meharry Medical College, Nashville, TN.

BRCA1 C-terminal (BRCT) domains are protein binding modules that relay signals throughout various cellular pathways. The human genome encodes 23 BRCT-domain containing proteins that are commonly found in tandem and have been characterized as phosphoprotein binding domains with functions throughout the DNA damage response. Emerging evidence suggests these domains bind other post-

translationally modified (PTM) substrates although the details are not defined. Recently, the BRCT domains from BRCA1 were shown to bind an asymmetrically dimethylated arginine (ADMA) p300 substrate to regulate the transcription of the p21 in response to DNA damage. Based on this observation, we hypothesize that the methyl-specific binding site for the ADMA interaction is distinct from the phospho-substrate recognition interface. To test this hypothesis, we conducted peptide binding and thermal stability experiments to demonstrate the change in stability upon binding phospho- versus methylated substrates. Our results show that phosphorylated substrates increase the stability of BRCA1's BRCT domains. Doubly phosphorylated substrates showed the greatest increase in stability while the methylated substrate demonstrated a decrease in stability. To define the BRCT-ADMA binding interface, we set out to determine the three-dimensional structure. High-throughput co-crystallization of the BRCA1 BRCT protein with a ADMA peptide derived from the p300 substrate identified one condition for crystal growth optimization. In silico modeling of the BRCA1 BRCT structure with the ADMA molecule has highlighted two potential binding sites for the ADMA substrate, which is not conserved throughout the BRCT domain family. Our results indicate that while BRCT domains share a conserved mode of binding phosphorylated substrates, which increases their stability, and their ability to binding methylated substrates may not be conserved. These finding will be critical in understanding how BRCT domains can accommodate binding various modified substrates and regulating signals throughout the DNA damage response.

Characterizing Alternative Splicing Dynamics of Calcium Channel $Ca_v1.3$.

S. Sabzanov, J. Mirkovic, M. F. Hossain, R. Wang, M. Ruggiu; St. John's University, Jamaica, NY.

L-type voltage-gated calcium channel $Ca_v1.3$ contains a pore-forming 1αsubunit that is encoded by *CACNA1D*, a gene which has been shown to undergo alternative splicing. Mutations in *CACNA1D* have been associated with neurological diseases such as spontaneous seizure disorder and epilepsy. Previous studies have shown that alternative splicing of the C-terminus of $Ca_v1.3$ results in a truncated variant of exon 42 (E42) that, when compared to the full-length exon, lowers the voltage threshold needed to activate the calcium channel. A lower voltage threshold of calcium channels increases neural excitability and therefore has many clinical implications. Previous studies have also linked the alternatively spliced N-terminus of $Ca_v1.3$ to autism spectrum disorder. In a human patient study, a naturally occurring missense mutation in both mutually exclusive exons 8a and 8b has been correlated with autism spectrum disorder. These results highlight the important role that alternative splicing plays in $Ca_v1.3$ function. We were able to confirm four alternatively spliced regions, E8-E11, E12-E15, E32-36, and E46-E48 in *Cacna1D*. By semi-quantitative RT-PCR analysis, we found that these alternatively spliced variants are expressed at higher levels in brain-derived tissues when compared to non-brain derived tissues. We were also able to construct minigenes of E9-E10, E13-14, E33-E34, E35, and E47 to investigate the regulatory mechanisms of alternative splicing of *Cacna1D*. While alternative splicing of $Ca_v1.3$ has been shown to play important roles in electrophysiological properties and neurological disorders, the dynamics of alternative splicing of $Ca_v1.3$ remain poorly understood. Our results serve to characterize the alternative splicing dynamics in *Cacna1D* for future studies aimed at determining whether or not certain splice isoforms can lead to changes in the channel's electrophysiological properties.

P1248/B376

Stop Codon Context Influences Quality Control of Truncated Proteins.

R. Fu, **D. Kolakada**, J. Hesselberth, S. Jagannathan; University of Colorado an schutz Medical Campus, Aurora, CO.

Cells protect themselves from the deleterious effects of truncated protein products via multiple quality control pathways. Nonsense-mediated mRNA decay (NMD) is one such mechanism that degrades mRNAs containing premature termination codons in order to prevent aberrant protein production. While much is known about NMD, mechanisms that confer variability in NMD efficiency, and how cells handle truncated proteins produced in such scenarios, are poorly understood. Here, we utilize human genetic data and cell-based reporter assays to investigate whether the sequence context of a premature stop codon influences the fate of the truncated protein product. Sequence analysis of nonsense variants found in the healthy human population (gnomAD database) shows a high degree of enrichment for glycine codons at the -1 position of the premature stop codon, suggesting that it is a more permissive context for nonsense mutations through the course of evolution. Consistent with a recent report of C-terminal glycine acting as a degron, reporter assays show that Gly|PTC dicodon context induces down-regulation of the truncated proteins, but only in the context of premature translation termination. Moreover, the identity of the -1 codon and the premature termination codon together influence the level of the premature protein product. Based on these results, we conclude that the concerted action of protein and RNA quality control acts as a failsafe mechanism to limit truncated protein products in a sequence-dependent manner.

Nuclear Pore Complexes

P1249/B378

Disassembly and Reassembly of the Nuclear Pore Complex in C9orf72 Als/ftd.

A. Coyne[1], B. Zaepfel[1], L. Hayes[1], B. Fitchman[2], Y. Zalthberg[2], K. Bowen[1], H. Trost[3], A. Harel[2], C. Svendsen[3], D. Sareen[4], J. Rothstein[1]; [1]Johns Hopkins University, Baltimore, MD, [2]Bar-Ilan University, Safed, ISRAEL, [3]Cedars Sinai Medical Center, Los an geles, CA, [4]Cedars Sinai Medial Center, Los an geles, CA.

Nucleocytoplasmic transport, controlled by the nuclear pore complex, has recently emerged as a pathomechanism underlying neurodegenerative diseases including C9orf72 ALS/FTD. However, little is known about the underlying molecular events. Using super resolution structured illumination microscopy of twenty three nucleoporins in nuclei from C9orf72 iPSC derived neurons and postmortem human motor cortex we identify a unique subset of eight nucleoporins lost from the neuronal nuclear pore complex. POM121, an integral scaffolding nucleoporin, appears to coordinate the disassembly and reassembly of the nuclear pore complex in human neurons impacting nucleocytoplasmic transport, and subsequent cellular toxicity in C9orf72 iPSNs. These data suggest that POM121 is an integral nucleoporin in the maintenance of the nuclear pore in human neurons and loss of POM121 from the nuclear pore complex, as a result of expanded C9orf72 ALS/FTD repeat RNA, initiates a pathological cascade affecting nuclear pore complex integrity, function, and overall neuronal survival.

P1250/B379

Nuclear Pore Complexes Assemble from Nucleoporin Condensates during Drosophila Oogenesis.

B. Hampoelz, A. Schwarz, P. Ronchi, M. Beck; EMBL, Heidelberg, GERMANY.

Nuclear Pore Complexes (NPC) span the nuclear envelope (NE) and allow transport between the cytoplasm and the nucleus. In gametes and early embryos NPCs are also abundant at the ER in specialized compartments termed an nulate Lamellae (AL). While two mechanisms have been conceptualized to explain how NPCs insert to the NE during mitosis and interphase respectively it is unknown how NPCs assemble in the absence of the nucleus as spatial cue. We address this question in vivo during oogenesis in *Drosophila* and suggest a third, non-canonical NPC assembly pathway. We show that in the germline Nucleoporins (Nups) form granules that display hallmarks of phase separated biocondensates. They are NPC precursors that interact to exchange Nucleoporin material for NPC biogenesis along the ER. Different from canonical NPC assembly, the Nucleoporin Nup358 appears key for this process: Regulated by the small GTPase Ran and the nuclear transport receptor Crm1 it condenses into NPC assembly platforms that in turn control pore biogenesis in a Ran and Microtubule dependent manner. We show that Nup358 condensation is necessary for NPC assembly that cannot proceed from the soluble Nucleoporin. We delineate a third previously uncharacterized NPC assembly pathway that operates from Nucleoporin condensates away from the nucleus and under conditions of cell cycle arrest.

P1251/B380

TorsinA and Neuronal Nuclear Pore Complex Biogenesis.

S. Kim[1], S. S. Pappas[2], S. J. Barmada[1], W. T. Dauer[2]; [1]University of Michigan, an n Arbor, MI, [2]UT Southwestern, Dallas, TX.

TorsinA is a AAA+ protein localized to the endoplasmic reticular (ER)/nuclear envelope (NE) endomembrane space. A loss-of-function mutation in the gene encoding torsinA causes DYT1 dystonia, a neurodevelopmental movement disorder. Yet, the biological function of torsinA remains largely unknown and the molecular defects underlying DYT1 dystonia remain poorly understood. In mouse primary neurons, we find a dramatic upregulation in nuclear pore complex (NPC) biogenesis during neuronal maturation. In contrast to wild-type neurons, torsinA-null neurons develop increasingly mislocalized clusters of NPCs. These clusters appear to represent halted intermediate states of NPC assembly, as they contain early- but not late-recruited NPC components. Consistent with this notion, torsinA-null neurons exhibit defects in NPC-mediated nucleocytoplasmic transport. Interestingly, NPC density is unaffected in torsinA-null neurons, suggesting that torsinA helps maintain NPC localization and assembly, but not number. Similar to prior findings in *vivo*, primary cultures of torsinA-null neurons develop evaginations of the inner nuclear membrane (NE buds). The emergence of NE buds coincides with the formation of mislocalized NPC clusters, implicating an association between these events. Considered together, our findings suggest that torsinA plays previously unidentified roles in the localization and assembly of new NPCs during a key period of neuronal development, implicating aberrant NPC biogenesis in the pathogenesis of DYT1 dystonia.

P1252/B381

Oligodendrocyte Nuclear Pore Biology in Health and Disease.

J. C. Glatzer, A. N. Coyne, D. E. Bergles, J. D. Rothstein; Johns Hopkins University School of Medicine, Baltimore, MD.

Laminopathies are a rare but devastating group of genetic disorders resulting in part from mutations in genes encoding lamin proteins. Lamins are intermediate filament proteins lining the inner nuclear membrane that facilitate structural integrity, genome organization, and arrangement of nuclear pore complexes (NPCs). Mammalian B-type lamins are ubiquitously distributed in the body, and a tandem gene duplication in *LMNB1*results in autosomal dominant leukodystrophy with autonomic disease (ADLD). ADLD is a fatal, degenerative demyelinating disease, with symmetrical demyelination beginning in the 4thor 5thdecade of life. While it appears that oligodendrocytes are particularly sensitive to increased *LMNB1* dosage, the nature of this vulnerability, and the effect of the mutation on oligodendrocyte progenitor cells (OPCs) have not been elucidated. This work aims to define how LMNBI changes the nuclear biology of oligodendrocyte lineage cells over the course of their differentiation, and examine how these cells are affected in the context of ADLD. Preliminary evidence from our lab and others shows that oligodendrocytes undergo dramatic changes in nuclear architecture (including arrangement of nuclear pore complexes, NPCs) and heterochromatin distribution over the course of differentiation. We have determined that mature oligodendrocytes have significantly reduced nuclear occupancy of multiple components of the NPC in comparison to neurons and astrocytes, suggesting that oligodendrocytes might be especially sensitive to perturbations in the ratio of these or other nuclear proteins. Additionally, we observe differences in expression of laminB1 at the protein level between gray and white matter oligodendrocytes in wild-type mice, with reduced immunoreactivity of laminB1 specifically in white matter oligodendrocytes. To define nuclear pore alterations in oligodendrocytes, we generated *LaminB1^{BAC}; MOBP-eGFP* mice in which laminB1 is over-expressed and all oligodendrocytes are fluorescent. Consistent with the late adult-onset nature of the disorder, we do not observe pathological signs in *vivo* or nuclear abnormalities in oligodendrocyte nuclei isolated from the brains of 2 month-old mice. Aging studies of these mice are currently in progress. To better mimic the human disorder, we describe a strategy to generate a new mouse model of ADLD using a dual-gRNA system for CRISPR-Cas9, a strategy which has been previously used to generate large structural variations in the genome. Together, these experiments add to the expanding biology of nuclear proteins in cell and tissue-specific disorders, and shed light on disease-relevant pathways in ADLD.

P1253/B382

Nuclear Envelope Dynamics in Torsin-deficient Cells in Relation to Nuclear Pore Biogenesis.

A. J. Rampello[1], E. Laudermilch[1], L. Shao[2], N. Vishnoi[3], S. Prophet[1], P. Lusk[3], C. Schlieker[1]; [1]Department of Molecular Biophysics and Biochemistry, Yale University, New Haven, CT, [2]Department of Neuroscience, Yale School of Medicine, New Haven, CT, [3]Department of Cell Biology, Yale School of Medicine, New Haven, CT.

Torsin ATPases are widely conserved, essential AAA+ ATPases residing in the nuclear envelope (NE) and endoplasmic reticulum. The molecular function(s) of Torsins remain largely elusive. A shared phenotypic hallmark observed upon Torsin manipulation in metazoan organisms and numerous tissue culture models is the presence of omega-shaped herniations in the NE. Both the molecular composition and the dynamics of these herniations are largely unknown. We identified FG-nucleoporins at the base of the

omega-shaped herniations (also known as “blebs”), which has a diameter comparable to that of the nuclear pore complex (NPC). NUP358, an NPC component that is added late during NPC assembly, is underrepresented at these sites. A comparative proteomics approach revealed myeloid leukemia factor 2 (MLF2) as an overrepresented constituent of NE fractions from Torsin-deficient cells relative to those of wild type cells. MLF2 specifically localizes to the bleb lumen, while model substrates of canonical nuclear transport (NLS-GFP/NES-GFP) appear to be excluded. Engineered variants of MLF2 can now be utilized as molecular probes to study bleb formation in a variety of experimental settings. MLF2-GFP, for example, represents the first bleb-specific live cell imaging marker, revealing unanticipated, cell cycle-dependent dynamics via lattice light sheet microscopy. Blebs resolve during mitosis, and reform rapidly and synchronously within a short period after NE reformation. Based on the observed kinetics of bleb formation, and their strict dependence on Pom121-an NPC component previously implicated in interphase NPC biogenesis- we suggest a role for Torsins during NPC assembly.

P1254/B383

Role of Retinoblastoma on Nup98-associated Leukemia.

M. Vaz, B. Fahrenkrog; Université Libre de Bruxelles, Gosselies, BELGIUM.

NUP98-associated leukemia is rare but recurring and characterized by high aggressiveness and poor treatment outcome. NUP98 chromosomal translocations are characterized by overexpression of HOXA clustered genes. HOXA gene over-expression, often in association with the HOX-binding partner MEIS1, contributes to the leukemogenic process, namely, to failed differentiation and accumulation of myeloid blasts. The nuclear envelope (NE) phenotype of NUP98-associated leukemia is correlated with nuclear lobulations and alterations in the nuclear lamina and the lamina associated protein 2 α (LAP2α). LAP2α is an important regulator of the tumor suppressor **retinoblastoma protein** (pRb), which is a known regulator of epigenetic modifications associated with HOXA gene transcriptional status. The aim of this research project is to study the impact of pRb on NE phenotype of NUP98-associated leukemia, additionally the **epigenetic landscape** that regulates HOXA gene expression associated to NUP98 fusion proteins. The NE-associated proteins, as lamin A, lamin B and LAP2α were studied by confocal laser scanning microscopy and electron microscopy in HeLa cells, mouse bone marrow cells expressing NUP98 fusion proteins and in leukemic blasts derived from patients. The NE components were analyzed upon depletion of retinoblastoma. To address the epigenetic modifications, silence and active histone markers were evaluated by quantitative analysis providing an overview of specific histone patterns. We observed that NUP98 fusion proteins induced aberrant NE phenotype and the alterations in NE morphology are dependent on pRb. Co-localization coefficients analysis between NUP98 chimeras and distinct histones marks suggests that NUP98 chimeras colocalize with specific active and repressive sites, trimethylation of lysine 4 on histone H3 (H3K4me2) and trimethylation of lysine 27 on histone H3 (H3K27me3), respectively. Leukemogenic NUP98-fusions cause diverse perturbations in NE organization which are dependent on pRb pathway. Our results unveil a novel role for pRb in AML and may suggest a potential role in NUP98-related leukemia. Furthermore, our data reveal that specific epigenetic modifications co-localize with NUP98 fusion protein, promoting active and repressive transcription. We could focus now on a properly targeted specific locus, HOXA9, deployed a dead RNA-guided nuclease Cas9 to the engineered peroxidase APEX2 and delineate the complex molecular mechanism associated to pRb.

P1255/B384

Basket Nucleoporin Tpr Is an Integral Component of Transcription and Export 2 (TREX2) RNA Export Pathway.

V. Aksenova[1], H. Lee[1], A. Smith[1], S. Chen[1], P. Bhat[2], J. Iben[1], C. Echeverria[1], A. Daniels[1], B. Fontoura[2], A. Arnaoutov[1], M. Dasso[1]; [1]National Institute of Child Health and Human Development, NIH, Bethesda, MD, [2]University of Texas Southwestern Medical Center, Dallas, TX.

Exchange of molecules between the cytoplasm and the nucleus occurs through conduits called nuclear pore complexes (NPCs). NPCs consist of roughly 30 distinct proteins (nucleoporins), forming a central channel with filaments extending into the nucleus and cytoplasm. Basket nucleoporins (Nup153, Tpr, and Nup50) localize to nucleoplasmic filaments and regulate many processes including nucleocytoplasmic trafficking, protein modification, chromatin remodeling and transcription, as well as mRNA processing and export. Moreover, the nuclear basket works as a docking platform for other proteins, including transport receptors and subunits of the TRanscription and EXport 2 (TREX-2) complex. Despite numerous studies, the structural organization of basket nucleoporins within the basket and their interaction with transcription and export machinery is still controversial. In addition, understanding the basket nucleoporins roles in vertebrate cells is complicated because their depletion by RNAi requires an extended incubation, during which all processes may be increasingly disrupted, resulting in highly pleiotropic phenotypes, many of which are secondary consequences of nucleoporin loss. To distinguish the individual functions of nucleoporins, we used CRISPR/Cas9 to biallelically insert auxin-inducible degrons (AID) tags into nucleoporin genes. Auxin addition caused complete degradation of the targeted nucleoporins within an hour; the loss of either Nup153 or Tpr caused growth arrest and eventual cell death within next 24 hours. Acute basket nucleoporin depletion did not destabilize other domains of the nuclear pore, nor did it cause nuclear envelope deformation. The degradation of any individual basket nucleoporin did not disperse either of the other two from assembled nuclear pores, except for Nup50 dispersion after Nup153 depletion. Given the minimal structural perturbations that we observed in the absence of these nucleoporins, we tested whether their loss causes defects in RNA abundance and localization. We found that loss of individual nucleoporins caused dramatically different impacts on transcriptome. Importantly, Tpr elimination caused rapid and profound changes in transcriptomic profiles within two hours of auxin addition with the retention of RNAs within the nucleus. These changes were dissimilar to shifts observed after loss of Nup153 or Nup50, but closely related to changes after depletion of transport factor NXF1 or the GANP subunit of the TRanscription-EXport-2 (TREX-2) mRNA export complex. Moreover, the NPC association of GANP was specifically disrupted upon Tpr loss. Together, our findings indicate a singular and pivotal role of Tpr in regulating gene expression through TREX-2-dependent mRNA export.

P1256/B385

Nup98-dependent Transcriptional Memory Is Established Independently of Transcription.

P. Pascual-Garcia, **S. C. Little**, M. Capelson; University of Pennsylvania, Philadelphia, PA.

Nuclear genome architecture is achieved in part through interactions between individual chromosomal regions and nuclear scaffolds. One such nuclear scaffold is the nuclear pore complex (NPC), which is embedded in the nuclear envelope, and consists of approximately 30 different subunits, called nucleoporins (Nups). In addition to its nuclear transport function, Nups can interact with underlying chromatin, specifically at regulatory DNA elements, including promoters and enhancers. Strikingly, we

discovered that the NPC component Nup98 facilitates the looping contacts between promoters and enhancers, revealing Nups as a new class of architectural proteins that organize the 3D architecture of the genome and influence gene regulation. Consistent with this idea, we characterized the role of Nups in developmental transcriptional memory, in which ecdysone hormone-induced genes are activated more robustly in cells that have previously experienced the presence of the hormone. Interestingly, loss of Nup98 does not affect transcription during initial induction, but results in slower activation during re-induction, demonstrating a loss of transcriptional memory. Using single-molecule RNA FISH to measure activation dynamics of ecdysone-induced genes and mathematical modeling we found that the stablishment of transcriptional memory is independent of active transcription during initial induction but instead, relies on the length of time between hormone treatments.

P1257/B386

In *Cellulo* Structure of the Nuclear Pore Complex and Its Implications in Mrna Export and Nuclear Pore Turnover by Autophagy.

M. Allegretti[1], C. E. Zimmerli[1], V. Rantos[2], P. Ronchi[1], F. Wilfling[3], K. H. Fung[1], C. Lee[3], Y. Schwab[1], J. Mahamid[1], B. Pfander[3], J. Kosinski[2], M. Beck[1]; [1]EMBL Heidelberg, Heidelberg, GERMANY, [2]EMBL Hamburg, Hamburg, GERMANY, [3]Max Planck Institute of Biochemistry, Munich, GERMANY.

The nuclear pore complex (NPC) is an essential membrane protein complex in eukaryotes shaping a hole in the nuclear envelope. Due to its dimensions (~100 MDa in *H. sapiens*) the elected method to determine the structure of the intact complex scaffold has been cryo electron tomography and subtomogram averaging (vonAppen, 2016) in combination with crystal structures from purified components (Lin, 2019). In addition, efforts to investigate the full NPC structure extracting it from its double membrane context have produced two structures in *S. cerevisiae* (Yang, 1988; Kim, 2018). In our study we perform extensive cryo-FIB-milling coupled to cryo-electron tomography and subtomogram averaging to get structures of the entire NPC scaffold in exponentially-growing cells with and without protein knock-outs. The new structures not only largely overcomes in resolution previously determined structures with the same method (Mahamid, 2016; Mosalaganti, 2018), but also shows significant differences in sub-complexes architecture to previous in *vitro* work (Kim, 2018), emphasizing the importance of determining structures of membrane proteins in their native membrane context. We combine the in *cellulo* structures with integrative modeling and crosslinks analysis: Y-complexes show a very extended conformation in comparison to previous studies and we propose a new model that takes into account our in *cell* conformation. In addition, the main mRNA export platform architecture reveals a new configuration that accommodates spatially and temporally the existent biochemical data with the release of transport factors occurring in the cytoplasm. Shifting a Nup116 knock-out strain to not-permissive temperature, we activate the formation of *herniae* (Wente, 1993), protrusions of the outer and inner nuclear membrane forming evaginations conserved in human cells and linked to Dystonia (Laudermilch, 2016). Milling this knock-out strain let us discover that at the basis of the *herniae* there is a partially assembled NPC, solving an outstanding conundrum in literature. The new mRNA export architecture discloses also the cytoplasmic exposure of an NPC-intrinsic autophagic receptor (Lee et al, submitted). We validate the NPC-Atg interaction obtaining high-resolution snapshots using correlative light and electron microscopy on plastic sections (Kukulski, 2011), conventional electron microscopy and 3D-cryo CLEM (Arnold, 2016) demonstrating that NPC degradation occurs through complex membrane remodeling events at the nuclear envelope and passes through an autophagosome intermediate owning

NPC-containing nuclear vesicles in the cytoplasm. Our results highlight the power of in *cell* structural biology to provide novel insights into two fundamental processes of eukaryotic life.

P1258/B387

Characterizing Nuclear Pore Complex Heterogeneity Using Quantitative Super-resolution Microscopy.

J. M. Varberg[1], A. N. Bestul[1], A. A. Kahn[1], Z. Yu[1], B. D. Slaughter[1], J. R. Unruh[1], S. L. Jaspersen[1,2]; [1]Stowers Institute for Medical Research, Kansas City, MO, [2]The University of Kansas Medical Center, Kansas City, KS.

Nuclear pore complexes (NPCs) span the inner and outer nuclear membranes and facilitate the transport of macromolecules across the nuclear envelope. NPCs also have transport independent functions, including regulating gene expression and chromatin organization, influencing nuclear envelope integrity and remodeling, and acting as signaling hubs at the nuclear periphery for proteins and complexes involved in DNA repair and protein homeostasis. While the NPC structure is largely conserved throughout eukaryotes, recent studies have found that NPC number, distribution and composition varies across cell types and can change dramatically in multiple disease states and throughout development. Despite these findings, the mechanisms used to regulate and alter NPC number and composition, as well as the functional consequences of NPC heterogeneity remain unclear. To address these questions, we developed quantitative microscopy and image analysis tools to determine NPC number, distribution and composition in the fission yeast *Schizosaccharomyces pombe*. First, we used three-dimensional structured illumination microscopy (3D-SIM) to provide the first quantitative description of NPC number and distribution in *S. pombe*. Additionally, by combining 3D-SIM with single-particle averaging we identified a region of the nuclear envelope near the spindle pole bodies that contains NPCs lacking a specific subset of NPC components. We are currently investigating how this pool of specialized NPCs is established and maintained, and whether the heterogenous NPC composition in this region is required for nuclear envelop remodeling events that occur during spindle pole body insertion.

P1259/B388

Elys and Nup153 an chor the Nuclear Pore Complex to Nuclear Lamins.

M. Kittisopikul[1,2], T. Shimi[1,3], M. Tatli[4], Y. Zheng[5], O. Medalia[4,6], K. Jaqaman[2], R. D. Goldman[1]; [1]Northwestern University, Chicago, IL, [2]UT Southwestern Medical Center, Dallas, TX, [3]Tokyo Institute of Technology, Yokohama, JAPAN, [4]University of Zurich, Zurich, SWITZERLAND, [5]Carnegie Institution for Science, Balitmore, MD, [6]Ben Gurion University of the Negev, Beer-Sheva, ISRAEL.

The nucleoporins Elys and Nup153 are localized on the nucleoplasm side of the nuclear pore complex (NPC) where they contribute to the structure of the nucleoplasmic ring and basket of the NPC and may thus interact with the nuclear lamina (NL). The NL contains type-V intermediate filament proteins that assemble into isoform specific fibrous meshworks. We probe how the lamin meshworks influence the distribution of NPCs using 3D structured illumination microscopy (3D-SIM) with sub-pixel computational image analysis. We quantitatively describe how the distribution of NPCs is defined by the lamin meshwork fibers in wild-type mouse embryonic fibroblasts (MEFs), lamin isoform knockouts, and nucleoporin knockdowns. For each case, we determine the distance between NPCs and the lamin fibers by using adaptive resolution multi-orientation image analysis to localize the center of each structure on a subpixel basis with 10 nm precision. The results demonstrate that the centers of a majority of NPCs lie between 60 and 100 nm from lamin A, B1, and B2 fibers, a distance slightly greater than the NPC radius.

This analysis reveals that NPCs are laterally associated with lamins A, B1, and B2. In contrast, this spatial relationship is not detected for LC fibers. Relative to LC fibers, NPCs appear to be randomly positioned according to a uniform distribution. Taking advantage of the enlarged meshworks of lamin fibers in lamin A/C (LA/C) and B1 (LB1) knockouts, we show that NPCs follow the lamin fibers forming the perimeter of lamin depleted holes in LB1 and LA meshworks, respectively. When Nup153 and Elys are knocked down, NPCs are shifted away from lamin fibers comprising the sparse meshworks in lamin knockouts and fill gaps created in dense wild-type lamin meshworks. These results suggest that LA, LB1, and B2 act through specific nucleoporins to regulate the normal distribution of NPCs. Cryo-EM tomography combined with immunogold labeling reveals that there are direct physical interactions between lamin fibers and the nucleoplasmic ring of the NPC. Our quantitative approach combining 3D-SIM, cryo-electron tomography and computational image analysis sheds light on how lamins and nucleoporins interact and how the NL is organized. These interactions are pre-requisite to understanding a wide range of diseases, including the laminopathies caused by mutations in lamin A. Supported by NIH grants RO1GM106023,T32CA080621, and R35GM119619.

P1260/B389

Examining the Modular Architecture of the Nuclear Pore Complex through Targeted Degradation.

S. Regmi, R. Kaufhold, V. Aksenova, S. Chen, H. Lee, E. Turcotte, A. Arnaoutov, M. Dasso; National Institutes of Health, Bethesda, MD.

The nuclear pore complex (NPC) is a channel through the nuclear envelope that allows macromolecular transport between the cytoplasm and nucleus. Disrupted NPCs and nucleocytoplasmic transport are hallmarks of many neurodegenerative diseases, including Huntington's and amyotrophic lateral sclerosis. NPCs contain roughly 30 proteins called Nups; Nup mutations are found in many tumors, further underscoring the need to better understand both individual Nups and NPC function overall. 32 copies of the vertebrate nonameric Y-complex assemble into rings that gird the inner and outer faces of the NPC. These rings are assumed to act as scaffolds of NPC architecture. To understand the roles of individual Y-complex subunits, we used CRISPR/Cas9 to add Auxin-Induced Degron (AID) tags at the genomic loci encoding Nup160, Nup133, Nup107, Nup96 and Nup85 in human DLD-1 cells. The tagged Nups assemble into functional NPCs and degrade rapidly (<4 hours) after auxin addition. In the resultant cell lines, we assessed how each Nup contributes to NPC structure and function. After Nup160, Nup133 or Nup85 depletion, NPCs retained non-tagged Y-complex members and stayed surprisingly intact and functional for transport. At the same time, post-mitotic NPC assembly was disrupted in their absence, suggesting that they are required for NPC formation but can be removed from intact NPCs without catastrophic consequences. By contrast, Nup96 or Nup107 depletion caused rapid dispersion of non-tagged Y-complex subunits and other Nups, particularly those from the cytoplasmic face of the NPC. Loss of Nup96 or Nup107 was also associated with substantially slower nuclear import. There results indicate that Nup96 and Nup107 are essential for maintenance of Y-complex ring structures and functional NPCs. Interestingly, mass spectrometry of nuclear envelope fractions from cells depleted Nup96 or Nup107 showed that not all Nups are dispersed upon their loss, and that members of the inner ring complex (IRC) were largely retained. To examine the relationship between the Y-complex and these retained Nups, we tagged Nup188, a member of the IRC. Depletion of Nup188 resulted in a pattern that inverse to the patterns generated after Nup96 or Nup107 loss, showing retention of the Y-complex but loss of most IRC components. These findings lead us to propose a model in which the NPC

has a modular architecture with interwoven pieces that can nevertheless stand in relative isolation from each other.

P1261/B390

Proximity Labeling for the Identification of *Plasmodium Berghei* Nucleoporins.

S. V. Ambekar, A. L. Padmanabhan, G. R. Mair; Iowa State University, Ames, IA.

The nuclear pore complex (NPC) is the gatekeeper for nucleocytoplasmic transport in all eukaryotic cells and plays a major role in the regulation of gene expression. Typically made up of 30 different proteins called nucleoporins (NUPs), the NPC forms a basket like structure interacting with, and controlling the transport of molecules in and out of the nucleus. Nucleoporins are widely conserved across eukaryotes but have diverged evolutionarily in the malaria parasite Plasmodium and are therefore difficult to identify. The protein composition of the Plasmodium NPC has remained largely elusive with the exception of five FG-repeat NUPs that likely line the central channel of the NPC. Using in vivo biotin proximity labeling (BioID) of FG-repeat NUPs in combination with mass-spectrometry we are exploring the NPC composition in the rodent malaria model Plasmodium berghei. To this end we are expressing BioID fusion proteins of the five P. berghei FG-repeat NUPs. Extraction and affinity-purification of the biotinylated proteins using a streptavidin column followed by mass spectrometry defined a proteomics data set of putative nuclear pore proteins including transmembrane domain NUPs. Immunofluorescence assays as well as labelling of BioID expressing parasites with streptavidin-fluorophore conjugate confirmed unique, parasite-specific proteins that localize to the nuclear periphery. We are currently exploring various in vivo proximity labeling techniques in the characterization of the Plasmodium NPC.

Cul3 Substrate Adaptor SPOP Regulates the Nuclear Pore Protein NupJ.

J. Y. Ong, J. Z. Torres; UCLA, Los an geles, CA.

Cell processes like growth and division are tightly regulated. One such mechanism of regulation is ubiquitination. Ubiquitination can change a protein's localization or activity, or it can mark the protein for degradation by the ubiquitin proteasome system. The final step of ubiquitination, transferring ubiquitin to the target protein, is mediated by E3 ligases and their substrate adaptors, proteins that allow E3 ligases to be selective in choosing their targets. Understanding the targets of E3 ligases and substrate adaptors, then, is crucial to understanding cell regulation and disease mechanisms linked to misregulation of protein levels and activity. SPOP is a Cul3 E3 ligase substrate adaptor whose targets, such as c-Myc, PD-L1, and ERG, are crucial for cell cycle progression and cancer proliferation. Through a mass spectrometry screen, we identified SPOP as a potential regulator of NupJ, a nuclear pore protein. Knockdown of SPOP via siRNA in HeLa cells leads to increased protein levels of NupJ via immunoblotting, and SPOP and NupJ both co-localize at the nuclear envelope via immunofluorescence microscopy. Moreover, co-immunoprecipitation assays demonstrate that SPOP and NupJ bind to each other in *vitro*. Similar to overexpression of NupJ, siRNA against SPOP leads to an increase in the number of nuclear envelope defects. Overexpressed NupJ leads to defects in cell division. Our results suggest that SPOP targets NupJ for ubiquitin-mediated proteasomal degradation.

P1263/B392

Mps1 Releases Mad1 from Nuclear Pores to Ensure a Robust Mitotic Checkpoint and Accurate Chromosome Segregation.

S. Cunha-Silva[1,2,3], M. Osswald[1,2,3], J. Goemann[1,2], J. Barbosa[1,2], L. M. Santos[4], P. Resende[1,2], T. Bange[5], C. Ferrás[1,2], C. Sunkel[1,2,3], C. Conde[1,2]; [1]IBMC- Instituto de Biologia Molecular e Celular, Porto, PORTUGAL, [2]i3S - Instituto de Investigação e Inovação em Saúde, Porto, PORTUGAL, [3]Instituto de Ciências Biomédicas Abel Salazar (ICBAS), University of Porto, Porto, PORTUGAL, [4]Faculty of Medicine, University of Geneva, Geneva, SWITZERLAND, [5]Institute for Medical Psychology, Ludwig-Maximilians-Universität-München, Munich, GERMANY.

The Spindle Assembly Checkpoint (SAC) protects eukaryotic cells against chromosome mis-segregation by restraining the transition to anaphase in the presence of unattached kinetochores. This feedback mechanism works as a rheostat in which the signaling strength is defined by the amount of Mad1-Mad2 heterotetramers at kinetochores. During interphase Mad1 and Mad2 are associated with nuclear pore complexes through the nucleoporin Megator/Tpr. This arrangement is proposed to stabilize Mad1 and Mad2 and provide a scaffold for the assembly of pre-mitotic MCC. However, the molecular underpinnings controlling the spatiotemporal redistribution of Mad1-C-Mad2 as cells progress into mitosis remain elusive. Here, we show that Mps1-mediated phosphorylation of Megator/Tpr abolishes its interaction with Mad1 in *vitro* and in *Drosophila* cells. Timely activation of Mps1 during prophase triggers Mad1 release from nuclear pore complexes, which we find to be required for competent kinetochore recruitment of Mad1-C-Mad2 and robust checkpoint response. Importantly, preventing Mad1 binding to Megator/Tpr rescues the fidelity of chromosome segregation and aneuploidy in larval neuroblasts of *Drosophila mps1*-null mutants. Our findings demonstrate that the subcellular localization of Mad1 is stringently coordinated with cell cycle progression by kinetochore-extrinsic activity of Mps1. This ensures that both nuclear pore complexes in interphase and kinetochores in mitosis can generate anaphase inhibitors to efficiently preserve genomic stability.

P1264/B393

3d Genome Conformation in the Proximity of Nuclear Pore Defines HIV-1 Integration.

M. Lusic, 69120; Depatment of infectious diseases, University Clinic Heidelberg, Heidelberg, GERMANY.

Marina Lusic 3D genome conformation in the proximity of NPCs defines lentiviral integration Bojana Lucic[1], Maja Kuzman[2], de Castro IJ[1], Heinze Julia[1], Margiotta Erica[3], Beck Martin[3,4 and] Lusic Marina[1] *1 Heidelberg University Hospital, Heidelberg, 69120, Germany, German Center for Infection Research, Heidelberg, 69120, Germany 2. Bioinformatics Group, Division of Molecular Biology, Department of Biology, Faculty of Science, University of Zagreb, Zagreb, Croatia. 3. Structural and Computational Biology Unit, European Molecular Biology Laboratory, Meyerhofstrasse 1, 69117 Heidelberg, Germany 4. Max Planck Institute of Biophysics, Frankfurt am Main* Integration into the cellular genome is one of the highlights of the lentiviral life cycle. The viral crosses the permeable barrier of the nuclear envelope (NE) and the Pre-integration complex (PIC), containing a reverse-transcribed genome, viral protein capsid (CA) and integrase (IN), docks to and is transported through nuclear pore complexes (NPCs). Our mechanistic understanding of these steps of the HIV life cycle is incomplete, although they are of utmost importance: by becoming an integral part of the host cell genome, the virus in disguise cannot be targeted by current antiviral treatments. Genes which are recurrently targeted by HIV-1, so called RIGs, position in the outer shells of the nucleus, are mostly active genes positioned in the outer shells of the

nucleus but excluded from lamina associated domains (LADs). These genes, as revealed by RNA Seq and ChiP Seq profiles are enriched in H3K27ac, H3K4me1 and BRD4, markers of super enhancers that drive cell-type-specific gene expression and are crucial to cell identity. By exploring the spatial gene positioning in activated CD4+ T cells, we found that genes with super-enhancers reposition towards the outer shells of the nucleus during T cell activation. This occurs during T cell activation, concomitant with the transcriptional upregulation of these genes and proved to be the sole property of genes with super-enhancers, and not of all active genes. Positioning of genes with Super-enhancers towards nuclear periphery prompted us to further explore the possibility that these genes belong to the NPC compartment. While the CHiP seq data using several Nups as anchoring points generated very poor profiles, the BiO ID profiles of gene of interest showed multiple interactions of Nup157 and Tpr (inner nuclear pore) whith proteins informed up.

P1265/B394

Nucleoporins Facilitate Heterochromatic Break Repair Off-pore.

T. Ryu[1], C. See[2], **C. Merigliano**[2], C. Caridi[2], D. Arya[2], I. Chiolo[2]; [1]Harvard Medical School, Cambridge, MA, [2]University of Southern California, Los an geles, CA.

Heterochromatin is comprised of transponsons and large arrays of repetitive satellites prone to aberrant recombination. In *Drosophila*, homologous recombination is used to safely repair heterochromatic double-strand breaks (DSBs), however ‘safe’ completion of this process requires the break site to relocalize to the nuclear periphery before strand invasion and repair. Relocalization is dependent upon a transient actin/myosin network that pulls DSBs to the nuclear pore and inner nuclear membrane proteins (INMPs) where anchoring occurs in a Nup107 complex-dependent manner. We recently discovered an additional nucleoplasmic function of a subset of nucleoporins to facilitate relocalization of repair sites. Nup88, Nup98, and Sec13 are recruited to heterochromatic DSBs before relocalization in a SUMOylation-dependent manner, and are necessary for DSB mobilization (and not for anchoring to the nuclear periphery). However, nucleoplasmic nucleoporins are not necessary for actin filament formation, suggesting an actin-independent pathway for break mobilization. Depletion of these nucleoporins to the nuclear membrane results in heterochromatin repair defects and genomic instability. Together, these data reveal that Nup88, Nup98, and Sec13 function off-pore to promote heterochromatic DSB relocalization downstream from Smc5/6.

P1266/B395

The Role of Controlling Signals and Their Guidance of Werner's Helicase Interacting Protein 1 in Pathways Maintaining Genomic Stability.

B. R. Jordan, J. S. Glavy; University of Texas at Tyler, Tyler, TX.

Werner's Helicase Interacting Protein 1 (WHIP or WRNIP1) has been shown to activate select molecular components of the ATM signaling pathway to maintain genomic stability and prevent instabilities from arising in subsequent cell cycles. In yeast, WHIP’s homologue MGS1 (maintenance of genome stability 1) knockouts exhibit an increased frequency in genetic errors, potentially leading to accelerated aging. Important to WHIP’s function is its localization in the nucleus, specifically at nuclear pore complexes. In our study, we utilize immunoprecipitation, deletion analysis, and immunofluorescence microscopy to demonstrate that WHIP’s localization is controlled by its predicted internal nuclear localization signal (NLS). Despite posttranslational modifications of WHIP, this signal is not controlled by phosphorylation

of neighboring serine threonine residues. As an extension of our investigations, we examined the localization of WHIP during mitosis. Our findings track the location of WHIP, as well as its co-localization with ATM signaling and mitotic components throughout the cell cycle. Thus far, our data suggests the cellular location of WHIP is important in sensing replication stress throughout the cell cycle.

KDM2A-SF: a Demethylase Lacking the Demethylase Domain.

T. Vacik[1], D. Ladinovic[1], O. Raska[1,2], D. Pinkas[1], F. Liska[1], **I. Raska**[1]; [1]Charles University, First Faculty of Medicine, Institute of Biology and Medical Genetics, Prague, CZECH REPUBLIC, [2]Charles University, Third Faculty of Medicine, Department of Pathophysiology, Prague, CZECH REPUBLIC.

The KDM2A histone lysine demethylase is present in mammalian cells as various isoforms. The canonical full-length KDM2A protein demethylates lysines of both histone and non-histone proteins. An alternative KDM2A mRNA isoform originates in *KDM2A* intron 12 and encodes a shorter protein that lacks the N-terminal Jumonji C demethylase domain. This short isoform, KDM2A-SF, contains all the other functional domain such as the CXXC DNA binding domain, PHD zinc finger domain, F-box domain and LRR domain. KDM2A-SF is thus able to bind to DNA, but it is unable demethylate lysines. We performed a detailed characterization of the *KDM2A-SF* mRNA using 5'RACE, northern blot and quantitative real time PCR. Although KDM2A-SF lacks the demethylase domain, it is, similarly to the long KDM2A isoform (KDM2A-LF), also ubiquitously expressed in various healthy and cancer cells. Further, our in *vitro* translation experiments showed that KDM2A-SF is translated from the start codon in the exon corresponding to exon 14 of the *KDM2A* full length mRNA. While we also explored nanotechnologies, immunofluorescence analyses of our KDM2A isoform specific knockdown experiments revealed that, unlike KDM2A-LF, KDM2A-SF forms distinct loci in the nucleus on pericentromeric heterochromatin in an HP1a-dependent manner. However, the functional consequences of this finding remain to be elucidated.

P1268/B397

Nuclear Architecture Modulates Transcriptional Dynamics.

L. Rinaldi, G. Fettweis, S. Fujiwara, D. Garcia Grisales, T. A. Johnson, G. L. Hager; National Cancer Institute, Bethesda Maryland, MD.

To facilitate effective gene regulation, the Human Genome is spatially organized into compartments, topologically associated domains (TADs), and loops. Transcription is governed by multiple Transcription factors (TFs) binding rapidly to genomic elements (enhancers and promoters) to promote gene activation. The coordinated role of compartments, TADs, and loops in transcriptional regulation is poorly understood. We show that real time Transcription Dynamics are altered by 3D nuclear organization. Specifically, ChIP-seq experiments and Single Molecule Tracking (SMT) of TFs in live cells demonstrate how cohesin and nuclear architecture regulate the interaction of Transcription Factors with chromatin in live human cells. To investigate the role of 3D genome structures in TF/chromatin interactions, we used computational methods to predict TAD borders, using CTCF binding data (ChIP-seq) and CTCF motif orientation. Interestingly, hormone-inducible TFs such as the Glucocorticoid Receptor (GR) bind

primarily within a TAD structure. Furthermore, we observed GR (and other TFs) bind principally to one of the TAD borders in an asymmetric manner, suggesting an expected role for TFs in the loop extrusion model. These preferred locations are co-bound by cohesin proteins (SMC1/3). Furthermore, loading of the Cohesin complex is potentiated upon activation of the glucocorticoid receptor, suggesting a possible synergy between GR and structural proteins to activate transcription. To explore the effect of Chromatin Loops on the Dynamics of Transcription Factors: we utilize the degron system (Auxin-RAD21mAID) for the acute depletion of RAD21, a core component of the Cohesin Complex. This produces an acute loss of chromatin loops. After rapid RAD21 depletion, we characterize the mobility of TFs using single molecule tracking (SMT). These factors include a hormone-inducible Transcription Factor, GR, and the architectural nuclear TF YY1, a fundamental interactor of the cohesin complex at enhancers. Acute depletion of RAD21 strongly reduces the binding of YY1 and GR to chromatin. Surprisingly, Chip-seq, ATAC-seq and RNA-seq show that, after RAD21 depletion, loss of TFs binding occurs exclusively at intergenic locations, while promoters are still bound by TFs such as YY1. Furthermore, the active H3K27ac mark is significantly altered after RAD21 depletion, suggesting a profound transition in the chromatin environment after rapid depletion of the cohesin complex. Our data suggest that nuclear structures are intimately involved in the real time interactions of Transcription Factors with chromatin targets.

P1269/B398

Mitogen-activated Protein Kinase P38 Mediates Heat Stress-induced Changes in Nucleolus-associated Chromatin Domains.

A. Vertii, P. D. Kaufman; University of Massachusetts Med Sch, Worcester, MA.

Febrile conditions are evolutionary conserved components of innate immune responses that are beneficial for the survival of the organism. However,unchecked fever causes serious side effects. Stem cells are among the most vulnerable cell types, and damage to such cells can imperil organogenesis. Heat stress causes well-characterized changes in transcription within euchromatin. However, the impact of febrile conditions on heterochromatin organization of differentiated and embryonic stem cells remains elusive. Here, we have tested heat stress for effects on three-dimensional heterochromatin organization in human (IMR90) and mouse (MEFs) fibroblasts and human embryonic stem cells (H1). Specifically, we analyzed the association of Nucleolus-Associated Domains (NADs) with nucleoli via 3D DNA-FISH assays. Our initial observations suggest that distinct classes of NADs display differential sensitivity to heat stress. Specifically, “Type II” NADs that don’t also localize to the nuclear lamina appear more heat sensitive that “Type I” NADs that are frequently lamina-associated. In addition, via pharmacological inhibition, we observed that the activity of stress-activated MAPK p38 is required for NAD relocalization after exposure to elevated temperatures. These data illustrate how signal transduction machinery can reorganize the genome.

P1270/B399

Probing Macromolecular Crowding in the Cell Nucleus.

C. Tan, F. Chang; University of California, San Francisco, San Francisco, CA.

The cell is filled with macromolecular complexes that must navigate through a crowded environment to perform their functions. Though macromolecular crowding is intrinsic to all cells, study of this physical property in the cell nucleus remains overlooked. Here, we are developing the use of genetically-encoded

multimeric nanoparticles (GEMs) (Delarue M et al. Cell [2018]) to probe macromolecular crowding in the nucleus and its effects on cell function using fission yeast. GEMs are spherical protein structures, ranging from 20 to 50 nm in diameter, that are labeled with fluorescent proteins. An alysis of the diffusive-like motion of these particles in the cell provides a measurement of local crowding within subcellular compartments. Further, we have developed methods to perturb macromolecular crowding. For example, we find that the addition of sorbitol, an osmotic agent, effectively promotes cellular crowding and decreases GEMs diffusion in both the cytoplasm and nucleus. In addition, we demonstrate that inhibiting ribosome biogenesis increases GEMs diffusion in both the cytoplasm and the nucleus, indicating that ribosomes may be a major crowding agent for both compartments. Finally, we find that upon inducing DNA damage, GEMs diffusion increases in the nucleus, which may have implications for DNA repair efficiency. In future studies, we hope to identify crowding factors in the nucleus and determine the relationship between crowding and nuclear function.

Crowding within the Nucleus: Torc1 Takes Charge.

T. Szoradi, G. Brittingham, S. Pinglay, L. Holt; NYU Langone School of Medicine, New York, NY.

The properties of the cell interior are crucial for the organization and efficiency of biochemical reactions, but the physical nature of the cytoplasm, nucleus and other organelles remains poorly understood, particularly at the mesoscale (10 nm - 1 μm). One of the key and underappreciated property of the cell interior is the high degree of macromolecular crowding. The diffusive and interactive behavior of molecules are significantly altered in a highly crowded environment, which in turn has a major impact on different biological processes and reactions. Macromolecular crowding is particularly relevant in the nucleus where large fraction of the volume is occupied by chromatin and the nucleolus. To date it remains a mystery how crowding within the nucleus is mechanistically regulated and what are the physiological consequences of perturbations to nuclear crowding. We have recently developed the nuclear-targeted Genetically Encoded Multimeric (GEM) nanoparticles that greatly facilitate the biophysical characterization of the cell. Key biophysical parameters including the degree of macromolecular crowding can be inferred from the motion of these probes. Using nuclear GEMs we show that inhibition of the TORC1 complex by rapamycin treatment decreases crowding within the budding yeast (*Saccharomyces cerevisiae*) nucleus. Genetic analyses revealed that downregulating rDNA transcription, a process that is tightly controlled by TORC1, phenocopies the effect of rapamycin treatment. Furthermore, TORC1 inhibition also decreased the size of the nucleolus, thus increasing the effective volume of the nucleoplasm. Therefore, we propose that TORC1 signaling adjusts molecular crowding within the nucleus by regulating rDNA transcription and/or the size of the nucleolus.

Polyubiquitin Chain-induced Rnf168 Phase Separation Drives Dsdna Damage Repair Compartment.

V. Murugesan, J. Brugues; Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, GERMANY.

DNA damage response involves the formation of transient compartments at the site of the damage that concentrates the necessary signaling factors and repair complexes. For ssDNA repair, this enrichment is driven by the phase separation of FUS nucleated by PAR, but a similar mechanism for dsDNA repair is still unknown. Here we report that RNF168, an E3-ubiquitin ligase that ubiquitinates histones, forms

condensates in *vivo* upon DNA damage in a ubiquitin-dependent manner. These condensates show liquid-like properties as they recover upon photobleaching and are sensitive to hexanediol. Recombinant RNF168 alone does not phase separate but readily demixes upon addition of linear polyubiquitin chains. The phase behavior of these proteins is dependent on the salt conditions and the valency of the polyubiquitin chains used. Further, we show that these RNF168-polyubiquitin droplets are immiscible with FUS droplets providing a mechanism that prevents cross-talk between the ssDNA and dsDNA repair at the site of complex DNA lesions.

Oligomerization as a General Mechanism for Enhancing Liquid-liquid Phase Separation.

G. Carter[1], C. Hsiung[1], L. Simpson[2], X. Zhang[1]; [1]Pennsylvania State University, University Park, PA, [2]The College of Wooster, Wooster, OH.

Liquid-liquid phase separation (LLPS) of proteins has been an attractive field of study in recent years, as it has been shown to be involved in cellular processes such as transcription, stress responses, and metabolite production. Oligomerization has previously been shown in some individual protein systems to be essential for LLPS of those proteins. In this work, we propose that oligomerization may be a universal mechanism by which any protein system can enhance LLPS. We demonstrate that RNA-binding protein TDP-43 is capable of LLPS in *vitro* without the use of its C-terminal prion-like domain, in a manner dependent on the oligomerization of its N-terminal domain (NTD). We show that fusing TDP-43's NTD to other proteins also enables or enhances their ability to LLPS, and we show that replacing TDP-43's NTD with other oligomerization domains enhances LLPS proportionately to the state of oligomerization. Finally, we demonstrate that oligomerization is used by TDP-43 to LLPS in *vivo*, where removing oligomerization abrogates LLPS. We believe oligomerization is a general mechanism to enhance LLPS, and that it will likely be seen as an important part of phase-separating systems in the future.

The Nucleolus Is Composed of Two Distinct Types of Phase Separations.

J. G. Lawrimore, M. Khan, E. Yeh, K. Bloom; University of North Carolina at Chapel Hill, Chapel Hill, NC.

The nucleolus is encapsulated within the nucleus via liquid-liquid phase separation (LLPS). Recent studies suggest the high density of ribosomal DNA (rDNA) loops within the nucleolus is sufficient to generate a polymer-polymer phase separation (PPPS). How the polymer driven rDNA phase versus the RNA/protein liquid phase contribute to the integrity of the nucleolus is not well understood. We utilized live-cell fluorescent imaging of the rDNA locus and the ribonucleoprotein complex (CBF5) to distinguish the liquid from the polymer phases within the nucleolus of the budding yeast *S. cerevisiae*. In polymer phases DNA crosslinkers colocalize with DNA, and the density and binding kinetics of crosslinkers dictate the polymeric properties. In the liquid phase the components appear homogenous and surround the DNA. We found that condensin, a known DNA loop extrusion complex, and CDC14-GFP, a protein phosphatase sequestered in the nucleolus until the exit from mitosis, co-localize with the rDNA locus, indicative of a PPPS. In contrast, CBF5-RFP did not localize with the rDNA locus and instead appears homogenous surrounding and intermingled with the DNA. These data indicate that nucleolar ribonucleoproteins are part of a LLPS while rDNA is part of a PPPS. To determine if we could preferentially compact one phase from the other, we expressed a tetrameric LacI-GFP protein, which

can form DNA loops in a strain containing a LacO sequence integrated into all copies of the rDNA locus. The rDNA/LacI-GFP tetramer signal was significantly smaller than a rDNA/LacI-GFP dimer signal. However, the CBF5-mCherry signal area remained the same regardless of the LacI construct (dimer or tetramer). To test the role of rRNA in liquid phase formation we imaged CBF5-mCherry in cells containing 2-micron plasmids with a rDNA repeat under the expression of a galactose promoter. In these cells, the endogenous rDNA locus was removed, and a single rDNA repeat was placed on chromosome V. Multiple distinct CBF5 signals were observed throughout the nucleus in G1 and mitotic cells; however, upon transcriptional repression CBF5 appears as single signal. Thus, the liquid-like CBF5 phase can distribute throughout the nucleus in the absence of the rDNA polymer phase. The nucleolus is a composite structure with both polymer and liquid phase characteristics.

P1275/B404

Spatial Organization of Nucleoli in Macronuclei of Several Ciliate Species with Subchromosomal Organization of Macronuclear Genome.

V. Popenko, O. Leonova; Engelhardt Institute of Molecular Biology RAS, Moscow, RUSSIAN FEDERATION.

The nucleolus is an essential structural component of the nucleus. Three main structural subregions can be electron microscopically defined in nucleoli of higher eukaryotes: fibrillar centers (FC); the dense fibrillar component (DFC), partly or completely surrounding FC; and the granular component, located at nucleolar periphery. However, recent studies showed that such "classical" tripartite nucleolar organization is an evolutionary acquisition of higher eukaryotes. Ciliated protists contain two different types of nuclei in each cell: a germinal functionally inert micronucleus, and a somatic macronucleus, which is DNA-rich and transcriptionally active during vegetative growth. In contrast to genomes of metazoan cells, the macronuclear genomes are represented by sets of relatively short DNA molecules (minichromosomes) either of “gene size” (0.5-25 kb) or of subchromosomal size (from several tens up to several hundred kb). Thus, ciliate macronuclei are a convenient object to study the peculiarities of nucleolus morphology in the nuclei with minichromosomes. In this work, *Bursaria truncatella, Paramecium multinucleatum and Didinium nasutum* were studied. They belong to the species with subchromosomal organization of macronuclear genome. The aim of this work was to study nucleolar architecture in these species using confocal microscopy; 3D electron microscopy reconstruction on the basis of ultrathin sections; and localization of fibrillarin in the nucleoli using specific antibodies. Different spatial organization of nucleoli was observed. Fibrillarin is one of the highly evolutionary conserved nucleolar proteins, found in various species from *Archaea* to human. During interphase, fibrillarin is present in nucleoli of higher eukaryotes mainly in FC and DFC. It was shown that in *B. truncatella and P. micronucleatum* fibrillarin mainly occurs in the central region of the nucleoli, similar to nucleoli of higher eukaryotes. On the contrary, in the *D. nasutum* nucleoli fibrillarin was located at the periphery of nucleolar domain. These results are in a good agreement with the electron microscopic data on morphology of the nucleoli, which showed an unusual "inverted" location of the fibrillar component and the granular component in the nucleoli of *D. nasutum.* This work was supported by the Program of fundamental research for state academies for 2013-2020 years (01201363823).

Ectopically Expressed Pno40 Suppresses Ribosomal Rna Synthesis by Inhibiting Ubf-dependent Transcription Activation.

Y. Lin, P. Ouyang; Chang Gung University, Taoyuan City, TAIWAN.

Ribosomal RNA (rRNA) production occurs in the nucleolus and is a critical process for ribosome biogenesis which affects protein synthesis capacity and determines the cell growth. Dysregulation of nucleolar homeostasis elicits a nucleolar stress response and is related to disease etiology, indicating that the regulation of nucleolar activity is crucial and tightly coordinated. We previously reported that nucleolar protein pNO40 overexpression mediates SR family splicing factors into the nucleolus and impairs mRNA metabolism, while the function of pNO40 in nucleolar homeostasis is unclear. Here, we demonstrate that overexpression of pNO40 downregulates RNA polymerase I transcription activity, resulting in pre-rRNA synthesis reduction and induces nucleolar segregation, a hallmark of rRNA synthesis inhibition and nucleolar stress response. Moreover, co-immunoprecipitation experiments revealed that ectopically expressed pNO40 interacts with UBF, a master transcription factor involved in pre-initiation complex (PIC) (containing SL-1 complex and RNA polymerase I complex) to activate and promote RNA polymerase I-mediated transcription, but disturbs its rDNA promoter binding ability. Collectively, our results demonstrate the role of pNO40 in rRNA biosynthesis regulation by compromising UBF function in rDNA transcription activation with subsequent rRNA synthesis inhibition.

P1277/B406

Sas10 Controls Ribosome Biogenesis by Stabilizing Mpp10 and Delivering the Mpp10-imp3-imp4 Complex to Nucleolus.

Y. Chen, S. Zhao; Zhejiang University, Hangzhou, CHINA.

Mpp10 forms a complex with Imp3 and Imp4 that serves as a core component of the ribosome small subunit (SSU) processome. Mpp10 also interacts with the nucleolar protein Sas10/Utp3. However, it remains unknown how the Mpp10-Imp3-Imp4 complex is delivered to the nucleolus and what biological function the Mpp10-Sas10 complex plays. Here we report that zebrafish Mpp10 and Sas10 are conserved nucleolar proteins essential for the development of digestive organs. Mpp10, but not Sas10/Utp3, is a target of the nucleolar-localized Def-Capn3 protein degradation pathway. Sas10 protects Mpp10 from Capn3-mediated cleavage by masking the Capn3-recognintion site in Mpp10. Def interacts with Sas10 to form the Def-Sas10-Mpp10 complex to facilitate the cleavage of Mpp10 by Capn3. Importantly, we find that Sas10 determines the nucleolar-localization of the Mpp10-Imp3-Imp4 complex. We conclude that Sas10 is essential not only for delivering the Mpp10-Imp3-Imp4 complex to the nucleolus for assembling the SSU processome but also for fine-tuning Mpp10 turnover in the nucleolus during organogenesis.

P1278/B407

Prostaglandins Restrict Nuclear Actin to Control the Nucleolus.

D. Wineland[1], **T. Tootle, 52242**[1], G. Kimble[1], D. Kelpsch[2]; [1]University of Iowa-Carver Coll Med, Iowa City, IA, [2]Carnegie Institution for Science, Baltimore, MD.

Prostaglandins (PGs), lipid signals produced downstream of cyclooxygenase enzymes, have numerous physiological and pathological functions, including pain and inflammation, reproduction, heart health

and disease, and cancer development and progression. One means by which PGs act is through regulating the actin cytoskeleton. Actin is not solely cytoplasmic, but localizes and functions within the nucleus. Using the robust genetic system of Drosophila and the well-characterized developmental process of oogenesis, we discovered multiple pools of nuclear actin that exhibit distinct developmental and subnuclear localizations. Specifically, fluorescently conjugated DNase I labels monomeric actin in the nucleolus of every cell. Anti-actin C4 labels a monomeric, nucleolar actin in a subset of cells during early oogenesis and recognizes polymeric nuclear actin in both the oocyte and undifferentiated germline cells. Anti-actin AC15 labels polymeric nuclear actin that localizes to the chromatin starting at mid-oogenesis in both germline and somatic cells. Additionally, ectopic expression of GFP-Actin results in nuclear actin rod formation during early oogenesis. We find that PGs are required to limit the levels of the different pools of nuclear actin. Loss of the Drosophila cyclooxygenase enzyme, Pxt, results in increased GFP-Actin rod formation, an increased frequency of cells exhibiting C4 nuclear actin, and premature and increased levels of AC15 nuclear actin. Thus, PG signaling is a critical negative regulator of nuclear actin. Our findings that both DNase I and C4 label actin within the nucleolus, PGs regulate C4 nuclear actin, and PGs regulate the structure of the nucleolus, led us to hypothesize that PGs tightly control nuclear actin to regulate the nucleolus. Supporting this loss of Exportin 6, which mediates the nuclear export of actin, results in defects in nucleolar structure that are similar to those observed for loss of Pxt. These data suggest that nuclear actin plays a critical role in regulating nucleolar structure. Together our findings lead to the model that PGs tightly control nuclear actin to regulate nucleolar structure and likely function. As both the nucleolar localization and functions of actin and the role of PGs in regulating the nucleolus are conserved across organisms, our findings reveal a novel pathway that may play critical roles in both normal and pathological instances. Indeed, high levels of PGs, increased nuclear actin, and nucleolar changes are each independently associated with cancer development and progression.

The Nucleolar Dense Fibrilar and Granular Components Observed by Atomic Force Microscopy.

M. L. Segura-Valdez, S. Cruz-Gómez, P. Mendoza-von der Borch, **L. F. Jimenez-Garcia**; UNAM, Mexico City, MEXICO.

The nucleolus is a plurifunctional nuclear organelle involved in ribosome biogenesis and other functions. With the electron microscope three major ultrastructural components are distinguished, namely, dense fibrilar component, granular component and fibrilar centers. It is composed of rDNA, rRNA, pre-rRNA, UsnRNAs and some 700 proteins. While light and electron microscopy have revealed the major components, scarce data are available with the atomic force microscope. In addition, defining the differences among their component has been difficult using bi-dimensional approaches. Here, we use the atomic force microscope working in contact mode to study the components of the nucleolus of the tree *Ginkgo biloba*, adding the vertical resolution as a parameter, in semithin sections of material prepared as fir transmission electron microscope. The microscope can distinguished dense fibrilar component from granular component because they display differences when using profiles through the sections. These profiles are different from those of compact chromatin and nucleoplasm. The resolution given by the z resolution can be used as a parameter to distinguish both components one from each other. The present results suggest that dense fibrilar component may be distinguished from fibrilar centers by atomic force microscopy in other species as *Giardia lamblia*, where both components are intermingled (we thank CONACyT 180835, DGAPA-UNAM IN217917, PAPIME PE213916).

Upregulated Flotillins, New Markers of Metastatic Development, Deregulate Endocytosis and Vesicular Trafficking to Induce Epithelio-to-mesenchymal Transition and Cellular Invasion.

C. Gauthier-Rouviere[1], D. Planchon[1], M. Genest[1], F. Comunale[1], P. Chavrier[2], I. Bièche[2], S. Bodin[1]; [1]CNRS-CRBM, MONTPELLIER, FRANCE, [2]Institut Curie, PARIS, FRANCE.

Metastasis formation is the major cause of death in patient with cancer. Flotillin upregulation is detected in many invasive tumors, both carcinoma and sarcoma, and is a marker of poor prognosis associated with a higher metastatic risk. *How flotillins participate in the acquisition of invasive and metastatic properties remains to be determined. Through* in *vitro* and in *vivo* approaches, we showed that in non tumoral epithelial and mesenchymal cells, upregulation of flotillins is sufficient to induce epithelio-to-mesenchymal transition (EMT), extracellular matrix degradation and cellular invasion. Conversely, flotillin knockdown in invasive cancer cells reduces extracellular matrix degradation and cellular invasion. This illustrates the critical role of flotillin upregulation in the acquisition of invasive properties by cancer cells. Flotillin 1 and 2 are two ubiquitous, highly conserved and related proteins present in many cellular membrane compartments. They exist as hetero-tetramers that assemble in large oligomers to form molecular membrane scaffolds known to participate in membrane proteins clustering. When overexpressed, they induce the formation of plasma membrane invaginations and of intracellular vesicles and modify the trafficking of several cargos; promoting the Upregulated Flotillin-Induced Trafficking (UFIT) pathway. The cellular distribution of upregulated flotillins is dramatically modified with a strong enrichment in vesicular compartments that we characterized as non degradative-endolysosomes. *We aim at identifying how the UFIT pathway modifies the trafficking of key cargos leading to the acquisition of invasive properties. Through* various cutting-edge cell biology approaches (such as optogenetic to promote flotillin the UFIT pathway) and using global comparative analyses (transcriptomic, proteomic, phosphokinase arrays), we identified protein cargos of the UFIT pathway, such as key transmembrane signaling receptors, adhesion proteins and also the metalloproteinase MT1-MMP, whose endocytosis, trafficking and activity is modified by flotillin upregulation. We propose that the UFIT pathway generates flotillin-positive endolysosomes acting as a “signalosome and recycling compartment” involved in the activation of oncogenic signaling pathways stimulating EMT and cellular invasion.

P1281/B411

Functional an alysis of Mitochondria-endosome Interaction in the Regulation of Endocytosis.

A. O. Satoh[1], Y. Fujioka[1], H. Sasajima[1], S. Paudel[1], A. Nanbo[2], Y. Ohba[1]; [1]Department of Cell Physiology, Faculty of Medicine, Hokkaido University, Sapporo, JAPAN, [2]National Research Center for the Control and Prevention of Infectious Diseases Nagasaki University, Nagasaki, JAPAN.

Endocytosis mediates the internalization and ingestion of a variety of endogenous or exogenous substances, including receptors, nutrients, and pathogens, into cells under the control of intracellular signaling. We have previously reported that the complex formed by the small GTPase Ras and phosphoinositide 3-kinase (PI3K) is translocated from the plasma membrane to endosomes upon epidermal growth factor (EGF) stimulation, and Ras-PI3K signaling thereby promotes endocytosis and endosome maturation (***Cell Signal***21: 1672, 2009; ***PLoS ONE***6: e16324, 2011). We have also reported

that endosomal localization of the Ras-PI3K complex is regulated through N-terminus region of the Ras-binding domain of PI3K, which is named RAPEL after Ras-PI3K endosomal localization (*Cell Struct Funct* 44: 61, 2019). To reveal the mechanism underlying these phenomena, we performed yeast two-hybrid assay to screen the binding proteins of RAPEL and identified six candidate proteins. Among these candidates, we focused on voltage-dependent anion channel 2 (VDAC2), a mitochondrial outer membrane protein that permeates ions and small molecules through its pore. When cells in which VDAC2 was knocked down were subjected to time-lapse microscopy, it was revealed that the endosomal localization of the Ras-PI3K complex was suppressed. In addition, uptake of dextran, which is a known substrate for endocytosis, was reduced and increased by the knockdown and overexpression of VDAC2, respectively. These data indicated that VDAC2 is involved in the spatiotemporal regulation of Ras-PI3K signaling and subsequent promotion of endocytosis. Next, we observed the intracellular dynamics of mitochondria and endosomes, and found that they transiently interacted with each other. Moreover, the mitochondria-endosome interaction was promoted by EGF stimulation, and such promotion was suppressed by knockdown of VDAC2. Therefore, to investigate the role of mitochondria-endosome interaction in the regulation of endocytosis, we developed an optogenetic approach, using cryptochrome 2 and cryptochrome 2-interacting basic helix-loop helix 1, so that the interaction is brought about by blue-light illumination. Interestingly, when the interaction was induced by light, endosome acidification was facilitated in a VDAC2-dependent manner. In conclusion, VDAC2 promotes endosomal localization of the Ras-PI3K complex and facilitates endosome maturation through mitochondria-endosome interaction.

P1282/B412

Feedback Effect of GGA3 Phosphorylation on TrkA Endocytic Trafficking.

X. Li; Jining Medical University, Jining, CHINA.

TrkA post-endocytic sorting significantly influences neuronal cell survival and differentiation. The process that directs the sorting of TrkA to diverse pathways have a significant impact on TrkA-mediated biological functions. We have demonstrated that GGA3 (Golgi-localized γ adaptin-ear-containing ADP ribosylation factor-binding protein 3) interacts directly with the TrkA cytoplasmic tail through an internal DXXLL motif and mediates the functional recycling of TrkA to the plasma membrane. We identified GGA3 as a key player in a novel DXXLL-mediated endosomal sorting machinery that targets TrkA to the plasma membrane, where it prolongs the activation of Akt signaling and survival responses. Indeed, GGA3 has been shown to be crucial for the sorting of EGFR and BACE to lysosomes through interactions with ubiquitin and for the recycling of the TrkA and Met receptor to the PM through an interaction with the DXXLL motif. Given that TrkA is ubiquitinated following ligand binding, we wonder how GGA3 preferentially uses the DXXLL motif to target TrkA to the recycling pathway. The phosphorylation of GGAs themselves has been shown to be a key factor in the regulation of their function. It would be appropriate to examine whether NGF stimulation leads to the phosphorylation of GGA3 and changes its binding capacity to ubiquitin or DXXLL motif, controlling the sorting fate of endocytic TrkA. Therefore, we aimed to check the phosphorylation status of GGA3 protein upon NGF stimulation and the feedback effects on TrkA endocytic sorting fate decision. We found NGF treatment could induce a molecular weight increase of GGA3 in PC12-615 cells, probably a result of phosphorylation. Ongoing studies are investigating the exact phosphorylated residues of GGA3 induced by NGF, and then we will make clear the consequences of the phosphorlation on GGA3 function, as well as on TrkA endocytic trafficking and physical functions.

P1283/B413

Cadherin Is a Cargo of WAVE-dependent Trafficking in Mature Epithelia.

S. Borinskaya[1,2], S. Sasidharan[1], L. Mantle[1], M. Soto[1]; [1]Rutgers University, Piscataway, NJ, [2]College of Saint Elizabeth, Morristown, NJ.

We are interested in how WAVE and Cadherin function together to maintain stable and healthy Apical Junctions (AJs) in mature epithelia. WAVE is a branched actin nucleation promoting factor and Cadherin is a transmembrane cell adhesion protein. Both WAVE and Cadherin regulate cell polarity and are also misregulated in many cancers. Our previous work about establishment of apical junctions in developing *C. elegans* embryos revealed interdependence between the WAVE and Cadherin complexes. They become enriched at similar times in development, and loss of WAVE or Cadherin suppresses F-actin enrichment at the AJs of epithelia. These results agree with findings in tissue culture which implicate WAVE in promoting formation of the Cadherin junction. We became intrigued by the effects of WAVE and branched actin on Cadherin enrichment and dynamics at the AJ. Interestingly, some regulators of endosomal recycling had similar effects on Cadherin. Therefore, in this presentation we focus on the unexplored role of WAVE at the endocytic recycling compartment (ERC). Cadherin is transported via ERC by RAB-10 and RAB-11 GTPases. Downregulation of WAVE caused imbalance of RAB-10 and RAB-11 vesicular transport at ERC. In the absence of WAVE, RAB-10 levels as well as vesicle number and velocity decreased. In contrast, loss of WAVE led to higher RAB-11 levels and vesicle velocity. RAB-10 depletion had different effect on RAB-11 dynamics suggesting that WAVE has distinct roles at RAB-10 and RAB-11 endosomes. Since vesicle formation, or movement, or both may be affected by WAVE-dependent branched actin, we are imaging and assessing actin presence and dynamics at ERC-associated vesicles. This is the first report elucidating the role of WAVE and branched actin in Cadherin trafficking and recycling at the ERC. Our research will explain how WAVE supports homeostatic accumulation of Cadherin at AJ in mature epithelia. Investigating WAVE-dependent Cadherin recycling may inform cancer treatments and may also reveal mechanisms of subversion of RAB-11-mediated delivery of Cadherin to AJs by various pathogens.

P1284/B414

Selective Uptake of Carboxylated Multi-walled Carbon Nanotubes Impairs Macrophage Phagocytic Activity Via Class a Type 1 Scavenger Receptors.

R. Wang, R. Lohray, E. Chow, P. Gangupantula, R. Draper; University of Texas at Dallas, Richardson, TX.

The global production and applications of multi-walled carbon nanotubes (MWNTs) have increased despite evidence that MWNTs cause pulmonary fibrosis in lab animals that may lead to mesothelioma. Studies to understand the pathological mechanisms of MWNTs often focus on macrophages as they are first responders to invaders in the body. Recent work in our lab shows that macrophages preferentially accumulate ~100X more carboxylated MWNTs (C-MWNTs) than pristine MWNTs (P-MWNTs). Also, Class a scavenger receptors type 1 (SR-A1) expressed in macrophages may be involved in selective C-MWNTs uptake (Wang et. Al., *Nanotoxicology*, 2018). We are currently investigating the accumulation of C-MWNTs by macrophages via SR-A1 receptors and their effects on phagocytic function: **1. Selective C-MWNTs accumulation correlates with surface SR-A1 receptor expression.** Three mouse macrophages and two Chinese Hamster Ovary (CHO) cell lines were used to demonstrate the specificity of SR-A1 receptors for C-MWNTs uptake. Both RAW 264.7 and wild type B6 mouse alveolar macrophages express

high SR-A1 receptors with active C-MWNTs uptake whereas ZK cells (alveolar macrophages derived from a SR-A1 knockout mouse) deficient in SR-A1 receptors fail to accumulate C-MWNTs. Non-phagocytic cell types, such as epithelial CHO cells, express low SR-A1 receptors and support little MWNTs uptake. Mutant CHO clones that express transfected mouse SR-A1 receptor genes show increased uptake of C-MWNTs but not of P- or N-MWNTs. In addition, the surface SR-A1 receptor levels was reduced by 50% in RAW 264.7 cells after a 24h continuous exposure to C-MWNTs, suggesting that active C-MWNTs phagocytosis may deplete SR-A1 receptors from the cell surface. **2. C-MWNT accumulation impairs phagocytic function via SR-A1 receptors. To** assess the potential adverse effects of C-MWNT accumulation in macrophages, RAW 264.7 cells were pre-exposed to C-MWNTs for 24h at 37 °C, washed, and then tested for the subsequent phagocytosis of ligands that are known to interact with SR-A1 receptors. The uptake of three fluorescent-conjugated phagocytosis markers, including polystyrene beads, heat-killed E. coli, and oxidized LDL (oxLDL), were assessed using confocal fluorescence microscopy and measured quantitatively by flow cytometry. There were significant reductions in the uptake of polystyrene beads and E. coliin cells pre-treated with C-MWNTs but not in cells pre-treated with either P- or N-MWNTs, compared to the untreated control cells. The study on oxLDL uptake is underway. These results confirmed the selective uptake of C-MWNTs in macrophages via SR-A1 receptors. In addition, prolonged high C-MWNT uptake correlate inversely with subsequent SR-A1-dependent phagocytic activities in macrophages.

P1285/B415

Oligo-arginine-bearing Tandem Repeat Penetration-accelerating Sequence Delivers Protein to Cytosol.

A. Okuda; Dept of Med Tech, Grad Sch Health Sci, Niigata Univ, Niigata, JAPAN.

Cell-penetrating peptides (CPPs) can deliver cargo proteins into cells; however, internalized CPP-cargo is mainly retained in endosomes. To facilitate the cytosolic delivery of larger molecules such as proteins, we developed a new CPP sequence, named Pas2r12, consisting of a repeated Pas sequence (FFLIG-FFLIG) and D-dodeca-arginine (r12). This peptide significantly enhanced the cellular uptake and cytosolic release of green fluorescent protein and immunoglobulin G.However, the cytosolic EGFP deliverywas suppressed by caveolae-mediated endocytosis inhibitors. These results suggest that Pas2r12 enhances membrane penetration of cargo macromolecules without the need for crosslinking, and that caveolae-mediated endocytosis may be the route by which cytosolic delivery is enhanced. (Ref.) Okuda et al.: Biomacromolecules 2019 20 (5) 1849-1859

Vps501, a Novel Vacuolar SNX-BAR Protein That Cooperates with the Sea Complex to Regulate Autophagy.

S. Goyal[1], A. Stecher[1], N. Nitika[1], A. W. Truman[1], A. M. Reitzel[1], V. A. Segarra[2], R. J. Chi[1]; [1]University of North Carolina at Charlotte, Charlotte, NC, [2]High Point University, High Point, NC.

The endosomal system facilitates the sorting and export of cargos that are packaged and conveyed by tubular and vesicular carriers destined for plasma membrane recycling or Golgi retrograde transport pathways, in part through the action of members of the sorting nexin (SNX) family of proteins. In particular, the SNX-BAR proteins, a sub-family of sorting nexins characterized by the presence of a C-terminus dimeric Bin/Amphiphysin/Rvs (BAR) lipid curvature domain, and the ability to recognize phosphatidylinositol 3-phosphate through an evolutionarily conserved Phox-Homology domain, are of

great interest. In budding yeast, the SNX-BAR subfamily has traditionally been thought to consist of six members, all of which are well-characterized. Sequence and phylogenetic analyses indicated the existence of a seventh member of this group. We now report the identification and functional characterization of this novel SNX-BAR, we have named Vps501. Using high-resolution fluorescence microscopy, we have found that Vps501 uniquely localizes to the vacuole and interacts with autophagy regulators, namely subunits of the SEA complex and TORC1. Furthermore, cells lacking Vps501 display a deficiency in starvation induced, nonselective autophagy that is severely exacerbated by ablation of subunits of the SEACIT. We also report that Vps501 interacts with the autophagy related protein Atg27 and regulates the dynamics of Atg27 trafficking at the vacuole. We hypothesize that Vps501 interacts with the SEA complex to negatively regulate autophagy via a novel vacuole membrane trafficking pathway. By contributing to a fuller understanding of the roles SNX proteins can play in cellular function, this discovery may inform future investigations of SNX-associated processes such as pathogen invasion or human conditions associated with defective SNX proteins, including neurodegenerative diseases and cancer.

P1287/B417

Analysis of Retromer Complex Dynamics on Supported Lipid Bilayers.

C. L. Deatherage[1], J. Nikolaus[2], E. Karatekin[2], C. G. Burd[1]; [1]Yale University, New Haven, CT, [2]Yale University, West Haven, CT.

In the endocytic system, vesicles from the plasma membrane containing lipids and integral membrane proteins fuse with sorting endosomes. There these cargoes are sorted and delivered back to the plasma membrane or to other organelles by the process of retrograde trafficking.The retromer complex, a trimeric (proteins Vps35, Vps26, and Vps29) endosomal sorting device , is a key component of retrograde trafficking and recognizes and sorts specific cargoes to multiple destinations. Despite the unequivocal importance of retromer in retrograde trafficking, the mechanism of how retromer sorts and packages cargo into retrograde sorting vesicles is unknown. It has been proposed that retromer sorting (i.e. cargo concentration/clustering) is facilitated first by intrinsic oligomerization of the retromer complex bound to cargo, which would begin to drive cargo into nascent sorting tubules. Further enrichment/concentration is proposed to be induced through an interaction with the WASH complex member Fam21, which has 21 retromer binding sites.We reconstituted the retromer coat complex assembly on a supported membrane bilayer, which allowed us to systematically probe the role of Fam21 and retromer interaction. In the reconstituted system we have both the membrane and the essential proteins of the retromer cargo-sorting complex, allowing us to investigate how these components interact and assemble on a supported bilayer using TIRF microscopy. When associated with the membrane, retromer exists as a distribution of oligomers, with a mean of eight subunits. Surprisingly, despite the presence of multiple retromer binding sites in Fam21, direct interaction between Fam21 and retromer on the bilayer does not influence the distribution of retromer oligomers. In addition, the oligomer distribution of retromer was not influenced by the presence of accessory coat factors that bind retromer, including Rab7-GTP, Sorting nexin 3 (Snx3), or cargo. These data suggest that, contrary to long-standing hypotheses, retromer does not substantially oligomerize on a membrane, either by itself, or in the presence of cargo, accessory factors, or the Fam21/WASH complex.

COMMD1 and PtdIns(4,5)P_2 interaction maintain ATP7B copper transporter trafficking fidelity in HepG2 cells.

D. J. Stewart, K. K. Short, B. N. Maniaci, **J. L. Burkhead**; University of Alaska an chorage, an chorage, AK.

Copper-responsive intracellular ATP7B trafficking is critical to maintain copper balance in mammalian hepatocytes and thus organismal copper levels. The COMMD1 protein binds both the ATP7B copper transporter and phosphatidylinositol (4,5)-*bis*phosphate (PtdIns(4,5)P_2), while COMMD1 loss causes hepatocyte copper accumulation. Although it is clear that COMMD1 is included in endocytic trafficking complexes, a direct function for COMMD1 in ATP7B trafficking has not been defined. In this study, experiments using quantitative fluorescence microscopy reveal that COMMD1 modulates the copper-responsive ATP7B trafficking through recruitment to PtdIns(4,5)P_2. Decreased COMMD1 abundance results in loss of ATP7B from lysosomes and the *trans*-Golgi network (TGN) in high copper conditions, while excess expression of COMMD1 also disrupts ATP7B trafficking and TGN structure. Overexpression of COMMD1 mutated to inhibit PtdIns(4,5)P_2 binding has little impact on ATP7B trafficking. A mechanistic PtdIns(4,5)P_2-mediated function for COMMD1 is proposed that is consistent with decreased cellular copper export due to disruption of the ATP7B trafficking itinerary and accumulation in the early endosome when COMMD1 is depleted. PtdIns(4,5)P_2 interaction with COMMD1 as well as COMMD1 abundance may both be important in maintenance of specific membrane protein trafficking pathways.

Yeast Eps15 Homologue Pan1p and Epsin Homologues Ent1p/ Ent2p Cooperatively Function to Transport Clathrin-coated Vesicle Along Actin Cable.

J. Y. Toshima[1], N. Yoshida[2], I. Ogura[2], M. Enshoji[2], M. Nagano[2], J. Toshima[2]; [1]Tokyo University of Technology, Schcool of Health Science, Tokyo, JAPAN, [2]Tokyo University of Science, Dept. Of Bio. Sci. An d Tech., Tokyo, JAPAN.

In yeast endocytosis, actin assembly is required for both internalization and transport of newly formed vesicles away from the plasma membrane. In the previous work, we have shown that phosphorylation of yeast Eps-15 like protein Pan1p induces disassembly of coat proteins, as well as actin filaments by blocking the interaction between Pan1p and actin filaments. Recently, we showed that dephosphorylated mutant of Pan1p (Pan1-18TA) causes abnormal cytoplasmic actin clumps, and persistent association between vesicles and actin cables. Interestingly, these interactions are partially suppressed in Pan1-18TAΔ855 mutants that lack its C-terminal actin binding and Arp2/3-activating regions. Thus, Pan1p seems to be one of the key regulators that fixe vesicles to the actin cable and then dissociate from the cable upon phosphorylation. However, the ability of vesicles to bind to actin cables in Pan1-18TAΔ855 was not completely lost in the mutant, implying the existence of additional actin-binding coat protein(s) that stabilize vesicle association with actin cables. To test whether Epsin homologue, Ent1p and Ent2p, participate in the interaction between vesicles and actin, we combined ent1*Δ* or ent2*Δ* with *Pan1-18TA Δ855* mutant. In these mutant cells, the number and size of actin containing clumps are significantly reduced, although substantial numbers of clumps containing Pan1p are still formed, suggesting actin binding ability of endocytic vesicle was largely disrupted in these mutant cells. To further examine the contribution of Pan1p, Ent1p and Ent2p in binding of endocytic vesicle with actin cable, we made single, double or triple mutants in which actin binding regions of these proteins were deleted. As a result, we observed significant defects in dynamics and transport of

endocytic vesicle in the *pan1 ent1 ent2* triple mutant cells. These results suggest that actin binding activities of these endocytic coat proteins is important for transport of endocytic vesicles along actin cable.

Nutrient Regulation Is Potentially Compromised in Cells with Disrupted Endocytosis and ESCRT-Dependent Protein Sorting.

S. Pesari, K. Hoban, S. Y. Lux, J. Poprawski, Y. Zhang, D. Prosser, C. Norris, B. Wendland; Johns Hopkins University, Baltimore, MD.

Endocytosis is a vital cellular mechanism that involves the uptake of transmembrane proteins, referred to as cargo and extracellular material. Deletion of endocytic genes can lead to diseases such as neurodegenerative and lysosomal storage disorders. Specifically, clathrin-mediated endocytosis (CME) is a process in which a clathrin coat assists in membrane invagination. Endocytic adaptor proteins bind to transmembrane cargo and recruit clathrin. Previous findings indicated that cells lacking four adaptor proteins, the yeast epsins, Ent1 and Ent2, and AP180 homologues, Yap1801 and Yap1802, while maintaining a single epsin ENTH domain for viability (4Δ+ENTH), led to severely inhibited cargo internalization. We performed an extensive screen for synthetic lethality using a 4Δ+ENTH strain that expresses a full-length Ent1 cover plasmid. One set of synthetic lethal interactions with the 4Δ+ENTH background resulted from mutations in *VPS4*. Vps4 assists in the disassembly of Endosomal Sorting Complexes Required for Transport (ESCRT), which contribute to the degradation of endocytic cargo by trafficking transmembrane proteins from the endosomal membrane to endosomal lumen. Further experimental results indicated that inactivation of the large ATPase domain of Vps4 led to a phenotype similar to a 4Δ+ENTH *vps4*Δ strain, showing that this ATPase activity is essential for the viability of 4Δ+ENTH cells. To determine if mutations in other endocytosis genes exhibit negative genetic interactions with the loss of *VPS4*, we performed an experiment with cells lacking End3, a late coat CME protein. In previous experiments, an *end3*Δ *vps4*Δ strain also appeared to be synthetic lethal, in that a plasmid expressing full-length End3 was required for viability when the cells were grown on medium that selected against the End3 plasmid. However, data obtained using a different approach showed that the *end3*Δ *vps4*Δ cells constructed without an End3 plasmid were severely slow-growing but viable on rich medium. Due to this result, a 4Δ+ENTH *vps4*Δ strain was re- streaked on counterselective medium supplemented with sorbitol for osmotic support, which allowed the cells to grow without the full-length Ent1 plasmid. These 4Δ+ENTH *vps4*Δ cells were then viable on minimal medium without counterselection or sorbitol, but were not viable on rich medium. Together, our results indicate that cells with endocytic and ESCRT-mediated trafficking defects are synthetic sick instead of synthetic lethal and can be rescued by osmotic support. Also, these cells are able to proliferate at higher rates on minimal medium than rich medium, which suggests that nutrient regulation may be comprised in this genetic context.

P1291/B421

Effect of Ap2 µ2 Serine 45 Phosphorylation on Clathrin-mediated Endocytosis.

A. Brzozowska[1], A. Tempes[1], A. Malik[1,2], T. Wegierski[1], K. Misztal[1], E. Sitkiewicz[3], M. Dadlez[3], J. Jaworski[1]; [1]International Institute of Molecular and Cell Biology, Warsaw, POLAND, [2]Nencki Institute of Experimental Biology, Warsaw, POLAND, [3]Institute of Biochemistry and Biophysics Polish Academy of Sciences, Warsaw, POLAND.

Clathrin-mediated endocytosis (CME) is one of the pathways, by which eukaryotic cells internalize receptors and their ligands. The process starts at the plasma membrane and over 50 different proteins are involved in the formation of clathrin-coated pit (CCP), which mature and after scission become clathrin-coated vesicle (SSV). The assembly of CCP is initiated by the multisubunit adaptor complex 2 consisting of α, β2, µ2 and σ subunits. In cytoplasm AP2 exists in inactive- closed conformation. Binding to the plasma membrane triggers the conformational changes of AP2, which lead to open, active state and subsequent cargo binding and clathrin recruitment. Our initial results revealed that inhibition of mTOR/S6K1 pathway alters CME. Therefore the aim of the study was to understand a molecular mechanism underlying such regulation. We used immunoprecipitation, in vitro kinase assays and mass spectrometry to assess functional interaction between mTOR pathway and AP2 as well as identification of phosphorylation sites. Moreover formation and internalization of CCPs was performed with TIRF microscopy. This latter was studied using transfected or stable HeLa cell lines. Here we report that AP2 µ2 binds S6K1 and is phosphorylated on S45 in the S6K1 dependent manner. Substitution of serine 45 by alanine residue of µ2 inhibits transferrin uptake. Proximity ligation assay revealed decreased interaction of TrfR with phospho-deficient µ2. Quantitative live-cell analysis showed that in cells expressing µ2 S45A mutant CCPs initiation, lifetime distribution of CCPs and clathrin recruitment is altered. The results of our study have revealed importance of AP2 µ2 serine 45 phosphorylation for clathrin-mediated endocytosis. *This work has been supported by Polish National Science Centre grants* 2016/21/B/NZ3/03639 and 2017/25/N/NZ3/01280.

Disassembly Asymmetry Score Classification: a Novel and Robust Tool for Phenotype Detection in Clathrin-mediated Endocytosis.

Z. Chen, 75235, X. Wang, S. Schmid, G. Danuser; UTSouthwestern Medical Center, Dallas, TX.

Clathrin-mediated endocytosis (CME) is a resilient machinery for cargo internalization in mammalian cells that involves 70+ endocytic accessory proteins (EAP). Perturbation of single EAP usually causes minor/none effect in biochemical measurement of CME outcome, resulting in inconclusive/misleading information regarding in *situ* functions of these EAPs. Live-cell imaging cues potential earlier roles of EAPs prior to the finale of CME. However, for years, this approach is contaminated by abortive-clathrin coat (AC) that interferes measurement of the bona fide cargo carrier, clathrin-coated pit (CCP). Here, we develop a thermodynamics-inspired method, “disassembly asymmetry score classification (DASC)”, that unambiguously separates ACs from CCPs without additional marker. After packaging and extensive verification, we use DASC-identified ACs and CCPs to quantify the dynamics of CME progression in 10 EAP knockdown conditions. DASC detects diverse phenotypes in multiple conditions where biochemistry shows no functional consequence, suggesting this new tool a necessity for uncovering EAP functions in CME dynamics.

P1293/B423

Hiv-1 Nef Hijacks Clathrin-mediated Endocytosis (CME) to Deplete Anti-viral Factors.

A. A. Ye, Y. Iwamoto, J. H. Hurley, D. G. Drubin; University of California, Berkeley, CA.

HIV-1 evades immune killing, and if left untreated, leads to acquired immune deficiency syndrome (AIDS). A cure has not been found largely due to the virus' ability to evade immune detection by removing important host defense factors from the cellular membrane through clathrin-mediated endocytosis (CME). The HIV-1 accessory protein, Nef, is the main culprit involved in hijacking CME by down regulating many host proteins to maximize viral survival and fusion. CME is one pathway in which cells internalize membrane-bound receptors. Cargo recognition is mediated by the CME adaptor protein-2 (AP2), through the YXXΦ and dileucine signal binding sites. AP2 is tightly regulated in cells. The signal-binding sites are not accessible in the 'locked' conformation. Nef induces the removal of these surface proteins by hijacking CME, potentially by activating AP2 and exposing the signal binding sites. However, the exact mechanism by which Nef induces down-modulation of surface proteins, many of which lack canonical AP2-interacting domains, is not known. Recent studies have identified SERine INCorporating protein 3 and 5 (SERINC3 and SERINC5) as potent antiviral factors that are down regulated in a Nef-dependent manner. Virions produced in cells with properly localized SERINCs have reduced infectious potency. Live-cell TIRF imaging shows that Nef and the SERINCs are recruited to clathrin-coated pits at approximately the same time as clathrin. Using an inducible Nef expression system, I showed that acute Nef expression causes a reduction of AP2 lifetime in Jurkat cells from an average of 40sec to 30sec. Using a combination of live-cell TIRF imaging and advanced quantitative analysis, I was able to determine the dynamics of Nef recruitment to CME sites, and how this recruitment affects AP2 and dynamin-2 lifetimes. These data may provide clues on the mechanism by which Nef modulates host CME to induce the removal of membrane-bound cellular defense proteins.

Regulation of Membrane Scission in *S. Cerevisiae* by Bar Domain Proteins.

D. Menon, M. Kaksonen; University of Geneva, Geneva, SWITZERLAND.

In clathrin-mediated endocytosis, a flat plasma membrane is pulled into an invagination that eventually forms a vesicle. In mammalian cells, forces that drive the transition from invagination to spherical vesicle are provided by the GTPase Dynamin that acts in concert with crescent-shaped BAR domain proteins. In yeast cells, what causes membrane scission is unclear. The yeast BAR domain protein complex Rvs161/167 (Rvs) is nevertheless an important player: deletion of Rvs reduces scission efficiency by 30%. A mechanistic understanding of the influence of Rvs on scission however, remains incomplete. We found that arrival of Rvs to endocytic sites is timed by interaction of its BAR domain with specific membrane curvature. A second domain of Rvs167- the SH3 domain- affects localization efficiency of Rvs as well as dynamics of membrane invagination. This indicates that both BAR and SH3 domains are important for the role of Rvs as a regulator of scission. We tested current models of membrane scission, and found that deleting yeast synaptojanins or dynamin does not change scission dynamics. Interfacial forces caused by synaptojanin-mediated lipid hydrolysis are therefore unlikely to be sufficient for scission, and forces exerted by dynamin are not required. Invagination length is insensitive to overexpression of Rvs, suggesting that the recently proposed mechanism of BAR- induced protein friction on the membrane is not likely to drive scission in yeast. Contrary to the prediction of this model, deleting Rvs instead reduces invagination lengths at which scission occurs. We propose that

recruitment of Rvs BAR domains delays scission and allows invaginations to grow by stabilizing them. We also propose that vesicle formation is dependent on forces exerted by a different module of the endocytic pathway, the actin network. Preventing premature membrane scission via BAR interaction could allow invaginations to grow to a particular length and accumulate enough forces within the actin network to reliably cut the membrane.

Ppp1r21, Core Component of the Novel Rab-5 Effector Complex, Is Essential for Early Zebrafish Morphogenesis Via Regulation of Cadherin Turnover and Wnt Signaling.

V. Zimyanin[1], M. Zerial[2]; [1]UVA, Charlottesville, VA, [2]MPI-CBG, Dresden, GERMANY.

The endocytic system has emerged as an essential integrative layer regulating signal transduction and cell-cell adhesion in a cell-context dependent manner. How cargo flux of key proteins through the endosomal network contributes to the integration of core embryonic processes during development remains largely unknown. We recently identified a novel Rab5 effector protein complex that regulates cargo trafficking at the early endosomal level in mammalian cell culture. PPP1R21 is a core subunit of this complex and has been recently implicated in a severe neurodevelopmental human disorder. Here, we report that PPP1R21 localizes to Rab5-positive early endosomes in vivo and is required to maintain cadherin-mediated cell adhesion integrity and WNT/β-catenin signaling activity during zebrafish gastrulation. Knockdown of zebrafish ppp1r21 does not disrupt the early endocytic system in vivo but modulates endosomal transport of E-cadherin and β-catenin, consequently altering their subcellular localization. ppp1r21 knockdown results in both reduced E-cadherin levels at the cell membrane and a reduction of β-catenin in the nuclei. That in turn correlates with reduced WNT/β-catenin signaling activity, progressive loss of cell-cell adhesion and collective cell migration defects in the whole embryo. Our data demonstrates that PPP1R21 is required for the precise regulation of endosomal transport of E-cadherin and β-catenin during zebrafish gastrulation and suggests that the functional integration of WNT/β-cateninsignaling with E-cadherin-mediated cell adhesion depends on endocytic regulation of limited protein pools. We propose that parallel/synergistic endosomal transport of proteins functions as a mechanism to integrate core processes such as cell adhesion and signaling during vertebrate development and explain how disruption of this process could lead to complex neurodevelopmental syndromes observed in humans.

Endosomal PI(3)P Regulation by the COMMD/CCDC22/CCDC933 (CCC) Complex Controls Membrane Protein Recycling.

A. Singla[1], A. Fedoseinenko[2], S. S. P. Giridharan[3], B. L. Overlee[2], A. Lopez[1], D. Jia[4], J. Song[1], K. Huff-Hardy[1], L. Weisman[3], E. Burstein[1], D. D. Billadeau[2]; [1]UT Southwestern Medical Center, Dallas, TX, [2]Mayo Clinic, Rochester, MN, [3]University of Michigan, an n Arbor, MI, [4]Sichuan University, Chengdu, CHINA.

Proper membrane protein recycling through the endolysosomal system relies on a variety of protein complexes that interact with cargo proteins, phospholipid membranes, and effector molecules. The COMMD/CCDC22/CCDC93 (CCC) complex plays a critical role in recycling events by regulating the action of both Retromer and Retriever, two multiprotein complexes that function at endosomes to sort the

cargo proteins either to the Golgi apparatus or to the plasma membrane. However, the mechanism by which the CCC complex can impinge on both pathways remains unexplained. In this study, we show that the integrity of the CCC complex is required to maintain normal levels of phosphatidylinositol-3-phosphate (PI(3)P) within the endosomal compartment. Absence of this complex leads to elevated PI(3)P levels, which we show result in enhanced recruitment and activation of the WASH complex, an actin nucleation promoting factor. Furthermore, this leads to hyper-accumulation of endosomal F-actin and trapping of internalized membrane proteins. Mechanistically, we find that the CCC complex modulates PI(3)P levels by regulating the phosphorylation and endosomal recruitment of the lipid phosphatase MTMR2. Taken together, the CCC complex emerges as a key regulator of endosomal PI(3)P levels that is critical to endosomal cargo recycling pathways.

Rin3 Binds to Bin1 and Cd2ap to Increase App-ctfs in Early Endosomes.

R. Shen[1,2]; [1]Neuroscience department, UCSD, san diego, CA, [2]Neurology departement, Shanghai Ruijin hospital, Shanghai, CHINA.

Background: Alzheimer's Disease (AD) is one of the most common neurodegenerative disorders. Recent genome-wide association studies (GWAS) and meta-analysis have uncovered more than 20 genes as potential risk factors of AD. Among them, RIN3 (the Ras and Rab Interactor 3) is a guanine nucleotide exchange factor (GEF) for the small Rab5 GTPase family and has been implicated as a risk factor for both late onset AD (LOAD) and sporadic early onset AD (sEOAD). However, it remains unknown how expression of RIN3 is linked to AD pathogenesis. **Methods**: Quantitative PCR and immunoblotting were used to measure the RIN3 expression level in brain tissue and cultured basal forebrain cholinergic neurons (BFCNs) from both APP/PS1 transgenic mice and Wild Type (WT) controls. Immunostaining was used to visualize Rab5 positive endosome is cultured primary BFCNs from APP/PS1 mice and WT mice. Recombination RIN3-flag-tagged proteins were expressed and purified from HEK293T cell line. Mass Spectrometry was used to define proteins associated with RIN3. Co-IP, immunofluorescence and yeast two hybrid assays were used to validate these RIN3 interacting partners. Live imaging of mCherry- or GFP-tagged constructs was used to examine axonal transport of APP, BACE1, and immunoblotting was used to detect APP processing under the setting of upregulating either RIN3, or BIN1, or CD2AP expression. $Rab5^{S34N}$ (dominant negative variant) was overexpressed to block Rab5 activity. **Results:** RIN3 mRNA level started elevating from embryonic day 18 in primary APP/PS1 BFCNs. Hippocampus RIN3 started to increase from 3-month-old and cortex RIN3 level elevated from 6-month-old. Upregulated RIN3 in primary BFCNs induced early endosome enlargement. BIN1 and CD2AP, another two LOAD risk factors, were identified by ip-MS. They were proved to interact and colocalize with RIN3 via multiple methods. They were recruited to early endosome rather than late endosome or recycle endosome by RIN3 PRD domain. BIN1 neuronal isoform was decreased in 3-month-old APP/PS1 mice brain, while its ubiquitous isoform was increased. CD2AP protein level just mildly increased. Overexpression of RIN3 and CD2AP promoted APP cleavage and produced more APP CTFs in PC12 cells, while upregulating BIN1 neuronal isoform mildly reduced APP-CTFs production. **Conclusion:** We have discovered that the RIN3 AD risk factor was significantly unregulated that correlated with endosomal dysfunction in neurons of APP/PS1 mouse model of AD. We have also identified that RIN3 recruited BIN1 and CD2APto early endosomes. RIN3 and CD2AP impaired axonal transport of APP and BACE1 in axons and dendrites, enhancing beta-cleavage of APP to increase toxic APP CTFs. Our study has thus defined an important role for RIN3 contributing to AD pathogenesis.

P1298/B428

Spatial and Temporal Intracellular Trafficking of Vascular Endothelial Growth Factor (VEGF) Receptors in Microvascular Endothelial Cells.

J. A. F. Silva, C. Francelin, X. Qi, M. B. Grant, M. E. Boulton; University of Alabama at Birmingham, Birmingham, AL.

Introduction: the vascular endothelial growth factor (VEGF) family is critical for both increased vascular permeability and pathological angiogenesis in a vast number of neovascular diseases like retinopathies. Our group has shown that VEGFRs can shape the neovascular phenotype of vascular endothelial cells when translocated to the nucleus. However, the mechanism of the intracellular trafficking route by which these receptors translocate to and from the nucleus remains unclear. **Aims: to** determine the effect of VEGF on the spatial and temporal translocation of VEGF receptors within microvascular endothelial cells. **Methods:** Primary human retinal microvascular endothelial cells (HREC) were obtained from 2 donors. Near confluent cells were washed 2 times and maintained without growth factors in serum-free medium for 45 minutes. Subsequently, 100ng/ml VEGF165 was added and cells were fixed at 0, 10, 30 and 120 minutes. Cells were immunostained to colocalize VEGFR1 and VEGFR2 with the nucleus, lysosomes, early endosome, trans Golgi, and endoplasmic reticulum (ER). Images were captured by confocal microscopy and the analyses performed on NIS elements and Imaris Software. **Results:** Both VEGFR1 and VEGFR2 were observed at relatively low levels in the nucleus, lysosomes, early endosome, trans Golgi, and ER of control cells not treated with VEGF. Between10 and 30 minutes following VEGF treatment a significant and maximal increase in VEGFR1 and VEGFR2 levels (40 and 60% respectively) were observed in the nucleus when compared to control cells. This increase was associated with a 60% increase in early endosomes and their colocalization with VEGFR2 together with spatial differences in plasma membrane and perinuclear colocalization. Interestingly, the time to reach maximal translocation of receptors to the nucleus was donor dependent. In addition, the increased levels of VEGF receptors in the nucleus were associated with trans Golgi and ER increase (80 and 70% respectively) compared to control. However, this did not change the colocalization coefficients between VEGFR2 and these organelles. By two hours following VEGF treatment, nuclear VEGFR levels had returned to that seen in untreated control cells. At the 2 hour time point a significant, 160% increase in lysosomes was observed in VEGF-treated cells and this increase was associated with increased colocalization with VEGFR2 (Pearson Coefficient >0.9). **Conclusion**: Our data indicates that VEGF stimulation of microvascular endothelial cells activates transcellular transport of VEGFRs to the nucleus via early endosomes and that nuclear VEGFRs are exported and degraded by the lysosomal pathway. The origin of the nuclear VEGFRs appears to be from a combination of plasma membrane receptors and intracellular receptors.

P1299/B429

Creg1 Promotes Endocytic Trafficking and Lysosomal Biogenesis.

J. Chao, J. Liu, Y. Qi, L. Lee, S. Li; Rutgers, the State University of New Jersey, New Brunswick, NJ.

CREG1 promotes endocytic trafficking and lysosomal biogenesis Joshua Chao, Jie Liu, Yanmei Qi, Leonard Y. Lee, Shaohua Li Department of Surgery, Rutgers University-Robert Wood Johnson Medical School, New Brunswick, NJ 08903 CREG1 is a small glycoprotein with a physiological function that remains largely unknown. Contradictory results were reported on its subcellular localization, which is

likely because the antibodies used in those studies were not validated for immunostaining. By using cells overexpressing Myc-tagged CREG1 and tissues of Creg1 knockout mice, we identified two commercially available CREG1 antibodies suitable for immunofluorescence. Using these antibodies, we demonstrate that CREG1 is localized to the early endosome, late endosome, and lysosome in both cultured cells and mouse tissues. Overexpression of CREG1 in hepatocytes enhances macropinocytosis and clathrin-dependent endocytosis as assessed with TRITC-dextran and Alexa 488-transferrin, respectively. This is accompanied by increased expression of lysosomal membrane proteins, proteases, and vacuolar ATPases. As a consequence, amino acid starvation-induced autophagy is significantly augmented. In contrast, deletion of mouse Creg1 in embryonic yolk sac as well as shRNA-mediated knockdown of CREG1 in hepatocytes inhibit endocytosis, reduce lysosomal protein expression, and suppress autophagy. These results demonstrate that CREG1 is an endosomal-lysosomal protein and promotes endocytic trafficking and lysosomal biogenesis.

P1300/B430

Regulation of Osteoclast Function by the Small Gtpase Arl8b.

G. Kumar[1], S. Arya[2], s. sharma[1], h. kaur[1], A. Tuli[1]; [1]CSIR-Institute of Microbial Technology, Chandigarh, INDIA, [2]Life Sciences Institute, University of Michigan, an n Arbor, MI.

Recent studies have established Arl8b-mediated positioning of lysosomes and lysosomes-related organelles as a crucial factor regulating amino acid sensing, cell migration and metastasis, NK cell-mediated cytotoxicity and antigen presentation. Arl8b mediates lysosomal transport to the cell periphery by recruiting its effector, SKIP, which in turn recruits the motor protein kinesin-1 on lysosomes. Arl8b also binds to the Rab7 effector- PLEKHM1, and this interaction repositions Arl8b-positive lysosomes to the perinuclear region of the cell and promotes autophagosomes-lysosome fusion. Interestingly, frameshift mutations in PLEKHM1 result in Osteopetrosis where the bone resorbing functions of osteoclasts is impaired. Osteoclasts resorb bone by secreting their lysosomal contents within the confines of a sealing zone between themselves and the bone surface. Here, we have explored the role of Arl8b in bone remodeling. Arl8b showed a striking localization beneath the actin rings and ruffled borders in osteoclasts, and lysosome secretion was significantly impaired in Arl8b-deficient osteoclasts. Further, unlike control osteoclasts, lysosomes in Arl8b-deficient osetoclasts failed to localize beneath the actin rings or in the ruffled borders. Taken together, our findings establish Arl8b as a crucial component of osteoclast-mediated bone remodeling.

P1301/B431

The Parkinson' Disease Kinase Lrrk2 Promotes Lysosomal Tubulation and Sorting in Ruptured Lysosomes.

L. Bonet-Ponce, A. Beilina, J. H. Kluss, Y. Li, M. R. Cookson; National Institute on Aging, NIH, Bethesda, MD.

Mutations in LRRK2 are a main cause of familial and sporadic Parkinson' disease (PD). Unfortunately, the role of LRRK2 in the cell remains elusive which heavily limits our therapeutic options. We observed that LRRK2 is recruited to a very specific subset of lysosomes in mouse primary astrocytes. Using an unbiased proteomic screening, we identified JIP4 as a LRRK2 interactor in the lysosomal membrane. Since JIP4 has been linked to stress response and LRRK2-positive lysosomes show variable levels of Cathepsin B (CTSB), we hypothesized that the LRRK2:JIP4 complex responds to lysosomal membrane damage. By treating

astrocytes with LLOME (a reagent that permeabilizes the lysosome), we observed a massive increase in LRRK2 recruitment to the lysosomal membrane in a seemingly lysophagy-independent manner. LRRK2 goes to ruptured lysosomes as observed by the lack of LysoTracker and Magic-red CTSB staining. LRRK2 recruits JIP4 to ruptured lysosomes through its kinase activity, since a blockage of active LRRK2 by pharmacological kinase inhibition or using Lrrk2-KO cells impairs the lysosomal recruitment of JIP4. Additionally, unbiased proteomics reveals the presence of RAB10 and RAB35 (known LRRK2 substrates) in LRRK2-positive lysosomes. LRRK2 recruits and phosphorylates both RAB GTPases in the lysosomal membrane, which leads to the subsequent recruitment of JIP4. Using super-resolution microscopy, we detected JIP4-positive tubules associated with lysosomes which could potentially link LRRK2 to lysosomal sorting. Interestingly, JIP4-positive vesicles seem to associate with other lysosomes, which could imply a form of lysosome-lysosome communication. We thus identified a newly described function of LRRK2 promoting lysosomal tubulation and content release, which can potentially have implications in lysosomal homeostasis and PD pathobiology.

P1302/B432

Putative Phase Separation of the Yeast Adaptor Protein 3 Complex.

L. W. Blodgett, J. C. Casler, M. Ray, B. S. Glick; the University of Chicago, Chicago, IL.

The delivery of proteins to cellular compartments is critical for maintaining organelle identity and cell function. Adaptor protein complexes play a vital role in membrane trafficking by selectively packaging cargo proteins into nascent transport vesicles. In budding yeast, adaptor protein 3 (AP-3) facilitates transport of cargo from the late Golgi to the vacuole. While the basic function of AP-3 has been characterized, less is known about the mechanism of AP-3 recruitment and vesicle formation. For instance, it is unclear if yeast AP-3 associates with coat proteins or how AP-3 might stimulate vesicle budding without a coat. Yeast AP-3 localizes to punctate structures that are adjacent to late Golgi elements. We hypothesize that AP-3 structures are not membrane-bound, and may instead represent liquid-like protein droplets in the cytoplasm. To test this idea, we identified an intrinsically disordered region (IDR) in a subunit of yeast AP-3. This IDR is necessary for normal AP-3 function and localization. When fused to oligomeric proteins in the yeast cytoplasm, the AP-3 IDR is sufficient to drive the formation of foci. These foci exhibit properties characteristic of dynamic liquid droplets: they recover fluorescence rapidly after photobleaching, fuse in live cells, and display temperature sensitivity. Our working hypothesis is that the propensity of the IDR to form liquid droplets drives the phase separation of AP-3. The biological role of this behavior remains to be determined. Recent work has shown that disordered domains of peripheral membrane proteins can sense and stimulate membrane curvature. The necessity of the IDR for AP-3 recruitment and function raises the possibility that the AP-3 IDR may curve membranes into budding vesicles in the absence of coat proteins. Alternatively, the AP-3 IDR may promote clustering in order to sequester excess adaptor or to supply adaptor efficiently to transport machinery. Ongoing experiments will explore these possibilities.

Synaptic Vesicles Precursors and Lysosomes Use Distinct Machinery for Axonal Transport.

R. De Pace[1], L. Djavaherian[1], J. Mercurio[1], A. M. Foster[1], D. Britt[1], D. Abebe[1], V. Hoffman[2], J. S. Bonifacino[1]; [1]NIH/NICHD, Bethesda, MD, [2]NIH/Division of Veterinary Resources DVR/DRSB, Bethesda, MD.

The ability of lysosomes to move throughout the cytoplasm is critical for various cellular functions such as autophagy, cell migration, and tumor invasion. This ability is particularly crucial in neurons because of their extreme asymmetry and length of axons and dendrites. We recently discovered an eight-subunit complex named BORC that recruits the small GTPase ARL8, the adaptor protein SKIP, and kinesins-1 and -3 to lysosomes, promoting their movement toward the plus-end of microtubules in the periphery of non-polarized cells. Knock-out (KO) of any of the BORC subunits causes clustering of lysosomes in the pericentrosomal area of the cell. Although no human mutations in the BORC subunits have been reported to date, single nucleotide polymorphisms causing altered expression of the diaskedin (BORCS7) subunit of BORC have been associated with schizophrenia, emphasizing the importance of understanding the function of BORC in neurons. In this regard, a study by another group using *C. elegans* showed that mutation of the myrlysin (BORCS5) subunit of BORC impairs axonal transport of synaptic vesicle precursors (SVPs). To analyze the requirement of BORC for transport of lysosomes and SVPs in mammalian neurons, we used the CRISPR/Cas9 system to generate a myrlysin-KO mouse. We found that the resulting KO embryos grew to term, but the pups died immediately after birth. Pathology analyses identified the cause of death as the inability of the pups to breathe, a problem that could be due to defects in the lungs or the nervous system. To address the importance of BORC in neuronal organelle transport, we prepared cultures of hippocampal neurons from control and myrlysin-KO embryos. The neurons were transfected with plasmids encoding lysosomal and synaptic vesicle markers fused to fluorescent proteins. We found that myrlysin-KO prevented transport of lysosomes into the axon but not the dendrites. In contrast, there was no effect on the transport of SVPs into the axon. An alysis of brain tissues, and neuromuscular junctions at the diaphragm, from WT and KO embryos, confirmed that BORC is necessary for lysosomes, but not for SVPs, to enter the axon and to reach synaptic terminals. These findings indicate that in mouse neurons BORC plays a role in transport of lysosomes but not SVPs into the axon. Neuropsychiatric disorders associated with altered BORC expression could thus result from impaired lysosome transport into the axon.

Lysosomal Functions Play a Critical Role in Restoring Cellular Cholesterol Homeostasis and Quality Control in NPC1-deficient Cells.

B. Song, 37208, A. Singhal, 37208; Meharry Medical College, Nashville, TN.

Niemann-Pick type C (NPC) disease is a fatal neurodegenerative disorder caused by mutations in *NPC1* and *NPC2* genes that result in cholesterol accumulation in lysosomes and a deficiency in cellular quality control. Currently, no FDA-approved therapies exist for NPC and the majority of children with NPC die in adolescence. How the NPC1/2 proteins are involved in the trafficking of lysosomal cholesterol and how the defect in lysosomal cholesterol export leads to neurodegeneration remain largely unknown. Using cell biological and biochemical approaches, we attempted to explore the mechanisms of NPC disease. 2-hydroxypropyl-β-cyclodextrin (HPβCD) is known to rescue lysosomal cholesterol accumulation and is undergoing testing in phase 2/3 clinical trials for NPC disease. However, HPβCD's ototoxicity has been a

major concern in moving it forward as a therapeutic agent. Our recent study and the reports from other laboratories showed that 2-hydroxypropyl-γ-cyclodextrin (HPγCD) alleviates cholesterol accumulation in NPC1-deficient cells in spite of its low binding affinity for cholesterol. To understand the mechanisms of NPC disease, we explored the cellular changes that are induced upon HPγCD treatment in NPC1 patient-derived fibroblasts. Here, we show that cell treatment with HPγCD results in the enhancement of lysosomal functions and an improvement in cholesterol homeostasis and cellular quality control. Interestingly, HPγCD administration induced the activation of the transcription factor EB (TFEB), a master regulator of lysosomal biogenesis and autophagy. Furthermore, our study indicates that HPγCD treatment restores the homeostasis of the lysosomes and endoplasmic reticulum and an increase in autophagy in NPC1-deficient cells. In summary, our study suggests that lysosomal functions play a critical role in restoring cellular cholesterol homeostasis and quality control in NPC1-deficient cells Understanding the HPγCD-induced cellular pathways or proteins could assist in developing effective therapies for NPC disease.

The Gator Complex Regulates the Lysosomal Dynamics of the Torc1 Inhibitor Tsc.

S. Yang, Y. Zhang, L. Bettedi, C. Ting, M. Lilly; National Institutes of Health, Bethesda, MD.

Tuberous sclerosis is a rare multiorgan genetic disorder affecting 1 in 6000 newborns per year. It is caused by mutations in the genes of the subunits of the Tuberous sclerosis complex (TSC), one of the inhibitors of the Target of Rapamycin Complex I (TORC1). Mutations in TSC components result in the hyperactivation of TORC1, which causes the growth of benign tumors in many parts of the body. Although the importance of the TSC in cell metabolism has been well established, how it is regulated remains poorly understood. In this study, we use the experimental of *Drosophila melanogaster* and tissue culture cells, to show that the Gap Activity Towards Rags (GATOR) complex is a novel regulator of TSC. The GATOR complex acts as an upstream regulator of TORC1. It contains two subcomplexes. The GATOR1 complex inhibits TORC1 in response to amino acid starvation. The GATOR2 complex promotes TORC1 activity by inhibiting the function of GATOR1. GATOR1 inhibits the activity of TORC1 by preventing the recruitment of the complex to lysosomes where it encounters its activator Rheb. Specifically, GATOR1 regulates TORC1 localization by serving as a GTPase activating protein for RagA/B, which in their GTP bound status, recruit TORC1 to lysosomes. Using Fluorescence Recovery After Photobleaching (FRAP) we determined that knocking out WDR24, one of the subunits of the GATOR2 complex, resulted in the increased recruitment of the TSC subunits TSC2 and TSC1 to lysosomes, both in Hela cells and in *vivo* in the *Drosophila* ovary. Furthermore, we demonstrated that the GATOR2 complex regulates TSC2 dynamics through the regulation of the guanine nucleotide binding status of the RagA or RagC small GTPases. Specifically, the GDP bound RagA and the GTP bound RagC promotes the recruitment of TSC2 to lysosome. Moreover, by using a photoconvertible protein tagged TSC2, we determined the fast binding of TSC2 to lysosome in *wdr24*$^{-/-}$ cell is accompanied by its rapid dissociation from lysosome. Taking together, we provide both in *vitro* and in *vivo* evidence to support that the GATOR complex regulates TSC's dynamic cycling between lysosome and cytoplasm and its ability to inhibit TORC1 activity.

P1306/B436

Fast Targeting of Antigen and Surface-derived MHCII into Degradative Compartments Implies Endosomal Prewiring for Antigen Presentation in B Cells.

S. Hernandez-Perez[1], M. Vainio[1], V. Sustar[1], V. Paavola[1], P. Petrov[1], A. Bruckbauer[2], **P. K. Mattila**[1]; [1]University of Turku, Turku, FINLAND, [2]Imperial College, London, UNITED KINGDOM.

In order to mount high-affinity antibody responses, B cells internalise specific antigens and process them into peptides loaded onto MHCII for presentation to T_H cells. While the biochemical principles of antigen processing and MHCII loading have been well dissected, how the endosomal vesicle system is wired to enable these specific functions remains much less studied. Here, we performed a systematic microscopy-based analysis of antigen trafficking in B cells to reveal its route to the MHCII peptide-loading compartment (MIIC). Surprisingly, we detected fast targeting of internalised antigen into peripheral acidic compartments that possessed the hallmarks of MIIC and also showed degradative capacity. In these vesicles, internalised antigen converged rapidly with membrane-derived MHCII and partially overlapped with Cathepsin-S and H2-M, both required for peptide loading. These early compartments appeared heterogenous and atypical as they contained a mixture of both early and late markers, indicating specialized endosomal route. Together, our data suggests that, in addition to previously-reported perinuclear late endosomal MIICs, antigen processing and peptide loading could start already in these specialized early peripheral acidic vesicles to support fast peptide-MHCII presentation.

P1307/B437

USP19 Cooperates with DNAJC5 to Promote Unconventional Secretion of Misfolded Cytosolic Proteins through Non-Degradative Endolysosomes.

J. Lee, Y. Ye, Y. Xu; NIDDK/NIH, Bethesda, MD.

Elimination of misfolded proteins is essential for the integrity of the protein homeostasis network and for cell viability in eukaryotic cells. Misfolding-associated protein secretion (MAPS) is an unconventional protein-disposing mechanism that specifically exports misfolded cytosolic proteins including some neurodegenerative disease-causing proteins such as alpha-Synuclein and TAU. However, how MAPS cargos are selected for release into the cell exterior is unclear. Here we establish a deubiquitinase (USP19)-chaperone (DNAJC5) axis as a 'triaging hub' for MAPS cargos. USP19, a previously established MAPS regulator binds HSC70 at the surface of the endoplasmic reticulum (ER), which collectively recruits misfolded proteins to the ER surface. This event occurs upstream of DNAJC5, a HSC70 co-chaperone preferentially localized to the surface of late endosomes/lysosomes. Following substrate recruitment to the ER membranes, DNAJC5 can chaperone MAPS client proteins into the lumen of endolysosomes, which are often in close contact the ER network. Misfolded proteins are then secreted from late endosomes presumably because vesicles derived from late endosomes can fuse with the plasma membrane. We further determined the mechanism by which DNAJC5 translocates MAPS cargos into the endolysosomal lumen, which is distinct from the previously established chaperone-mediated autophagy (CMA) pathway because unlike the CMA pathway, the secretion of misfolded proteins in MAPS does not require cargo unfolding, is inhibited by serum starvation, and is not dependent on the CMA motif in cargos. Finally, upon secretion, misfolded proteins can be taken up by recipient cells through endocytosis and eventually degraded in the lysosome. We conclude that MAPS is a novel protein quality control mechanism that promotes protein homeostasis by exporting misfolded proteins to cell exterior

when excessive proteotoxic stress overwhelms the protein homeostasis network. However, when mis-regulated, this process may contribute to the intercellular transmission of misfolded proteins that are often associated with the progression of many neurodegenerative diseases.

P1308/B438

Regulation of Vacuolar Membrane Integrity by a Protein Trafficking Complex in Yeast Cell Death.

Z. D. Stolp[1], S. Lin[1], M. Kulkarni[1], F. Pineda[1], X. Teng[2], J. Hardwick[1]; [1]Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, [2]Soochow University, Suzhou, CHINA.

Fungal pathogens are a growing concern with an estimated 1 billion infections and 1.5 million deaths annually. In addition, plant fungal pathogens increasingly threaten global food sources. Limited treatment options and rising resistance to available drugs underscore the need for development of new approaches to combat this growing public health threat. The topic of microbial cell death has been controversial, but growing evidence on several fronts has demonstrated, at least for some fungi, cell death is required (e.g. *Magnaporthe* and *Podospora*). Elucidation of previously unrecognized cell death mechanisms using *Saccharomyces cerevisiae* as a tool could provide a new platform for the development of novel therapeutics. Using a genome-wide screen, we have identified a clathrin adaptor protein trafficking complex (AP-3) as a critical factor in limiting yeast survival after thermal stress; deletion of any AP-3 subunit results in profound increased survival following some but not all types of stress. The complex has a conserved established function in sorting protein cargo for vesicular trafficking from the Golgi apparatus to the yeast vacuole/lysosome and its role in regulating cell death in yeast after stress appears to require this trafficking function. We show that heat induced death is preceded by vacuolar permeabilization and that loss of AP-3 function protects cells. These results are consistent with a hypothesis that AP-3 sorts “killer” proteins that control stress-induced vacuolar lysis.

P1309/B439

Single Cell an alysis of Vacuolar Ph Using Confocal Microscopy.

A. Godoy[1], M. Chan[1], R. C. Segura[1], J. Campos[1], J. Calma[2]; [1]San Francisco State University, San Francisco, CA, [2]UC Berkeley, Berkeley, CA.

In order for ion storage, protein degradation and protein folding to occur properly, vacuolar pH must lie within a specific range. Due to the breadth of the vacuoles function, pH regulation has direct implications in cellular age. This impact could provide insight into human diseases such as lysosomal storage diseases and Alzheimer’s disease. Despite this, there have been few studies to directly observe to what extent vacuolar pH impacts other vacuolar phenotypes. In our previous work, we have observed vacuolar pH via confocal microscopy to collect single-cell data using the pH-sensitive vacuolar dye, BCECF-AM. However, the use of this dye resulted in data with high levels of variance, which has led to inconclusive results. To rectify this, we have developed a fluorescent protein tag that utilizes an eGFP-mCherry double tag, which allows us to measure vacuolar pH without the use of dyes. This tag works similar to other pH-sensitive dyes, leading us to hypothesize that our protein tag will yield similar results to our previous findings. In this work, we compare the effectiveness of this protein tag to our previous findings with BCECF-AM. Our preliminary results show that this protein tag has a similar pH indicator range to other pH probes, and is more stable than other probes, highlighting its advantages as a pH indicator. Taken together, our findings show that our double-tag indicator has the potential to provide

better quality data, which will allow us to further understand the impact of vacuolar pH on other cellular functions.

ER and Golgi Transport

Mutations in the core-TRAPP subunit *TRAPPC4* are associated with severe syndromic intellectual disability and affect both membrane traffic and autophagy.

N. Van Bergen[1], Y. Guo[2], N. Al-Deri[3], Z. Lipatova[4], D. Stanga[3], D. Pehlivan[5], T. Mitani[5], J. Lupski[5], **M. Sacher**[3,6], N. Segev[4], H. Hakonarson[2], J. Christodoulou[1]; [1]Royal Children's Hospital, Melbourne, AUSTRALIA, [2]Children's Hospital of Philadelphia, Philadelphia, PA, [3]Concordia University, Montreal, QC, CANADA, [4]UIC, Chicago, IL, [5]Baylor College of Medicine, Houston, TX, [6]McGill University, Montreal, QC, CANADA.

The transport protein particle (TRAPP) complexes II and III regulate key trafficking events and TRAPP III is also required for autophagy. TRAPPC4 is a core component of the TRAPP complexes and one of the essential subunits for guanine nucleotide exchange factor activity. Pathogenic variants in specific TRAPP subunits are associated with neurological disorders. We undertook whole exome sequencing in three unrelated families of Caucasian, Turkish and French-Canadian ethnicities with seven affected children with features of early onset seizures, developmental delay, microcephaly, sensorineural deafness, spastic quadriparesis and progressive cortical and cerebellar atrophy in an effort to determine the genetic etiology. In all seven affected individuals we identified a rare homozygous variant in a non-canonical well-conserved splice site within TRAPPC4 (hg19:chr11:g.118890966A>G; TRAPPC4: NM_016146; c.454+3A>G). In silico analysis predicted the variant to cause aberrant splicing. Consistent with this, we showed both a reduction in full-length transcript and a shorter transcript missing exon 3, suggestive of an incompletely penetrant splicing defect. TRAPPC4 protein levels were significantly reduced and biochemical analysis demonstrated a defect in TRAPP complex assembly and/or stability. Intracellular trafficking demonstrated significantly delayed entry into and exit from the Golgi in fibroblasts derived from one of the affected individuals that was rescued upon lentiviral expression of wildtype TRAPPC4. Consistent with the recent association of the TRAPP III complex in autophagy, we found that the fibroblasts had a basal autophagy defect and a delay in autophagic flux, likely due to unsealed autophagosomes. These results were validated using a yeast *trs23* temperature sensitive mutation that exhibits constitutive and stress-induced autophagic defects at permissive temperature and a secretory defect at restrictive temperature. Our study suggests that reduced levels of TRAPPC4 affect both autophagy and membrane trafficking. This is the first report of a TRAPPC4 disease-associated variant and our findings add to the growing number of TRAPP-associated neurological disorders.

P1311/B441

Efficient Golgi Forward Trafficking Requires GOLPH3-Driven, PI4P-Dependent Membrane Curvature.

J. Rahajeng, R. S. Kuna, S. L. Makowski, T. T. T. Tran, M. D. Buschman, S. Li, N. Cheng, M. M. Ng, **S. J. Field**; University of California, San Diego, La Jolla, CA.

Vesicle budding for Golgi-to-plasma membrane trafficking is a key step in secretion. Proteins that induce curvature of the Golgi membrane are predicted to be required, by analogy to vesicle budding from other membranes. Here, we demonstrate that GOLPH3, upon binding to the phosphoinositide PI4P, induces

curvature of synthetic membranes in vitro and the Golgi in cells. Moreover, efficient Golgi-to-plasma membrane trafficking critically depends on the ability of GOLPH3 to curve the Golgi membrane. Interestingly, uncoupling of GOLPH3 from its binding partner MYO18A results in extensive curvature of Golgi membranes, producing dramatic tubulation of the Golgi, but does not support forward trafficking. Thus, forward trafficking from the Golgi to the plasma membrane requires the ability of GOLPH3 both to induce Golgi membrane curvature and to recruit MYO18A. These data provide fundamental insight into the mechanism of Golgi trafficking and into the function of the unique Golgi secretory oncoproteins GOLPH3 and MYO18A.

P1312/B442

Utilizing Crispr/Cas Editing to Tag Endogenous COL1A2 in Order to Visualize Intracellular Trafficking and Quality Control of Procollagen in Osteoblasts.

L. Gorrell[1,2], S. Omari[1], E. Makareeva[1], S. Leikin[1]; [1]National Institute of Child Health and Human Development, NIH, Bethesda, MD, [2]Rensselaer Polytechnical Institute, Troy, NY.

The intracellular trafficking of type 1 collagen, despite being the most abundant protein in the human body, is still poorly understood. Procollagen has been shown to accumulate in the ER and disruptions in procollagen secretion are implicated in several connective tissue disorders. The mechanisms underlying these defects and the resulting cell stress remain unclear. The mechanisms of procollagen secretion and quality control have been probed using transient overexpression of fluorescently- tagged procollagen chains. Live cell imaging revealed many unknown features of procollagen trafficking including an unexpected composition of vesicles trafficking procollagen from ER to Golgi as well as a non-canonical autophagic pathway that redirects misfolded procollagen from ER exit sites to lysosomal degradation. Transient transfections are limited in temporal resolution as well as have varying levels of expression per cell. We are limited in the questions that can be answered using this tool. Here, we used CRISPR/Cas to knock in GFP cDNA into the endogenous *Col1a2* gene in an MC3T3 mouse osteoblast cell line, replacing a stretch of gDNA from the middle of exon 2 to the middle of exon 6 to retain endogenous splice sites. In the resulting proα2(I) chain of type I procollagen, GFP replaces most of the N-terminal propeptide. Unique FRT sites were placed in introns 1 and 6 of *Col1a2* to enable *Flp*-recombinase mediated cassette exchange (*Flp*-RMCE) of the GFP cDNA with other tags. Several heterozygous clones were obtained. We identified the clones that produced normal heterotrimers of type I procollagen and formed a bone-like mineralized matrix for use in future studies. We are currently using a similar technique to introduce common pathogenic mutations in *Col1a2* to create cell lines that could be used for systematic studies of the pathophysiology of osteogenesis imperfecta mutations. We are also using the cell line to investigate the role of various genes implicated in new cases of skeletal dysplasia like *Creb3L1*.

P1313/B443

Uncoating of CopII from Endoplasmic Reticulum Exit Site Membranes Precedes Cargo Accumulation and Membrane Fission.

O. Olga Shomron[1], A. A. Mironov[2], C. Kaether[3], **K. Hirschberg**[1]; [1]Tel Aviv University, Tel Aviv, ISRAEL, [2]IFOM, Fondazione Istituto FIRC, Milan, ITALY, [3]Leibniz Institute for Age Research - Fritz Lipmann Institute, Jena, GERMANY.

COPII and COPI are considered to be analogous sets of vesicle coat protein heterocomplexes. Coupled to cargo selection, they mediate the formation of membrane vesicles translocating in opposite directions

to different destinations within the secretory pathway. Here, live cell imaging and electron microscopy provided direct evidence for a different localization and mode of function of the COPII coat during protein export from the endoplasmic reticulum (ER). We have studied the ER export of fluorescently tagged Vesicular Stomatitis Virus G as well as CFTR and procollagen I. Pharmaceutical and genetic perturbations of ER-Golgi transport were used to demonstrate that COPII is recruited to membranes defining the boundary of ER-ER Exit Sites (ERES). Within this ER-ER Exit Sites boundary the COPII heterocomplex facilitates selective cargo concentration in ERESs membranes. Thus, the uncoating of COPII from ERESs membranes precedes cargo accumulation and the budding of Golgi-bound carriers. Moreover, we report what may be direct transfer of cargo to the Golgi apparatus from Golgi-associated BFA-sensitive subpopulation of ERESs. Finally, in *ldlF* cells the stably expressed functional epsilon-COPI-EYFP labeled both ERESs and anterograde carriers. Thus, we demonstrate an alternative model of how the COPII complex orchestrates the functions of the ERES domain. We propose two distinct mechanisms that together facilitate the selective cargo entry into ERESs. The first is the known cytosolic cargo export motif interaction with the COPII Sec24subunit. The second is based on alleviation of mismatching interactions of cargo protein TMD with its surrounding membrane. These findings change our understanding of the role of coat proteins in ER to Golgi transport.

P1314/B444

ALS/FTD-linked UBQLN2 Mutations Result in Aberrant Serpin Accumulation.

J. E. Greenslade, N. R. Higgins, J. J. Wu, M. D. Tatman, M. J. Monteiro; University of Maryland-Baltimore, Baltimore, MD.

Missense mutations in *UBQLN2*, encoding a protein that functions in protein quality control, cause X-linked dominant amyotrophic lateral sclerosis (ALS) with frontal temporal dementia (FTD). However, the mechanism(s) by which the mutations cause disease remains unclear. To gain insight into the pathophysiologic mechanisms driving disease, we generated lines of transgenic (Tg) mice expressing either wild-type human UBQLN2 (WT356 line) or carrying the P497S ALS/FTD mutation (P497S line). The P497S line recapitulated key features of the human disease, including development of age-dependent motor neuron disease, cognitive impairments, and pathologic accumulation of UBQLN2 inclusions in the spinal cord and brain. These symptoms and pathology were largely absent in the WT356 line, despite equivalent transgene expression. A comparison of the proteomic changes in the hippocampus and spinal cord of the animals revealed several members of the serpin protein family as being more highly expressed in P497S animals compared to either WT356 or Non-Tg animals. Serpins are a diverse group of intracellular and secreted proteins that function primarily in serine protease inhibition. They entrap and destroy proteases through a conformational switch of the protein. However, this metastability makes them highly prone to misfolding and polymerization, causing diseases termed serpinopathies. We examined the possibility that ALS/FTD mutations in UBQLN2 perturb proteostasis causing serpins to misfold. Indeed, double immunofluorescent confocal microscopy revealed colocalization of Serpin A1 and C1 with UBQLN2 inclusions that form in the hippocampus and spinal cord of P497S mutant mice, while Serpin I1 formed inclusions independent of UBQLN2 colocalization. Additionally, serpins A1, B1, C1 and I1 all showed an age dependent accumulation. To investigate the aberrant aggregation of serpins we conducted GST-pulldown assays examining whether UBQLN2 binds serpins. We also studied the effects of CRISPR/Cas9-targeted inactivation of UBQLN2 on serpin aggregation. Our findings indicate UBQLN2 binds directly with serpin proteins, and that ALS/FTD mutations in UBQLN2 enhance binding with the proteins. Furthermore, knockout of UBQLN2 expression in HeLa and NSC motor neuron cells

resulted in increased aggregation of serpins. These studies are consistent with ALS/FTD mutations in UBQLN2 causing aberrant serpin accumulation through both a gain- and loss-of-function mechanism. Taken together, our studies have identified a novel function of UBQLN2 in proper regulation of serpin expression and show that misaggregation of serpin proteins is a pathologic consequence of UBQLN2 mutations.

P1315/B445

Bad-lamp Controls Human Tlr9 Access To, and Generation Of, Signaling Endosomes in Plasmacytoid Dendritic Cells in Response to Innate Sensing.

E. Gatti; CNRS-CIML, Marseille, FRANCE.

Toll-like receptors (TLR) are essential components of the innate immune system. Several accessory proteins, such as UNC93B1, are required for transport and activation of nucleic acid sensing Toll-like receptors in endosomes We have demonstrated[1] that, upon microbial activation of human plasmacytoid dendritic cells (pDC) BAD-LAMP (LAMP5) controls traffic and activatory processing of TLR9 via an unconventional secretion route, from ERGIC to LAMP1+ late endosomes. As a result, a fine-tuned bimodal signaling leads first to IRF-driven Interferon type I production, rapidly replaced by NF-κB -driven pro-inflammatory response. The specific and sequential recruitment of signaling complex components occurs thanks to the appearance of a VAMP3+/LAMP2+/LAMP1− endolysosome compartment. BAD-LAMP-silencing enhances TLR9 retention in this post-ERGIC compartment and consequent downstream signaling events. Conversely, sustained BAD-LAMP expression in pDCs contributes to their lack of type I IFN production after exposure to a TGF-β-positive microenvironment or isolation from human breast tumours. Hence, BAD-LAMP limits interferon expression in pDCs indirectly, by promoting TLR9 sorting to late endosome compartments at steady state and in response to immunomodulatory cues. 1.Combes et al.(2017) *Nature Communications*, *8*(1), 913. http://doi.org/10.1038/s41467-017-00695-1

P1316/B446

Regulation of Protein Transport into the E.R. By Phosphorylation of the β-subunit of the Sec61 Channel.

G. Barbieri[1], K. Römisch[1], M. Schuldiner[2], D. Nguyen[1], V. Helms[1]; [1]Saarland University, Saarbrücken, GERMANY, [2]Weizmann Institute, Rehovot, ISRAEL.

The beta subunit of the Sec61 channel is phosphorylated in both yeast and mammals. We asked whether phosphorylation of yeast Sbh1p is used to modulate channel activity as a fast response to acute needs. In the cytosolic domain of yeast Sbh1p, 7 sites have been found phosphorylated in different combinations in phosphoproteome screens. At the Sbh1p N-terminus there are 2 proline flanked phosphorylation sites -S3 and T5-, of which T5 is conserved in mammalian Sec61β. Neither is present in yeast Sbh2p, which is the β subunit of the Sec61 homologous Ssh1 channel. The aims of my project are to identify the effects of Sbh1p phosphorylation on Sec61 channel functions and the kinases responsible for this modification. In addition, I have been identifying the proteins whose ER import is affected by Sbh1p phosphorylation, to characterize their ER targeting sequences. Sbh1p is the only non-essential subunit of the Sec61 channel. To identify ER translocation substrates dependent on the presence of Sbh1p and the substrates whose ER import depends on Sbh1 phosphorylation, I performed an automated microscopic screen in yeast on ER import or membrane insertion of 400 secretory and transmembrane proteins tagged with GFP. At the same time, for the identification of the kinase and

phosphatase responsible for phosphorylation and dephosphorylation of Sbh1p we performed a microscopic screen on all yeast kinase and phosphatase knockouts and overexpression mutants expressing a GFP-tagged, Sbh1p phosphorylation-dependent substrate. We were able to identify 45 Sbh1p-dependent ER translocation substrate, as well as 7 Sbh1p phosphorylation-dependent ER translocation substrates, which were also Sbh1p-dependent. Sbh1-dependence was confirmed by Western Blotting for cytosolic precursors in sbh1 mutant strains. We have found that signal peptides dependent on Sbh1p for ER import had less polar C-regions than generic signal peptides. Transmembrane domains (TMD) dependent on Sbh1p had strong polybasic patches to one side of the TMD. Sbh1p-phosphorylation-dependent targeting sequences were subsets of these, whose features we are currently characterizing both by bioinformatics and experimentally. We were also able to identify 13 potential kinases responsable for the phosphorylation of Sbh1p, and we are optimizing a method, using Phos-Tag gels, to enable us to identify by differential gel migration the kinase and phosphatase responsable for modifying Sbh1p. We also raised an antibody against the S3-phosphorylated N-terminus of Sbh1p which allows us to analyze the conditions leading to this modification. This work will allow us to understand the feedback loop between biosynthetic protein import into the ER, the UPR, and kinase signaling.

P1317/B447

An Optical Assay to Study Proteotoxic-induced Chromosome Duplication.

D. K. Lam, S. E. Neal, Y. Slaiwa, M. P. Flagg, A. Kao, R. Y. Hampton; UC San Diego, La Jolla, CA.

The Hampton lab has recently shown that the ER-resident rhomboid derlin Dfm1 is required for removal of misfolded proteins from the ER membrane. In cells lacking Dfm1, misfolded proteins accumulate and cause proteotoxic stress. In response, cells undergo an alternative clearance mechanism for misfolded proteins through aneuploidy-induced duplication of chromosome XV. To establish a readout of chromosome XV duplication, we have integrated green fluorescent protein (GFP) optical reporter onto chromosome XV. Cells with an extra copy of chromosome XV exhibit double the fluorescence of those with a single copy. Accordingly, we are able to use this as a tool to study how yeast use chromosome duplication, as indicated by colony fluorescence, to overcome cellular stress caused by misfolded proteins. This strain allows for a straightforward optical assay to genetically define components of the stress response in Dfm1-deficient cells. In this way, we aim to characterize mechanisms responsible for this novel form of protein quality control in the ER membrane.

P1318/B448

Investigating the Trafficking of Glycosylation Enzymes within the Golgi Apparatus.

L. G. Welch, J. J. H. Shin, F. Begum, S. Munro; MRC Laboratory of Molecular Biology, Cambridge, UNITED KINGDOM.

The Golgi apparatus is a major site of glycan processing in the cell which is carried out by a large family of Golgi-resident glycosylation enzymes. These enzymes are generally type II transmembrane proteins with short cytosolic tails at their N-terminus, relatively short transmembrane domains (TMD) and a disordered lumenal ‘stem’ region followed by a catalytic domain. Recent work has suggested the tail and TMD operate via distinct mechanisms to promote the packaging of enzymes into retrograde COPI vesicles to facilitate Golgi retention. It is proposed that it is energetically favourable for the short TMDs of enzymes to segregate into the compatibly thin membranes of budding COPI vesicles. Meanwhile, the

tails of only a handful of enzymes have been shown to interact with COPI coats directly or indirectly via the putative COPI adaptor GOLPH3. What is not clear is the extent and relative contribution of each proposed mechanism to Golgi retention. Using affinity chromatography and mass spectrometry, we confirm GOLPH3 and close relative GOLPH3L can interact with COPI and we also identify a plethora of novel potential GOLPH3+3L clients. Using LOPIT-DC spatial proteomics, we demonstrate that in GOLPH3+3L double knockout U2OS cells a number of these clients are mislocalised from the Golgi to the lysosome for degradation. Cell surface lectin stains show that knockout cells exhibit global defects in glycosylation. We use a flow cytometry-based in *vivo* Golgi retention assay to demonstrate that the tail of a novel client is sufficient for the Golgi retention of a plasma membrane reporter in a GOLPH3-dependent manner. Furthermore, using the same assay we show that the short TMD of the same enzyme is also sufficient for Golgi retention in a more robust, GOLPH3-independent manner. In conclusion, we show that the tail and TMD of Golgi enzymes promote Golgi retention via distinct, complementary and additive mechanisms. We also identify and validate a vast array of novel GOLPH3+3L clients and in doing so, demonstrate that GOLPH3+3L are important for the trafficking of a large proportion of Golgi-resident transmembrane proteins including Golgi enzymes.

Conditional Genetic Inactivation of Nonmuscle Myosin II in Mouse Renal Epithelium Results in Aberrant Er Processing of Gpi-anchored Protein Uromodulin.

K. L. Otterpohl[1], I. Ratnayake[2], R. G. Hart[1], B. W. Busselman[1], P. Ahrenkiel[2], K. Surendran[1], I. Chandrasekar[1]; [1]Sanford Research, Sioux Falls, SD, [2]South Dakota School of Mines and Technology, Rapid City, SD.

Conditional genetic inactivation of Nonmuscle Myosin II in adult mouse renal epithelium results in aberrant ER processing of GPI-anchored protein uromodulin. Karla L. Otterpohl, Ishara Ratnayake, Ryan G. Hart, Brook W. Busselman, Phil Ahrenkiel, Kameswaran Surendran and Indra Chandrasekar Nonmuscle myosin II isoforms are actin-associated molecular motors that play key roles in multiple biological processes. We previously demonstrated critical roles for NMII isoforms encoded by the *Myh9* and *Myh10* genes in membrane remodeling during mammalian endocytosis. To identify the roles of NMII proteins in specialized cellular transport pathways, we used mouse kidney as the model system. We generated doxycycline inducible, conditional knockout (cKO) mice in which the *Myh9* (NMIIA) *and Myh10* (NMIIB) genes are simultaneously inactivated in the renal epithelium of adult mice. The Myh9&10 cKO mice show progressive renal tubular dilatation, interstitial hypercellularity and mild fibrosis leading to chronic kidney disease. The *Myh9&10* cKO mouse kidneys show progressive mislocalization and eventual loss of thick ascending limb (TAL) specific, GPI-anchored protein uromodulin and reduced expression of $Na^+K^+2Cl^-$ co-transporter (NKCC2). Histopathology in the cKO animals is similar to that of uromodulin associated autosomal dominant tubulointerstitial kidney disease. In transgenic mouse models, expressing mutant uromodulin, disease progression is driven by increased endoplasmic reticulum (ER) stress caused by retention of the mutant protein in the ER, eliciting an unfolded protein response (Bernascone et.al, 2010). Immunoblot analysis using whole kidney lysates in the Myh9&10 cKO animals showed increased levels of the non-glycosylated, immature form of uromodulin. We hypothesized that loss of Myh9 and Myh10 results in aberrant anterograde trafficking of uromodulin through the ER, resulting in accumulation of uromodulin. Transmission electron microscopy analysis of cKO kidney tissues showed abnormal ER expansion, increased vacuoles and intracellular vesicles. Immunostaining for the ER marker Concanavalin a showed abnormalities in ER

structure in both the proximal and TAL renal epithelial cells in the kidney. Interestingly, immunostaining results showed mislocalization of the N-glycosylated protein chaperone calnexin, only in uromodulin expressing epithelial cells. The unfolded protein response pathway is being evaluated in the cKO mouse model. We conclude that Myh9 and Myh10 proteins play key roles in regulating transport of the GPI-anchored protein uromodulin. Ongoing studies involve evaluating the role of NMII proteins in ER mediated anterograde transport pathways using the cKO mouse models and a novel TAL epithelial cell culture system developed in the lab.

BioID-based Screening of Biotinylation Sites Using Tamavidin 2-REV Globally Identifies Interactors of Stimulator of Interferon Genes (STING).

K. Motani, **H. Kosako**; Fujii Memorial Institute of Medical Sciences, Tokushima University, Tokushima, JAPAN.

Stimulator of interferon genes (STING), an endoplasmic reticulum (ER)-resident membrane protein, mediates cytosolic DNA-induced innate immune signaling via vesicle-mediated trafficking. After activation by ligand binding, STING moves from the ER through the Golgi apparatus to endosomes and lysosomes. Global identification of proteins that spatiotemporally interact with STING will provide a better understanding of the molecular basis of this organelle translocation and whole signaling networks of STING. The proximity-dependent biotin identification (BioID) method is a powerful technology to identify physiologically relevant protein-protein interactions as well as proximate proteins in living cells. However, biotinylated peptides are rarely detected in the conventional BioID method using streptavidin beads that pull-down biotinylated proteins, because biotin-streptavidin interaction is too strong to elute biotinylated peptides. As a result, only non-biotinylated peptides are identified, which cannot be distinguished from peptides of non-specifically pull-downed false positive proteins. Here we developed a simple method to efficiently and specifically enrich biotinylated peptides using Tamavidin 2-REV, an engineered avidin-like protein with reversible biotin-binding capacity. From RAW264.7 macrophages stably expressing TurboID-fused STING, we successfully identified over 2,500 biotinylation sites on proteins that are proximal to and/or interact with STING. While various ER proteins were biotinylated in unstimulated cells, STING activation caused biotinylation of many proteins localized in the Golgi, endosomes, and lysosomes. These proteins included previously known interactors of activated STING, such as TANK-binding kinase 1 (TBK1) and p62/SQSTM1. Furthermore, interferon-induced transmembrane protein 3 (IFITM3), an endolysosome-localized antiviral protein, bound to STING at the late activation stage. These dynamic interaction profiles may provide a new insight into the STING signaling, and our approach using Tamavidin 2-REV would enable researchers to utilize BioID and other identification methods based on protein biotinylation more effectively.

Analysis of the Molecular Mechanisms That Regulate Export of a Planar Cell Polarity Protein, Frizzled6, Out of the Endoplasmic Reticulum.

X. TANG, T. MA, Y. GUO; HONG KONG University of Science and Technology, Hong Kong, HONG KONG.

Planar cell polarity (PCP) is defined as a polarization process in which cells are polarized along the plane of the tissue. PCP plays important roles in many developmental processes and defects in PCP cause various diseases including cancer metastasis. PCP is regulated by signaling receptors which are

asymmetrically localized in cell boundaries. Newly synthesized PCP proteins are delivered along the secretory transport pathway from the endoplasmic reticulum (ER) to the plasma membrane. However, the molecular mechanisms that regulate this transport process remain largely unclear. Here, we analyzed the export of a PCP protein, Frizzzled6, out of the ER. We found that Frizzled6 contains two conserved polybasic motifs: one located on its first intracellular loop and the other located on its C-terminal cytosolic domain. These motifs are important for the interaction between Frizzled6 and the Coat protein complex II (COPII) coat, an important protein complex that regulates packaging cargo proteins at the ER. We found that the Sar1A subunit of the COPII coat directly interacts with the polybasic motif on the first intracellular loop of Frizzled6. A synthetic peptide that corresponded to the first intracellular loop of Frizzled6 blocked vesicular release of Frizzled6. These results demonstrate the importance of the polybasic motif for ER export of Frizzled6. We also identified two N-glycosylation sites on Frizzled6 luminal domain, which are important for ER export of Frizzled6. Moreover, our immunofluorescence data and vesicle immuno- isolation data indicate that another PCP receptor, Celsr1 is in the same vesicle with Frizzled6, and promote surface delivery of Frizzled6, suggesting that these two PCP proteins are associated with each other in the early secretory transport pathway en route to their final destinations. Our results reveal an insight into the molecular machinery that regulates ER export of Frizzled6.

P1322/B452

Characterizing the Role of Jagunal Homolog 1 Protein in Vertebrate Physiology.

P. E. VanWinkle, P. Stasiak, H. Thomas, E. Lee, T. Nawara, D. Kuna, J. Parant, E. Sztul; University of Alabama- Birmingham, Birmingham, AL.

The highly conserved endoplasmic reticulum protein Jagunal (JAGN1) was first identified as a requirement for Drosophila melanogaster oocyte growth. Subsequently, mutations in JAGN1 in human patients with Severe Congenital Neutropenia (SCN) were correlated with defects in neutrophils, including altered granules, diminished fungal-killing capacity, and aberrant glycosylation of proteins. SCN patients also exhibit aberrant bone development and altered neurological and pancreatic functions. Yet, despite its physiological importance, the cellular role of JAGN1 is not known. We chose the zebrafish (*Danio rerio*), and mammalian cells in culture as models to address the general and tissue-specific molecular functions of JAGN1. The zebrafish is an optimal model to study developmental biology of neutrophils and other tissues, as zebrafish larvae are transparent and can be used to visualize transgenically fluorescent tissue development. Zebrafish have two homologs of human JAGN1: JAGN1a and JAGN1b. This provides an additional advantage since each may have a distinct function and define distinct molecular mechanisms of JAGN1 action. We have used CRISPR-Cas9 technology to generate homozygous JAGN1a-/- and JAGN1b-/- knockout fish, and are in the process of elucidating the role of these proteins by monitoring the development of tissues that are affected in patients with JAGN1 mutations: neutrophils, bone, and pancreas. In addition, we are generating JAGN1a/JAGN1b-/- double knockout fish to determine the consequences of eliminating both JAGN1 homologs on early development. We aim to identify the interactors of JAGN1 in mammalian cells using an affinity approach, and have generated the N-terminal and C-terminal regions of JAGN1 as a recombinant protein matrix for pull-downs from mammalian cells. Identifying JAGN1 interactors is necessary to place it within specific pathways and to propose possible functions. Our studies aim to elucidate a specific role for JAGN1 function in vertebrate physiology.

P1323/B453

Sec24 Isoform Specificity Regulates the Assembly of Gamma-secretase from Dimeric Subcomplexes.

C. Michiels[1], R. Wouters[1], B. Kleizen[2], K. Dillen[1], W. Vermeire[1], R. Schekman[3], R. Sannerud[1], **W. An naert**[1]; [1]KULeuven&VIB, Leuven, BELGIUM, [2]Bijvoet Center for Biomolecular Research, Utrecht, NETHERLANDS, [3]University of California at Berkeley, Leuven, CA.

γ-Secretase is a diaspartyl protease with presenilin (PSEN) as the catalytic subunit. It targets a plethora of type I transmembrane proteins and, as such, affects a broad range of physiological processes. Because of this, aberrant functioning of γ-secretase is linked to several diseases including cancer and Alzheimer's disease (AD). γ-Secretase consists, besides PSEN, of nicastrin, APH1 and PEN-2 and this tetrameric nature necessitates a stoichiometric assembly process of which the spatial and temporal regulation remains poorly understood. Cell fractionation combined with blue native electrophoresis shows that subcomplexes are mainly present in the endoplasmic reticulum (ER)-enriched fractions while full complexes appear in the ER-Golgi intermediate compartment, indicating that final assembly occurs beyond the ER. In *vitro* reconstitution of ER export reveals that none of the γ-secretase subunits is required for ER-exit of the others. However, knock-out of any subunit induces the accumulation of preceding subcomplexes in COPII vesicles. Mutating a DPE motif in the cytosolic loop domain of PSEN1, which is lost in the familial AD-associated PSEN1ΔE9 mutant, abrogates ER-exit of PSEN1 as well as PEN-2, but not of nicastrin. This is explained molecularly by the selectivity of Sec24A/B and Sec24C/D in packaging PSEN1 and nicastrin, respectively, and argues against full complex assembly prior to ER-exit. In conclusion, and for the first time, our data support a model wherein the prior formation of dimeric subcomplexes in distinct COPII vesicles combined with active Golgi-to-ER recycling are key events in the assembly of γ-secretase.

VAP-A and VAP-B, two isoforms, interact through a FFAT motif with more than 100 cytoplasmic proteins. Many of them, when complexed with VAP-A or VAP-B, form membrane contact sites (MCS) that connect ER to various organelles [1,2]. These narrow cytosolic gaps (<30 nm) are of key importance for intracellular

lipid transport, intracellular signaling, organelle inheritance and lipid metabolism. They have received considerable attention in recent years due to their involvement in certain metabolic diseases. We reconstructed the first functional MCS between ER-like proteoliposomes containing a cytosolic domain of VAP-A and PI4P containing Golgi-like liposomes in presence of the oxysterol binding protein (OSBP). We have shown that in this MCS OSBP is able to transfers cholesterol from ER using the energy associated with counter-transport of PI4P from trans-Golgi apparatus [3,4]. Here, we expressed, purified and reconstituted full length VAP-A in vesicles with variable protein density. Then, we designed an in *vitro* MCS model system to control the formation of contact sites. We combined Cryo-Electron Microscopy and Tomography to describe the architecture of the VAP-A alone or engaged in MCS. Data analysis provided evidence of unexpected features of OSBP and VapA playing an important role in contact formation. First, we shown that the OSBP N-terminus regions act as an entropic barrier to control protein orientation and increase protein dynamic at membrane contact sites [5]. Secondly, Cryo-EM results show a strong flexibility of Vap-A that can span from 8 towards 17 nm depending on local protein density. As a consequence, this behavior enables Vap-A structural adaptation, necessary to form MCS of varying lengths. Moreover, we were able to show that the presence of ORD domain increase disorder distribution of tethers in the MCS regions that might be necessary to allow ORD movements between two facing membranes.

COPI and COPII Cooperate at ER Exit Sites to Support ER-to-Golgi Protein Trafficking Revealed by 3D Ultrastructure an alyses and Live-Cell Imaging.

A. Weigel[1], C. Chang[1], G. Shtengel[1], D. Hoffman[1], M. Freeman[1], C. S. Xu[1], S. Pang[1], E. Betzig[2], H. Hess[1], J. Lippincott-Schwartz[1]; [1]Janelia, Ashburn, VA, [2]University of California, Berkeley, CA.

The endoplasmic reticulum (ER) is the site of many important cellular processes, among them the birth and early steps of the secretory pathway. Cargo synthesized in the ER continues through a series of dynamic compartments before reaching its final destination. This includes specialized sites on the ER called ER exit sites (ERESs), transport intermediates, and the Golgi apparatus. Here, we visualize ERESs using a cryo-correlative light electron microscopy (cryo-CLEM) system. Cells with ERESs fluorescently labeled by Sec23 were high pressure cryo-fixed, visualized by cryo-structured illumination microscopy (SIM), and then directly correlated to focused ion beam scanning electron microscopy (FIB-SEM). FIB-SEM data provides isotropic, high-resolution (4-8nm), large volume EM while cryo-SIM grants super-resolution (100nm lateral) protein specific localization. We found that ERESs were composed of a highly intertwined nest of tubules with a diameter of 360±60nm (n=110). The tubule diameter within the ERES was more constricted than the ER by 20%, 30±20nm (n=782). Using acargo synchronization and release system, RUSH (Retention Using Selective Hook), we directly studied cargo movement through the secretory pathway. When the ERESs were stressed by overloading with cargo we found that the total volume occupied by each ERES swelled 1.45-fold and the comprising tubule diameter expanded by 2.6-fold. Further investigation of coat protein localization at ERESs revealed that more than 70±10% (n=15 cells) of COPII positive ERESs also contained COPI. Using AiryScan microscopy and point localization techniques we observed a separation between COPI and COPII labeling on ERESs of 136±4nm (n=29), which increased by 1.45-fold with cargo overexpression. This was in agreement with FIB-SEM measurements of ERES sizes. Confocal imaging revealed that upon RUSH cargo release, COPI readily moved with cargo away from the ERES in transport intermediates, which often appeared as tubules, while COPII remained at the ERES. Applying cryo-CLEM in cells overexpressing RUSH cargo that were

cryo-fixed soon after cargo release allowed visualization of transport intermediates carrying RUSH cargo. Correlated FIB-SEM of these cells revealed that the transport intermediates existed as pearled membrane tubules running alongside microtubules. Among the pearled membrane tubules observed were those still connected to the ERES, those detached from ERESs, and those that had fused with the Golgi. Examples of the same structures were seen in FIB-SEM of untransfected cells. Together, this data provides a 3D view of the early secretory pathway never before seen with equivalent isotropic resolution, large depth-of-field, and precise protein localization.

P1326/B456

Mtorc1 Requires Ergic Vesicle Trafficking to Phosphorylate S6 Kinase, Not 4ebp1.

V. Vaghela; CUNY Graduate Center, New York City, NY.

The aim of this study is to characterize glutamine sensing by mTORC1 in RAS mutant cancers. In particular, the RAG GTPase independent glutamine sensing characterized by Jewell et al. was considered to describe a role for vesicle trafficking dependent mTORC1 activation in T24 and MDA-MB-231s (1,2). The study utilized protein knockdown, western blotting, and immunofluorescence assays to examine mTORC1 protein kinase activity under glutamine stimulation and vesicle trafficking inhibition at the ERGIC membrane compartment. The ERGIC-localized GEF GBF1 inhibiting drug Golgicide a (GCA) was utilized and characterized alongside rapamycin, a known mTORC1 inhibitor. The study's final conclusions are that by inhibiting ERGIC compartment vesicle trafficking, S6K phosphorylation by mTORC1 can be blocked entirely during glutamine sensing. Furthermore, by releasing the block on ERGIC derived vesicle trafficking 4EBP1 and GRB10 can be shown to be phosphorylated prior to S6K (and ULK1) and that S6K phosphorylation requires trafficking of the mTOR protein away from a Golgi-adjacent localization to one both on and in the nucleus, in both cell lines. Specifically, mTOR was found to saturate adjacent to the Cis and Trans Golgi membranes (but not on) during glutamine stimulation when GCA was included. Allowing the ERGIC compartment to reform and traffic mTOR shows a "backwards trafficking" event when tracked by the transmembrane ERGIC protein ERGIC53. Finally, the aforementioned information was utilized to "hyperactivate" P-S6K T389, meaning blocking and releasing ERGIC trafficking was used to increase S6K phosphorylation 400 percent above the normal glutamine stimulated increase. The sum of these results demonstrate that trafficking from the ERGIC compartment to both the Golgi and the ER are required for glutamine sensing in RAS mutant cancers via mTORC1. ERGIC trafficking manipulation can be used to uncouple mTORC1 target phosphorylation, and is particularly useful for determining the events and localization required of mTOR to phosphorylate S6K in RAS mutant cancers, some of which is characterized in this study. 1. Jewell, J.L., et al. (2015). Differential regulation of mTORC1 by leucine and glutamine. Science *347*, 194-198. 2. Xu, L., et al. (2011). Phospholipase D mediates nutrient input to mammalian target of rapamycin complex 1 (mTORC1). J Biol Chem *286*, 25477-25486.

P1327/B457

Cargo Crowding Drives Sorting Stringency in the Secretory Pathway.

N. Gomez Navarro, A. Melero, E. Miller; MRC Laboratory of Molecular Biology, Cambridge, UNITED KINGDOM.

Accurate delivery of every protein to the correct compartment relies on both positive sorting signals and efficient retention of organelle resident proteins. In the endoplasmic reticulum (ER), secretory proteins are captured into transport vesicles by the COPII coat. These vesicles exclude ER resident proteins and

misfolded proteins by a mechanism that remains unresolved. Here we combined biochemistry and genetic methods with correlative light and electron microscopy (CLEM) to explore how this selectivity is achieved. We observed that changes in vesicle morphology do not fully explain the ER leakage phenotype in yeast mutants with defects in ER retention. Our data suggest that vesicle occupancy dictates ER retention in the context of these mutants: in the absence of abundant cargo, non-specific bulk flow increases. We demonstrate that ER leakage can be influenced by vesicle size and cargo occupancy. We propose that cargo recruitment into vesicles creates lumenal steric pressure that drives selectivity. Sorting stringency is thus an emergent property of the biophysical process of cargo enrichment into a constrained spherical membrane-bound carrier.

Loss of the Short Form of Syntaxin-5 Causes Dysfunctional Golgi Trafficking and Glycosylation.

P. Linders[1], A. Ashikov[1], E. Gerretsen[1], N. Revelo[1], M. ter Beest[1], D. Lefeber[1], G. van den Bogaart[2]; [1]Radboud Institute for Molecular Life Sciences, Nijmegen, NETHERLANDS, [2]Groningen Biomolecular Sciences & Biotechnology Institute, Groningen, NETHERLANDS.

The SNARE (soluble N-ethylmaleimide-sensitive factor attachment protein receptor) protein syntaxin-5 is an essential Qa-SNARE for anterograde transport to the Golgi apparatus and intra-Golgi transport. In humans, the STX5 gene encodes two isoforms (Stx5 Short and Long) that result from alternative starting methionines at position 1 (Long) and 55 (Short). We identified a novel human disorder caused by a single nucleotide mutation in this gene, resulting in the loss of the short isoform (M55V). Patients carrying this mutation suffer severe pathologies, including abnormal N-glycosylation, skeletal disorders and very short survival (<3 months). In this study, we resolved the cellular mechanisms underlying these pathologies. Whereas Golgi morphology was unaltered in primary human dermal fibroblasts isolated from the patients, the cells showed defective glycosylation and mislocalization of glycosyltransferases MGAT1 and MAN2A1. Measurement of anterograde trafficking, based on biotin-synchronizable forms of Stx5 (the RUSH system) and determination of cognate binding SNAREs based on Förster resonance energy transfer (FRET) revealed functional differences of the long and short syntaxin-5 isoforms. Despite the presence of an ER-retention motif, the long isoform exits the Golgi faster and interacts more with early secretory pathway SNAREs, whereas the short isoform interacts more with intra-Golgi SNAREs. Thus, we identified a new trafficking disorder caused by mutations in a SNARE-encoding gene.

P1329/B459

Visualizing Procollagen and Hsp47 Trafficking in Live Cells.

S. Omari[1,2], E. Makareeva[1], L. Gorrell[1], A. Roberts-Pilgrim[1], L. Mirigian[1], J. Lippincott-Schwartz[2], S. Leikin[1]; [1]Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD, [2]Howard Hughes Medical Institute, Janelia Research Campus, Ashburn, VA.

Currently, the mechanisms underlying ER to Golgi transport of large cargo are the subject of much controversy. For instance, there are three different hypotheses with regards to the trafficking of procollagen, which is the precursor of collagen, the most abundant protein in all vertebrates. Since the existing models are based on interpretation of mostly static imaging data, we performed high-speed (500 ms/frame), enhanced-resolution (~ 100 nm) dynamic imaging of procollagen transport vesicles in live cells. We developed multiple fluorescent protein-tagged constructs for transfection of immortalized osteoblastic cell lines (MC3T3). The dynamics of these fluorescent protein-tagged constructs were

visualized with time-lapse Airyscan imaging, including fluorescence recovery after photobleaching (FRAP) experiments. As procollagen-specific chaperone Hsp47 (Serpinh1) is commonly believed to be co-transported with procollagen from the ER to the Golgi, we imaged the dynamics of procollagen, HSP47, and fluorescent markers of different organellar compartments. We observed three-types of vesicle-like structures containing procollagen: (1) highly dynamic, rapidly moving procollagen transport vesicles (<500nm) exiting ER and entering Golgi that did not contain HSP47 and had no COPII coat; (2) static vesicle-like pools of dilated ER lumen that did contain HSP47; and (3) lysosomes that were relatively static and sometimes contained both procollagen and HSP47. These three vesicle-like compartments containing procollagen could be distinguished only by high-speed and high-resolution imaging with markers of ER lumen and lysosomes. Combined with previously published data, our observations indicate that procollagen transport vesicles emerge from ER exit sites (ERES) after ERES fusion with ERGIC membranes reduces pH and thereby releases HSP47 from procollagen. This interpretation is supported by the presence of the ERGIC membrane protein ERGIC53 in the transport vesicles.

P1330/B460

Isoform Specific IP3 Receptor Regulation of ER to Golgi Transport.

A. Held[1], B. Gottschalk[2], C. T. Madreiter-Sokolowski[2], R. Malli[2], W. F. Graier[2], J. Hay[1]; [1]University of Montana, Missoula, MT, [2]Medical University of Graz, Graz, AUSTRIA.

Luminal calcium regulates vesicular trafficking from the ER to the Golgi. Previous studies indicate significantly reduced transport and a buildup of budding COPII vesicles and vesicle proteins upon severe luminal Ca^{2+} depletion. This may be due to Ca^{2+}-dependent COPII coat modulation at ER exit sites (ERES). However, the dynamics of Ca^{2+} involved in ER-to-Golgi transport are poorly understood. Inositol 1,4,5-trisphosphate Receptors (IP3Rs) release Ca^{2+} from the ER lumen upon agonist stimulation, triggering further Ca^{2+}-Induced Calcium Release (CICR) and hence, act as the nucleating step in ER Ca^{2+} signaling. Expression levels of the three isoforms of IP3R vary between cell types and biological differences between isoforms and homo- vs. hetero-tetramers are poorly understood. Using a single cell morphological assay for ER-to-Golgi transport in normal rat kidney (NRK) epithelia cells, we found that depletion of IP3R3, but not IP3R1, using siRNA resulted in significantly accelerated ER export of the membrane cargo VSV-G. Since NRK cells only express IP3R1 and IP3R3, this result implicated IP3R1, specifically IP3R1 homotetramers as playing a stimulatory role in ER export. Unexpectedly, live cell imaging using a FRET-based genetically encoded ER luminal Ca^{2+} sensor demonstrated a *decrease* in luminal Ca^{2+} concentration upon either IP3R1 or IP3R3 depletion. Imitating this change in luminal calcium with the Sarco/endoplasmic Reticulum Calcium-ATPase (SERCA) inhibitor Thapsigargin (TG), however, did not recapitulate the transport effects, indicating that the ER luminal Ca^{2+} concentration *per se* is not predictive of vesicular trafficking capacity. Rather, we suggest that IP3R1-regulated Ca^{2+} dynamics at ERES is a more rate-limiting determinant of secretion. Additional Ca^{2+} measurement experiments eliminated the possibility that the IP3R knockdowns altered basal ER leak or overall SERCA activity of the cells, further implicating Ca^{2+} signaling or other dynamics at ERES as the functionally critical parameter. In addition, the effects of IP3R knockdowns do not appear to be due to expression changes in COPII components and other trafficking machinery. We suggest that Ca^{2+} handling by IP3R1 at ERES controls a rate-limiting step in ER export.

Sequestration of the Exocytic SNARE Psy1 into Multiprotein Nodes at Non-growing Regions of the Plasma Membrane.

K. E. Miller, J. O. Magliozzi, N. A. Picard, J. B. Moseley; Dartmouth College, Hanover, NH.

Spatial control of protein localization is important for many cellular processes in yeast and mammalian cells. Fission yeast is a long-standing model system for studies in cell morphology and polarity due to a highly polarized pattern of growth. These rod-shaped cells grow exclusively at their ends by restricting exocytosis and secretion to these sites. This growth pattern implies the existence of mechanisms that prevent exocytosis and growth along cell sides. We previously identified a set of 50-100 megadalton-sized node structures along the sides of fission yeast cells. On average, each node contains 70 copies of the interacting proteins Skb1 and Slf1. Here, we show that nodes also contain the syntaxin-like SNARE Psy1, which mediates exocytosis in fission yeast. Psy1 localizes throughout the plasma membrane with enrichment at cell tips, where it promotes exocytosis for polarized growth. At cell sides, where exocytosis should be prevented, Psy1 is sequestered in nodes with Skb1 and Slf1. Both Skb1 and Slf1 are necessary for Psy1 localization to nodes, and Psy1 associates with Skb1 and Slf1 by co-immunoprecipitation. Mutations that prevent node assembly lead to changes in the pattern of exocytosis and polarized growth, and these defects are exacerbated during osmotic stress. Studies suggest that spatial regulation of exocytosis is a common feature of most eukaryotic cells that is tightly linked to the overall polarity of a cell. Our work suggests that sequestration of syntaxin-like proteins at non-growing regions of the cell cortex reinforces cell morphology by restricting exocytosis to proper sites of polarized growth.

P1332/B462

Osmotic Squeezing and Membrane Tension Mechanically Drive Vesicle Evolution and Regulate Neurotransmitter and Hormone Release.

R. Su[1], S. Thiyagarajan[1], Z. McDargh[1], W. Shin[2], G. Arpino[2], L. Wu[2], B. O'Shaughnessy[1]; [1]Columbia University, New York, NY, [2]National Institute of Neurological Disorders and Stroke, Bethesda, MD.

Neurotransmitter and hormone release are fundamental to life and accomplished by exocytosis, when vesicles fuse with the plasma membrane (PM) to form omega-shaped membrane complexes that release contents via the fusion pore. It is widely accepted that the vesicle-PM complex evolves along one of two pathways, regulating contents release (Alabi and Tsien, 2013). (1) Full fusion. The pore dilates and the omega-profile flattens into the PM, with full contents release. (2) Kiss and run. The pore transiently opens and then closes, giving partial contents release. Recently this classical view was challenged by the Wu lab, using confocal and super-resolution STED microscopies to visualize neuropeptide release from dense-core vesicles in live chromaffin cells (Chiang et al., 2014; Wen et al., 2016). Instead of full fusion, they found full contents release is accomplished by the radically different “shrink-fusion” pathway, in which fused vesicles shrink into the PM retaining their Omega shape. Shrink fusion was suppressed by increased extracellular osmolarity or inhibition of F-actin by drugs or actin knockout (Wen et al., 2016). These findings are unexplained. Here we mathematically modeled the

evolution of dense core vesicles fused to the chromaffin cell PM and performed additional experiments. The model accounts for membrane bending energies and tension, osmotic forces and membrane-cytoskeleton adhesion, and is highly constrained by experiment. A novel mechanism emerged from the model, quantitatively explaining the experiments with no fitting parameters. Vesicle-PM merging is driven by: (i) osmotic squeezing, due to a reverse osmotic squeezing pressure on the vesicle, rapidly established following fusion, and (ii) membrane tension gradients that reel membrane from the vesicle onto the cytoskeleton, due to osmotic squeezing which deflates the vesicle and abolishes its tension, leaving the PM membrane tension unopposed. In agreement with experiment, a shrink-fusion sequence of vesicle shapes is predicted, separated by a large energy barrier (~140 k_BT) from the classical full collapse trajectory. Importantly, the model explains the observed dependence of Omega-shrink on the actin cortex (because actin-membrane adhesion helps reel in the vesicle membrane) and on extracellular osmolarity (which sets the osmotic squeezing pressure). The model predicts that sufficiently large vesicles are squeezed into elongated tubular shapes, a vivid manifestation of the novel osmotic squeezing mechanism. In new experiments we confirmed these remarkable tubular shapes with STED microcopy, strongly corroborating the squeezing forces. Comparing vesicle shapes from electron microscopy with shape predictions, we inferred that vesicles are squeezed with pressures from ~40 to ~400 Pa.

Neurotransmitter Release Kinetics, Release Probability, and Calcium Sensitivity Are Regulated by Snare Proteins.

Z. McDargh, A. Polley, B. O'Shaughnessy; Columbia University, New York, NY.

Release of neurotransmitters (NTs) at neuronal synapses is evoked by calcium influx into the axon terminal of the presynaptic neuron. On sub-millisecond timescales, a remarkable multi-component machinery senses the calcium and fuses the synaptic vesicle and plasma membranes, releasing NTs through a fusion pore into the synaptic cleft. SNARE proteins constitute the core of the membrane-fusing component of the release machinery, but decades of studies assumed that NT release kinetics are principally regulated by the Ca-sensing component. How the two components of the machinery are coupled is poorly understood, and the possible role of the membrane-fusing component in regulating NT release has not been explored. In an important experimental study, NT release was enhanced in mouse Calyx of Held neurons by a constitutively open mutant of the t-SNARE Syntaxin which increased the number of assembled SNARE complexes at the fusion site (Acuna et al., 2014). The vesicle release probability, the NT release rate and the apparent Ca-sensitivity of release were all increased, while delay times and the apparent cooperativity of release were unaffected. Thus, NT release depends on the number of SNAREs and the ca-sensing and membrane-fusing components of the machinery appear coupled in a complex way. The molecular origin of these findings is unknown. Here, we present molecular dynamics simulations of the NT release machinery that realistically represent key molecular components for the first time. Our simulations use highly coarse-grained models of the neuronal SNARE complex (Mostafavi et al., 2017), and the Ca-sensor for synchronous NT release, Synaptotagmin 1. The model quantitatively reproduced three critical findings of the experimental study by Acuna et al. (1) We find that the reported acceleration of NT release and increased release probability is because the final membrane fusion step is faster when more SNARE complexes are present. The origin of the faster fusion is that more SNAREs generate stronger entropic forces that expand the SNARE complex ring at the fusion site and pull the vesicle and plasma membranes together with greater force. (2) the model

quantitatively reproduces the enhanced apparent Ca sensitivity of release observed in these experiments, and shows that it is due to increased probability that a binding event by a Ca ion unclamps a SNARE complex, i.e. releases it from a bound state with Synaptotagmin. (3) the model reproduces the finding that increasing the number of SNAREs does not affect the synaptic delay. This is because the most probable time for a vesicle to fuse with the plasma membrane is immediately following Ca-mediated unclamping of the SNAREs. Thus, synaptic delay primarily reflects ca-mediated unclamping, unaffected by the number of SNAREs present.

The Neuronal Calcium Sensor Syt1 and Snare Proteins Cooperatively Dilate Fusion Pores in a Mechanical Lever Action.

N. Dharan[1], **S. Thiyagarajan**[1], Z. Wu[2], E. Karatekin[2], B. O'Shaughnessy[1]; [1]Columbia University, New York, NY, [2]Yale University, New Haven, CT.

Neurotransmitters, hormones and other cargoes are released from vesicles through nanometer-sized fusion pores. Following fusion pore creation by SNARE proteins and auxiliaries, a vital step is the enlargement of the pore to allow contents release, but the mechanism of pore size regulation is unclear. Here we combined mathematical modeling and experiments to study the mechanisms. Conductance measurements of single fusion pores between nanodiscs and Hela cells showed that the calcium sensor Synaptotagmin-1 (Syt1) enlarges fusion pores in the presence of SNARE proteins and calcium. ~4 copies of full-length Syt1 and ~ 4 copies of VAMP2 per disc face were reconstituted into the nanolipoprotein particles. Compared with fusion pores in the presence of SNAREs alone, the mean conductance of fusion pores was three-fold larger in the presence of Syt1, calcium and SNAREs. We developed a mathematical model that quantitatively explained these findings, and suggests a novel mechanical post-fusion role for Syt1 during exocytosis. The Syt1 C2B domain is known to bind SNARE complexes, and the model incorporates Syt1-SNARE complexes following the published crystal structure (Zhou et al., 2015). We find a novel calcium-dependent post-fusion role for Syt1 in pore dilation, beyond its well-established pre-fusion function as the calcium sensor, in which Ca-triggered binding of the Syt1 C2 domains to the plasma membrane reorients the Syt-SNARE complex, tilting it upwards as a lever which pushes the fused membranes apart. This in turn enlarges the fusion pore due to the pore membrane energetics (with larger membrane separation, a larger pore has lower energy). In the model, SNARE complexes (SNAREpins) can be in the trans state (partially zippered) and free to roam (favored by entropy), or fully zippered at the waist of the fusion pore (favored by the zippering energy of the SNARE transmembrane domains). SNAREpins at the waist repel one another due to entropic crowding forces that expand the fusion pore, and can bind Syt C2B domains. The calcium-binding loops of C2B have a powerful tendency to bury into the target membrane when calcium is bound, an affinity which has been experimentally quantified and is incorporated into the model. The model predicts that the increase in membrane separation in response to calcium enlarges the pore radius from ~1 nm without calcium to ~1.7 nm, producing a ~2.3 fold increase in pore conductance, close to the experimentally measured ~2.2 fold increase.

P1335/B465

COG and GARP Vesicle Tethering Complexes Control the Fate of Golgi Glycosylation Enzymes.

Z. D'Souza, T. Kudlyk, I. Pokrovskaya, **V. Lupashin**; University of Arkansas for Medical Sciences, Little Rock, AR.

The Golgi is a central hub in the secretory pathway where cargo is delivered to undergo modifications and sorting to final destination. In order for Golgi's functions to be carried out properly, correct localization of the glycosylation enzymes within the Golgi sub-compartments is crucial. The eight subunit Conserved Oligomeric Golgi (COG) complex controls membrane trafficking and ensures Golgi homeostasis by orchestrating retrograde vesicle trafficking within the Golgi. In humans, COG defects lead to severe multi-systemic diseases known as COG-Congenital Disorders of Glycosylation (COG-CDG). The four subunit (VPS51-54) Golgi Associated Retrograde Protein (GARP) complex controls the retrograde transport from endosomes to TGN. The CRISPR approach was utilized to generate HEK293T cells deficient for individual COG and GARP subunits as well as for several double KO (DKO) combinations. COG KO cells show fragmentation of the Golgi cisternae, formation of the hybrid enlarged endolysosomal EELS compartment, defects in retrograde trafficking, sorting and glycosylation. GARP KO cells show defects in retrograde trafficking and, surprisingly, in both N- and O-glycosylation. Glycosylation and trafficking defects were even more severe in COG/GARP DKO cells. EELSs were mimicking some properties of late endosomes/lysosomes such as having an acidic lumen and endolysosomal membrane proteins, but lacking active lysosomal proteases. Lipid homeostasis was perturbed and some key Golgi lipids, including cholesterol and PI4P, were mislocalized to the EELS's membrane. Furthermore, tested Golgi resident proteins were found to undergo degradation in EELSs. Intriguingly, the maintenance of the EELSs was dependent on GARP activity showing interplay between the two complexes to regulate Golgi and endosomal homeostasis. Superresolution live cell microscopy, lectin staining, flow cytometry and EM were utilized to compare Golgi dynamics in KO mutants, wild-type and rescued cells. We found that stability of both cis/medial (MGAT1) and trans-Golgi (B4GALT1 and ST6GAL1) enzymes was compromised in COG and GARP KO cells, indicating that both tethering complexes are essential for the maintenance of Golgi glycosylation machinery. To gain a better understanding of Golgi enzyme fate in cells deficient for vesicle tethering complexes, we have used a RUSH pulse-chase approach, investigating intracellular trafficking and degradation of newly synthesized B4GalT1 and MAN2A1. We found that analyzed enzymes were not retained in the Golgi in both COG and GARP KO cells and, instead, were mistargeted to vesicles and endolysosomal degradative compartments. This work was supported by the NIH grant GM 083144

P1336/B466

The Three-dimensional Localization of Proteins on Single Exocytic Vesicles with Gold-labeled Fusion Proteins and Platinum-replica Electron Microscopy.

B. Prasai[1], G. J. Haber[1], M. Strub[1], K. A. Sochacki[1], J. A. Ciemniecki[2], J. W. Taraska[1]; [1]National Institutes of Health, Bethesda, MD, [2]National Institutes of Health, Apt 1308, MD.

Exocytic processes such as adrenaline and insulin release are regulated by a variety of proteins in eukaryotic cells. While the biogenesis, transport, and delivery of cargo-loaded vesicles (e.g. dense-core vesicles), and the proteins involved in these processes are well studied, how and where these proteins are organized at the nanoscale remains unknown. Here, we report a targetable genetically-encoded EM labeling method that uses a histidine-based affinity-tag system and metal-binding gold nanoparticles

along with 3D platinum replica transmission electron microscopy (PREM) and electron tomography to directly image proteins that are key regulators of exocytosis at the plasma membrane in mammalian cells. The method was validated by imaging well studied coat proteins on endocytic structures including clathrin-coated vesicles and caveolae. Next, the unknown 3D locations of key DCV associated proteins including Rab27a, Rabphilin, Rab3a, and Granuphilin were visualized on single vesicles in 3D at the scale of nanometers. The spatially averaged distribution of tagged gold particles revealed that these proteins are distributed across the entire surface of single docked vesicles. This global distribution of Rabs and Rab-binding proteins likely aids in the efficient capture and docking of DCVs in excitable cells. The nanoscale molecular architecture of DCVs generated from our method will help determine how key proteins assemble at the plasma membrane to regulate the docking, priming, and fusion of single DCVs in endocrine cells.

Sphingolipids That Contain Very Long-chain Fatty Acids Regulate Homotypic Vacuole Fusion by Promoting the Vertex Enrichment of Regulatory Lipids, SNAREs, and Rab-/Rho-GTPases.

L. R. Hurst[1], T. Kazmirchuk[2], C. L. Brett[2], R. A. Fratti[1]; [1]University of Illinois at Urbana-Champaign, Urbana, IL, [2]Concordia University, Montreal, QC, CANADA.

Studies of sphingolipids in the endo-lysososmal membrane system of *Saccharomyces cerevisiae* are sparce due to the relatively low amounts found in these membranes. Here, we present evidence that sphingolipids containing very long-chain fatty acids (VLCFAs) positively regulate homotypic vacuolar fusion by acting as “regulatory lipids”. Vacuoles isolated from yeast cells that lack the C26 VLCFA elongase Elo3p display morphological abnormalities, and reduced amounts of in *vitro* fusion/hemifusion. We found that vacuoles isolated from C26 VLCFA deficient yeast fail to selectively concentrate a subset of SNAREs, Rab-GTPases, and other regulatory lipids at the vertex domain between apposed vacuoles. The vertex enrichment of regulatory lipids and fusion proteins on docked vacuoles is an interdependent process; they rely on each other for proper localization and timing of activity. These vacuoles were also found to lack Rho-GTPases, which impairs their ability stimulate actin polymerization. Studies using detergent resistant membranes isolated from wild type and mutant yeast vacuoles provide evidence that C26 VLCFA containing sphingolipids are a constituent of the vertex region, and they promote the clustering of fusion proteins. Taken together, these results suggest that sphingolipids containing C26 VLCFAs act as regulatory lipids in the homotypic vacuolar fusion cascade by promoting the protein/lipid assembly of vertex regions of docked vacuoles.

Revealing the Mechanism That Controls Fusion Pore Dynamics in Giant Secretory Vesicles.

T. Biton, K. Kumari, N. Scher, E. D. Schejter, B. Shilo, O. Avinoam; Weizmann Inst Science, Rehovot, ISRAEL.

Secretion by exocytosis occurs in every living cell and is essential for many cellular processes including metabolism, signaling and trafficking. To accommodate different cargos and cellular needs, exocytic vesicles are produced across multiple scales ranging from synaptic vesicles that are smaller than 50 nm in diameter to giant exocrine vesicles that reach up to a few μm in diameter. The later typically secret viscous cargos, such as digestive enzymes from pancreatic acinar cells and surfactant proteins from type II lung cells. Nevertheless, to enable cargo release these different types of vesicles all dock and fuse with

the plasma membrane. Yet, how vesicle size affects docking and fusion is poorly characterized on the mechanistic level. It is well established that during exocytosis of small vesicles, vesicle fusion can proceed in one of two morphological scenarios: in the first a fusion pore opens and expands irreversibly, leading to complete incorporation of the vesicular membrane to the cell membrane. The second is a "kiss-and-run" scenario, when the fusion pore "flickers", opening briefly and collapsing back, separating the two membranes. Here, we aimed to elucidate how fusion of giant vesicles progresses. We used the *D. Melanogaster* salivary gland, which secretes an adhesive protein through vesicles that are 5-8 µm in diameter, as a model. We visualized the secretion process using super resolution live-gland imaging and observed that unlike smaller vesicles, the fusion pore between giant vesicles and the membrane initially expand but then stabilize with a wide opening reaching up to 3 µm and subsequently constricting back down to hundreds of nm or less. Since constricting a membrane tube requires considerable energy input, we hypothesized that a dedicated protein machinery mediates this phenomenon. To identify this machinery we used the enormous power of Drosophila genetics to perform a candidate gene based screen and identified several conserved proteins from the BAR domain superfamily that act as key regulators of pore dynamics. This research has wide reaching implications on our understanding of exocrine secretion, leading to new and exciting insights into the molecular mechanism of membrane fusion and the regulation of membrane homeostasis in secreting cells.

P1339/B469

Membrane Homeostasis during Exocrine Secretion Is Maintained by Membrane Crumpling and Sequestration.

K. Kumari, N. Scher, T. Biton, E. D. Schejter, B. Shilo, **O. Avinoam**; Weizmann Institute of Science, Rehovot, ISRAEL.

Dynamic membrane trafficking comprises the essence of cellular homeostasis in every living eukaryotic cell. However, membrane dynamics becomes especially challenging in secretory epithelial tissues, where the continuous fusion of vesicles with the apical membrane takes place. This is most dramatically demonstrated in exocrine tissues that secrete viscous cargoes from giant vesicles, ranging up to 8 microns in diameter. Secretion of such giant vesicles adds large amounts of membrane to the apical surface of cells. Yet, it remains unclear how homeostasis of the cell surface in terms of size, shape, and composition is maintained under these extreme circumstances. To address this question, we used as a model system the *Drosophila* larval salivary gland, which secrets a viscous mucin-like protein called 'glue' via giant vesicles. After fusion with the apical membrane, a contractile actomyosin network is recruited to the surface of the vesicles to expel their content, and could thus be used as a marker to follow the fate of the vesicular membrane over time. Using live super-resolution microscopy, we observed that the vesicular membrane does not simply collapse into the apical surface during content release, but instead presents a crumpled appearance. To determine the precise ultrastructure of the vesicular membrane at different phases of secretion, we used correlative fluorescence and 3D-electron microscopy (CLEM). We observed that the vesicle membrane becomes increasingly crumpled and folded as secretion progresses, indicating that the membrane is not incorporated into the apical surface. To quantify this phenomenon, we used a correlative block-face and FIB-SEM approach and found that the compacted membrane indeed accounts for most of the original vesicular membrane before secretion. Furthermore, we found that the sequestered membrane recruits the clathrin-mediated endocytosis machinery, which recovers the membrane over a prolonged period of time post secretion. These results indicate that membrane homeostasis is maintained by actomyosin mediated crumpling and

sequestration of the vesicular membrane. This novel mechanism for maintaining membrane homeostasis may be ubiquitous and essential for exocrine tissue physiology.

Human VPS33B and VPS16B Form a Multimeric Complex with a Two-lobed Structure.

R. Liu[1], S. Z. Chen[1], D. Urban[1], C. H. Chen[1], M. Drobak[1], L. Li[2], P. K. Kim[1,2], S. Benlekbir[2], J. L. Rubinstein[1,2], W. H. Kahr[1,2]; [1]University of Toronto-47731885, Toronto, ON, CANADA, [2]The Hospital for Sick Children, Toronto, ON, CANADA.

VPS33B and VPS16B are highly conserved proteins required for apical-basolateral cell polarization and vesicular trafficking in mammalian cells. Mutation of either *VPS33B* or *VPS16B* (*VIPAS39*) can cause ARC (arthrogryposis, renal dysfunction and cholestasis) syndrome, a neonatal lethal condition affecting multiple tissues. We have previously observed that VPS33B and VPS16B form a complex, VPS33B/VPS16B, that is required for the production of platelet secretory alpha granules by precursor megakaryocytes (*Blood* 2012;120:5032-40). VPS33B and VPS16B are homologous with the HOPS/CORVET complex components VPS33A and VPS16A, but these proteins and their complexes have distinct functions. While HOPS/CORVET has been well characterized, relatively little is known about VPS33B/VPS16B. We undertook to determine the composition and structure of VPS33B/VPS16B to gain insights into its role in megakaryocytes and other cells. Differential tag expression and blue native PAGE immunoblot analysis indicated the presence of at least 2 copies of each protein in the complex. VPS33B/VPS16B expressed in insect cells or isolated from human HEK293 cells co-migrated on native gels. A large-scale yeast expression and affinity purification system was developed to produce quantities of human VPS33B/VPS16B sufficient for biochemical analysis. Purified complex was analyzed via size exclusion chromatography with multi angle light scattering (SEC-MALS), small angle X-ray scattering, and single particle electron microscopy (EM). The results confirmed that each VPS33B/VPS16B complex contains multiple copies of both subunits. Low resolution envelopes obtained by negative staining EM and cryo-EM revealed a two-lobed VPS33B/VPS16B particle, with dimensions consistent with those of a predicted double heterodimer. Truncation of the VPS16B N-terminus did not affect subunit composition of the complex. We are currently examining the effects of amino acid alterations and VPS33B truncations on the size and structure of VPS33B/VPS16B.

A Functional Genomics an alysis of 20 S Particle Proteins Involved in Plant Defense to Parasitic Nematodes.

V. P. Klink, B. McNeece, K. Sharma, P. Niraula, H. A. Troell; Mississippi State University, Mississippi State, MS.

Prior RNA-seq-assisted analysis of a nematode-induced feeding structure in plant roots undergoing resistance resulted in the identification of alpha soluble NSF attachment protein (α-SNAP) whose induced expression resulted in suppressed levels of infection. The RNA-seq study also identified other genes expressed to high levels in these cells, but their role in resistance had not been tested. The genes include, several syntaxins (SYP), soluble N-ethylmaleimide-sensitive fusion factor adapter protein 25 (SNAP-25), N-ethylmaleimide-sensitive fusion protein (NSF), synaptobrevin (SYB), synaptotagmin (SYT), synaptosomal-associated protein 25 (SNAP-25) and vesicle associated membrane protein (VAMP). A

functional genomics analysis of some of these genes is providing a better understanding of how the proteins function in resistance.

P1342/B472

The Role of Munc13 in Snare Complex Formation.

A. Bolembach, M. Magdziarek, B. Quade, J. Rizo-Rey; UT Southwestern Medical Center, Dallas, TX.

The role of Munc13 in SNARE complex formation Interneuronal communication through neurotransmitter release is crucial for brain function. Neurotransmitters are packed in synaptic vesicles and are released by calcium dependent fusion with the plasma membrane into the synaptic cleft where they trigger a signal on postsynaptic cells. There are many proteins involved in this process, but it is the SNARE complex that constitutes the core component of the vesicle fusion machinery. The SNARE complex consists of Synaptobrevin, Syntaxin-1 and SNAP25, which assemble into a tight complex through their SNARE motifs and bridge the membranes. Membrane fusion requires also other proteins that assist in forming and disassembling the complex. One of them is Mun13 which together with Munc18 is said to orchestrate the complex assembly. Munc18-1 closes Syntaxin-1 preventing it from forming the four helix bundle of the SNARE complex, but then binds to synaptobrevin to template assembly. Munc13 is believed to change the Syntaxin-1 conformation, stimulating the complex assembly. Although there is much data proving that Munc13 plays an important role in synaptic vesicle fusion, the exact mechanism remains unknown. To address this problem we are using a reconstitution approach, native gel assays and cross linking experiments. The data obtained so far supports the notion that Munc-13 modulates SNARE complex formation by opening Syntaxin-1.

P1343/B473

P4-Atpase TAT-1 Is Important for Phagosome-lysosome Fusion and Degradation of Residual Body.

X. Li[1,2], Z. Lu[1,2], H. Wang[1], X. Wang[1,2]; [1]National Laboratory of Biomacromolecules, CAS Center for Excellence in Biomacromolecules, Insititute of Biophysics, CAS, Beijing, CHINA, [2]College of Life Sciences, University of Chinesse Academy of Sciences, Beijing, CHINA.

Cellular membranes are comprised of lipid bi-layers and membrane proteins. Distinct patterns of phospholipids with membrane proteins and their interactions can give rise to membrane system different identities, and can determine vesicles sorting and trafficking. Phosphatidylserine (PS) is one of the critical phospholipids, widely distributed in plasma membrane and endomembrane systems. In normal condition, PS is asymmetrically localized at the cytosolic side of lipid bi-layers, which is maintained by PS transporting enzymes. PS asymmetry is involved in apoptotic cell recognition and engulfment, and in endocytic trafficking processes. In worms, *tat-1* encodes a P4-ATPase, responsible for PS flipping. In *tat-1* mutant male gonad, residual bodies, generated during spermatogenesis, accumulate in the engulfing cell due to defects in clearance. Further experiments indicated that phagosome-lysosome fusion is delayed in *tat-1*, leading to residual body degradation defects. A retromer complex mutant was recovered in the *tat-1* suppressor screen. In *tat-1* mutant, retromer complex reporters stay longer on phagosome surface and hence postpone the fusion with lysosomes. During phagosome maturation, RabGTPase RAB-7 consecutively recruits retromer complex for cargo recycling and then HOPS complex for fusion. In *tat-1* mutant, we found that RAB-7 activity is higher, resulting in persistence of retromer complex on the phagosome surface and defects in phagosome-lysosome fusion.

P1344/B474

A Species-specific Mechanism Regulates Trimer Formation of Broadly Conserved Class Ii Fusogen Hap2 during Gamete Fusion in Chlamydomonas.

J. Zhang[1], J. Pinello[1], I. Fernandez[2], E. B. Salazar[2], F. Rey[3], W. Snell[1]; [1]University of maryland, College Park, MD, [2]Unité de Virologie Structurale, Institut Pasteur, Paris, FRANCE, [3]Unité de Virologie Structurale, Institut Pasteur, paris, FRANCE.

The transmembrane protein HAP2 has been shown to be essential for gamete fusion in taxa across kingdoms. Although not yet detected in chordates and fungi, the distribution of HAP2 indicates that it is likely the ur-gamete fusogen. Its structural similarity to viral class II fusion proteins and its requirement by only one gamete of a fusing pair suggest that this eukaryotic fusogen will function similarly to its viral counterparts. The viral proteins undergo oligomeric rearrangements of their metastable pre-fusion forms into “hairpin”-like folded-back homo-trimers that drive merger of lipid bilayers during viral entry. Although the X-ray structures of HAP2 ectodomains showed a homo-trimer in the hairpin-like post-fusion conformation, this oligomeric state has not yet been detected in vivo. Thus, whether trimer formation occurs upon fusion in vivo and whether it is essential for gamete fusion remain unknown. Moreover, while low pH in the confines of target cell endosomes is the trigger for formation of trimers of class II fusion proteins in well-studied viruses (e. g., dengue and Zika), it is unlikely that HAP2 function will be controlled by a simple environmental cue. Here, we report that during gamete fusion in the unicellular green alga *Chlamydomonas reinhardtii*, HAP2 indeed forms oligomers with biochemical properties of homo-trimers, that trimer formation is essential for fusion, and that species-specific membrane adhesion is required for trimer formation. An alysis of HAP2 in unmixed mt- gametes by semi-native SDS-PAGE showed only monomers. As mt- gametes fused with mt+ gametes, pre-fusion HAP2 was converted into SDS-resistant trimers; and when fusion was complete, 90% of HAP2 remained in the pre-fusion form. Engineering mutations at the homo-trimer interface resulted in HAP2 mutants impaired in trimer formation in vitro and in vivo and incapable of supporting gamete fusion. Studies with fusion loop mutant forms of HAP2 impaired in their ability to insert into lipid bilayers indicated that bilayer insertion facilitated trimer formation. Furthermore, upon mixing with mt+ gametes, fusion loop HAP2 mutants incapable of gamete fusion formed unproductive trimers until most monomers were converted, indicating that trimer formation was regulated by fusion per se. Finally, fusion-driving trimers failed to form when mt- gametes were mixed with mutant *fus1* mt+ gametes lacking the species-specific membrane adhesion protein FUS1. Thus, broadly conserved eukaryotic class II fusogen HAP2 indeed forms trimers that drive gamete fusion, and formation of functional trimers depends on species-specific membrane adhesion. Supported by NIH R35 GM122565 to WJS, F32 GM126735 to JP, and F32 GM133158 to JZ. FR was supported by the European Research Council advanced grant Celcelfus.

P1345/B475

Functional an alysis of the ALPS Domain in *S. Cerevisiae* OSBP Homologue 4 (Osh4p).

K. G. Kozminski, I. An dreev, R. J. Smindak; University of Virginia, Charlottesville, VA.

A wide range of cellular events require polarized exocytosis including, but not limited to, the formation of polarized intestinal epithelial cells and the formation of new daughter cells in yeast. In the budding yeast *S. cerevisiae*, the oxysterol binding protein homologue (Osh) family is required for polarized exocytosis and proper bud formation. In the absence of other Osh family members, Osh4p (Kes1p) is sufficient for polarized exocytosis, though in a manner that requires sterol and PI4P binding (Smindak *et*

al., *JCS* 2017). To date, many functional studies of Osh family proteins or mammalian OSBP-related proteins, both in *vitro* and in *vivo*, focused on lipid binding, modeling these proteins as lipid transfer proteins between closely apposed membranes. Structurally, these proteins have a lipid binding beta-barrel closed at one end and open at the other with a lid that can cover the open end of the barrel. The lid itself consists of the N-terminus of the protein; it can be either short, sufficient to cover the barrel, or long, presenting other functional domains in addition to covering the barrel. Although it appears that the lid controls protein orientation at membrane contact sites without affecting lipid transfer (Jamecna *et al*., *Dev Cell* 2019), less is known about the function of the lid in relation to specific cellular processes such as polarized exocytosis. In the case of Osh4p, the lid is short (29 amino acids) and consists of an Arf-GAP lipid packing sensor (ALPS) domain. Although it is known that the Osh4p ALPS domain influences sterol binding what, if any role, this protein domain has in Osh-dependent polarized exocytosis is unclear. We show that the Osh4p ALPS domain is essential for Osh4p function in polarized exocytosis, in particular exocytic vesicle docking at the plasma membrane (PM). We also show that the Osh4p ALPS domain decreases Osh4p localization to exocytic vesicles and sites of polarized exocytosis on the plasma membrane. Our results are consistent with a model in which the ALPS domain of Osh4p contributes to the temporal regulation of Osh4p.

Neuronal Organelle and Protein Dynamics

P1346/B477

Structural Basis of GABARAP-mediated $GABA_A$ Receptor Trafficking and GABAergic Synaptic Transmission.

J. Ye[1], G. Zou[1], J. Li[2], W. Xiong[1], M. Zhang[2], **C. Wang**[1]; [1]University of Science and Technology of China, Hefei, CHINA, [2]Hong Kong University of Science and Technology, Hong Kong, CHINA.

$GABA_A$ receptor is one of the two major inhibitory receptors in the neuronal systems and responsible for balanced neural circuits. Dysfunction of trafficking and localization of $GABA_A$ receptor to the cell membrane is closely related to severe psychiatric disorders in humans. GABARAP serves as a main stabilizer for $GABA_A$ receptors localization on cell membranes, although the detailed molecular mechanisms are still not well understood. Here we show that GABARAP directly binds to a novel fragment of gamma2 subunit of $GABA_A$ receptor. The GABARAP/$GABA_A$ receptor crystal structure reveals the detailed interaction mechanisms governing the complex formation through a LIR-dependent manner. Overexpression of GABARAP in cells lead to $GABA_A$ receptor-mediated synaptic responses increase while mutations in either GABARAP or $GABA_A$ receptor blocking the binding dismiss the effect, in line with our in vivo electrophysiology results. We further showed GABARAP worked through the trafficking pathway rather than endocytosis in stabilizing GABA receptors. Our results correct the interaction between $GABA_A$ receptor and GABARAP and define a mechanism for synaptic localization of $GABA_A$ receptor through trafficking regulation by GABARAP.

P1347/B478

Functional an alysis Reveals Abnormal Expression of Gaba$_A$ Receptor Sub-units and Hypomotility Upon Loss of *Gabra1* in a Zebrafish.

N. G. Reyes-Nava[1], H. Yu[2], C. R. Coughlin, II[2], T. H. Shaikh[2], A. M. Quitana[1]; [1]The University of Texas at El Paso, El Paso, TX, [2]University of Colorado School of Medicine, Aurora, CO.

We used trio based whole exome sequencing (WES) to determine the genetic etiology of a patient diagnosed with a multi-system disorder characterized by a severe seizure disorder. WES identified a heterozygous *de novo* missense mutation in the *GABRA1* gene (c.875C>T), which resulted in a single amino acid substitution in one of the three transmembrane domains (p.Thr292Ile). *GABRA*1 encodes the alpha subunit of the Gamma-Aminobutyric Acid receptor a ($GABA_AR$). The $GABA_AR$ is a ligand gated ion channel that mediates the fast inhibitory signals of the nervous system and mutations in the sub-units that compose the $GABA_AR$ have been previously associated with human disease. To better understand the mechanisms by which mutations in *GABRA1* cause disease, we developed a zebrafish model of *gabra1* deficiency. *gabra1* expression is restricted to the nervous system and behavioral analysis of morpholino injected larvae suggests that the knockdown of *gabra1* causes hypoactivity. At a molecular level, hypoactivity is associated with defects in the expression of the most common sub-units of the $GABA_AR$. Collectively, our data raise the possibility that defects in *gabra1* expression, alter the normal composition of the $GABA_AR$, subsequently resulting in hypomotility.

The Glutamate Receptor Glr-1 a Candidate Substrate for Endoplasmic Reticulum Associated Degradation in *Caenorhabditis Elegans*.

J. Aguilera, S. Witus, D. Hassell; Western Washington University, Bellingham, WA.

Organisms require constant synthesis of proteins that are necessary to carry out specific functions at particular locations. For example, proteins found in cellular membranes are synthesized at the endoplasmic reticulum (ER). However, up to 30% of new proteins are improperly folded and must be removed. A build-up of misfolded proteins can trigger the Unfolded Protein Response (UPR) which initiates other pathways of protein quality control and determines the fate of a cell. ER-associated degradation (ERAD) is a ubiquitin-dependent process in eukaryotic cells that help alleviate protein accumulation by breaking down misfolded proteins recognized by the proteasome. The ERAD system is well described in yeast but is less well studied in multicellular systems. We use *C. elegans* as a model organism to study ERAD and a single membrane protein of interest that function in the pathway. Our membrane protein of interest is the glutamate receptor-1 (GLR-1), a model protein tagged with GFP (GLR-1::GFP), which allows us to observe if GLR-1 is a candidate substrate for ERAD. GLR-1 is expressed in a subset of interneurons in the ventral nerve cord (VNC) and accumulates at the synaptic membrane along the neurites of the VNC. We are assessing GLR-1's accumulation in the absence of ERAD E3 ubiquitin ligases in *C. elegans*. Three putative ERAD E3 ligases in *C. elegans* are: HRD-1, MARC-6, and HRDL-1. Deletion of most of the gene encoding HRDL-1, caused an increased accumulation of GLR-1::GFP in *C. elegans*. In addition, more of the accumulated protein (GLR-1) was retained at the ER in *hrdl-1* mutant animals, compared to controls. Together, these data suggest that *hrdl-1* has a role in regulating GLR-1 degradation at the ER and that GLR-1 may be a candidate endogenous substrate for ERAD. In order to understand how ERAD effects GLR-1, we are using tunicamycin to block ER-dependent glycosylation and initiate the UPR. Tunicamycin treatment induces ER stress, which activates a UPR-

reporter construct P*hsp-4*::GFP in *C. elegans*. An imals expressing the ER stress reporter *hsp4*::GFP respond to tunicamycin at lower doses when they harbor the mutation gene *hrdl-1*. We are using quantitative fluorescence imaging and immunoblotting to determine whether the GLR-1::GFP accumulation defects are due to underlying ER stress caused by the lack of HRDL-1, or if GLR-1::GFP's accumulation is due to a specific interaction between HRDL-1 on GLR-1::GFP.

Understanding Clock Protein Dynamics and Localization Over the 24-hour Circadian Cycle.

S. Yadlapalli, Y. Xiao, M. Jimenez; University of Michigan, an n Arbor, MI.

All living organisms including bacteria, plants, and mammals have evolved time keeping mechanisms such as circadian clocks to synchronize their internal state to the external environment. Almost every cell in the human body has a molecular clock, which is based on a negative transcription-translation feedback loop, and these clocks orchestrate daily rhythms in many physiological processes, from sleep to metabolism. In our studies we use the *Drosophila melanogaster* clock neurons as they feature a highly conserved clock similar to humans and are amenable to powerful genetic and molecular tools. Specifically, the *Drosophila* clock is based on a negative transcription-translation feedback loop made up of four key clock genes–Clock (CLK), Cycle (CYC), Period (PER), and Timeless (TIM). In preliminary studies we performed 4-D live-cell super-resolution imaging to investigate the subcellular spatio-temporal dynamics of PER in individual clock neurons in *Drosophila* brains over the 24-hour cycle. Specifically, we generated fluorescent protein tagged flies (endogenous PER tagged with mNeonGreen, a green fluorescent protein) using CRISPR and first confirmed that the tagged protein is functional. Next, from live imaging studies we found that PER is concentrated in distinct, dynamic nuclear foci (*i.e.* change in position and size with time) in the clock neurons—through a process of liquid-liquid phase separation. We are currently investigating the role of clock protein phase separation in the regulation of circadian clocks. This work is expected to provide important new insights into how circadian rhythms are regulated and also illuminate general principles of gene regulation and phase separation in cellular organization.

The Glycolytic Protein Phosphofructokinase Dynamically Relocalizes into Subcellular Compartments with Liquid-like Properties in *Vivo*.

S. Jang[1], Z. Xuan[1], R. C. Lagoy[2], L. M. Jawerth[3], **I. J. Gonzalez**[1], M. Singh[1], S. Prashad[1], H. Kim[1], A. Patel[3,4], D. R. Albrecht[2], A. A. Hyman[3], D. A. Colón-Ramos[1,5]; [1]Department of Neuroscience and Department of Cell Biology, Yale University School of Medicine, New Haven, CT, [2]Department of Biomedical Engineering and Department of Biology and Biotechnology, Worcester Polytechnic Institute, Worcester, MA, [3]Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, GERMANY, [4]Dewpoint Therapeutics GmbH, Dresden, GERMANY, [5]Instituto de Neurobiología, Universidad de Puerto Rico, San Juan, PUERTO RICO.

While much is known about the biochemical regulation of glycolytic enzymes, less is understood about how they are organized inside cells. Here we built a hybrid microfluidic-hydrogel device for use in *Caenorhabditis elegans* to systematically examine and quantify the dynamic subcellular localization of the rate-limiting enzyme of glycolysis, phosphofructokinase-1/PFK-1.1. We determine that endogenous PFK-1.1 localizes to distinct, tissue-specific subcellular compartments in *vivo*. In neurons, PFK-1.1 is

diffusely localized in the cytosol, but capable of dynamically forming phase-separated condensates near synapses in response to energy stress from transient hypoxia. Restoring animals to normoxic conditions results in the dispersion of PFK-1.1 in the cytosol, indicating that PFK-1.1 reversibly organizes into biomolecular condensates in response to cues within the cellular environment. PFK-1.1 condensates exhibit liquid-like properties, including spheroid shapes due to surface tension, fluidity due to deformations, and fast internal molecular rearrangements. Prolonged conditions of energy stress during sustained hypoxia alter the biophysical properties of PFK-1.1 in *vivo*, affecting its viscosity and mobility within phase-separated condensates. PFK-1.1's ability to form tetramers is critical for its capacity to form condensates in *vivo*, and heterologous self-association domain such as cryptochrome 2 (*CRY2)* is sufficient to constitutively induce the formation of PFK-1.1 condensates. PFK-1.1 condensates do not correspond to stress granules and might represent novel metabolic subcompartments. Our studies indicate that glycolytic protein PFK-1.1 can dynamically compartmentalize in *vivo* to specific subcellular compartments in response to acute energy stress via multivalency as phase-separated condensates.

P1351/B482

Regulation of Mbp Local Translation Is Crucial for Adult Myelin Maintenance.

M. Fu, A. Valenzuela, B. Barres; Stanford University, Stanford, CA.

Efficient electrical signaling along axons depends on formation of compact myelin. This process of compaction requires myelin basic protein (MBP) to function as a molecular zipper to exclude cytoplasmic proteins and organelles from regions of compact myelin. *Mbp* is the most highly expressed mRNA in oligodendrocytes by 10-fold and it is transported along oligodendrocyte processes by kinesin and dynein before it is locally translated. Here, we further elucidate the mechanisms that regulate MBP local translation. First, ribosomal abundance inversely correlates with MBP protein levels. In primary oligodendrocytes, ribosomes accumulate slowly on the timescale of days prior to MBP protein translation. However, oligodendrocytes with high levels of MBP protein have few ribosomes, indicating that ribosomes may be degraded following MBP translation. In compartmentalized Boyden chambers, RNA isolated from oligodendrocyte processes contain high levels of ribosomal RNA, indicating that ribosomes may themselves be locally translated. Second, we ask whether transport of *Mbp* mRNA is required for MBP translation. In a proteomic screen using the RNA-binding reporter MS2, we found that *Mbp* mRNA associates with a myosin motor that is mutated in patients with distal myopathy and white matter lesions. We show that the myosin inhibitor blebbistatin causes *Mbp* mRNA to accumulate along microtubules, no longer distribute along actin, and also blocks MBP translation. We confirm this effect is specific to *Mbp* mRNA using a mouse model that replaces the *Mbp* 3'UTR with a stabilizing polyA sequence; these mice still express the *Mbp* CDS and thus are theoretically capable of translating MBP. Oligodendrocytes cultured from these mice strikingly lack *Mbp* mRNA granules outside the cell body, but have aberrant, large donut-shaped *Mbp* mRNAs outside the cell body that co-localize with late endosomes/lysosomes markers (Rab7, LAMP1). However, in both 2D and 3D microfiber cultures, these cells do translate MBP outside of the cell body. Thus, though 3'UTR-less *Mbp* mRNA can nonspecifically localize outside the cell body, they cannot be translated. This is consistent with the striking phenotypes of these adult mice - hypomyelination, tremors, and severe motor coordination defects. Third, we measure the dynamics of MBP translation. Using a photoactivatable reporter, we find that MBP translation does not occur gradually, but mostly in the fifth day of differentiation. Imaging with membrane-anchored GFP, we observe compaction events that occur rapidly, on the timescale of 3-5 minutes. Together, these experiments indicate that MBP translation is a highly regulated event that

relies on the convergence of ribosome accumulation and regulation of *Mbp* mRNA transport and translation activation via the 3'UTR.

P1352/B483

Dynamics of Endoplasmic Reticulum Proteins in Nerve Terminals.

L. Benedetti[1], C. J. Obara[1], P. De Camilli[2], J. Lippincott-Schwartz[1], T. A. Ryan[3]; [1]HHMI Janelia Research Campus, Ashburn, VA, [2]Yale University School of Medicine, New Haven, CT, [3]Weill Cornell Medical College, New York, NY.

The endoplasmic reticulum (ER) is the largest membrane-enclosed organelle in eukaryotic cells. It spreads throughout the cytoplasm, where it plays an essential role in membrane and secretory protein synthesis, in the biogenesis of most membrane lipids, Ca^{2+} storage and metabolite processing. The ER is a network of interconnected tubules and cisternae that forms specialized subdomains such as the nuclear envelope, the ribosome-rich ER (RER) and the smooth ER (SER). The three-dimensional reconstruction of subcellular organelles from FIB-SEM image stacks of mouse brain tissue revealed that neuronal cell bodies and dendrites are enriched with a continuous network of tubules and cisternae decorated by ribosomes[1]. In axons small narrow tubules of smooth ER are most abundant[2], and thin axonal segments contain a single continuous tubule of smooth ER that branches or expands in small cisternae at synaptic varicosities[1]. Several mutations in ER-resident proteins have been reported to cause the neurological disorder hereditary spastic paraplegia[3], however the role of axonal ER at the nerve terminal is still not well understood. It has been recently shown that changes in axonal ER luminal calcium regulate nerve terminal function through a mechanism involving the ER membrane protein STIM1. When ER calcium levels drop significantly below ~ 150 µM, STIM1 is mobilized and inhibits presynaptic function, through a poorly characterized mechanism [4]. In order to gain insight into the dynamics of ER proteins in axons we have used single particle tracking of Halo-tagged ER proteins, including STIM1. Given the highly dynamic rearrangements or ER structures and the rapid redistribution or ER proteins[5,6], we hope to elucidate its role in the modulation of presynaptic function.

A Novel System for Compartmentalized Study of Neuronal Intermediate Filament Proteostasis in Axons.

M. Faridounnia, R. Battaglia, A. Beltran, N. Snider; UNC-Chapel Hill, Chapel Hill, NC.

Sensory and motor axons extend long distances to transmit electrical impulses between the central nervous system and the periphery. Neuronal intermediate filaments (IFs), which include neurofilaments, α-internexin and peripherin, are major structural components of the axon. Several neurodegenerative diseases present with large axonal swellings that are sites of localized IF protein accumulation. Axonal IF protein accumulation directly impairs neuronal function, which is most dramatically exemplified in the progressive and fatal neurodegenerative disorder giant axonal neuropathy (GAN). GAN is caused by loss-of-function genetic mutations in the E3 ubiquitin ligase adaptor protein gigaxonin, which controls IF protein turnover. This work aims to develop novel patient-derived cellular models to study and target axonal dysfunction caused by IF protein accumulation in GAN. We generated induced pluripotent stem cells (iPSCs) by reprogramming skin fibroblasts from seven GAN patients carrying gigaxonin mutations the severity of which is associated with specific motor function measure scores (MFM). We used CRISPR/Cas9 gene editing to correct the homozygous missense mutation p.G332R in the iPSCs line

derived from a patient with severe symptoms, as determined by the MFM score (30.2/100). Using established motor neuron differentiation protocols, we differentiated the iPSCs to neural progenitor cells (NPCs) and seeded them on pre-assembled microfluidic devices (XonaChipTM). The NPCs were differentiated to motor neurons using defined media conditions for 45 days. We used confocal microscopy to investigate the expression, localization, and aggregation of several IFs proteins at cell soma, dendrites, and along the axons in both the isogenic controls and parental cells carrying the disease mutations. The use of microfluidic system, coupled with confocal imaging, dramatically improve the localization analysis and resolution of IF protein aggregates along the length of the axons. This system revealed abundant aggregation of neurofilaments (heavy and medium), phospho-neurofilament, and α-internexin. The imaging analysis further revealed differences in aggregate size and distribution pattern along the length of the axon, likely reflecting differences in protein composition of the inclusions. In contrast, isogenic control iPSC-derived motor neurons displayed normal filament structures with smooth and uniform axons. In conclusion, we successfully established a novel in vitro tool to study defective IF proteostasis in axons within a microenvironment distal to the cell soma. This system enables investigation of GAN disease mechanisms and testing of therapeutic candidate compounds to alleviate IF protein accumulation specifically in axons.

Direct Delivery Is the Predominant Trafficking Pathway of Axonally Polarized Membrane Proteins.

A. T. Nabb, M. Bentley; Department of Biological Sciences and the Center for Biotechnology and Interdisciplinary Studies, Rensselaer Polytechnic Institute, Troy, NY.

Neurons are polarized cells with axons and dendrites. These domains serve different functions in electrochemical signaling and require different complements of plasma membrane proteins. Membrane proteins are synthesized in the cell body and delivered to neurites via microtubule-based vesicle transport. Because axons can be up to a meter long in humans, they are particularly reliant on vesicle transport. The exact trafficking pathway of axonal membrane proteins is not well understood. Two models have been proposed: 1) in the direct delivery model, proteins are packaged into axon-selective vesicles at the Golgi. These vesicles can move in dendrites but only fuse with the axonal plasma membrane. 2) in the transcytotic model, proteins are packaged into vesicles that fuse with the dendritic plasma membrane. There they are endocytosed into vesicles that fuse with the axonal plasma membrane. The relative contribution of these two pathways towards the delivery of axonal membrane proteins is unknown and has been a long-standing question in neuronal cell biology. Because different sorting machineries act at the Golgi and the plasma membrane, determining the location of protein sorting into axon-selective vesicles is a crucial step towards understanding how axons are maintained. We developed a novel assay in hippocampal neurons to determine if any given axonal vesicle contains transcytotic proteins. We engineered modified versions of two important axonal proteins, neuron-glia cell adhesion molecule (NgCAM) and vesicle-associated membrane protein (VAMP) 2. We designed these proteins with a streptavidin-binding peptide in their ectodomain and a GFP label. Fluorescent streptavidin in the culture medium only labels vesicles that contain endocytosed proteins. Transcytotic vesicles are labelled with both GFP and streptavidin while vesicles directly delivered to the axon are only labeled with GFP. Two-color live-imaging of axonal vesicles found that the vast majority of axonal NgCAM vesicles (>95 %) and nearly three quarters of axonal VAMP2 vesicles (72 %) were the product of direct delivery. Simultaneous labeling of NgCAM and VAMP2 found that both proteins occupied the same Golgi-derived vesicles, whereas transcytotic VAMP2 vesicles were a distinctly different population.

These results have important implications for understanding neuronal membrane trafficking. Direct delivery is the predominant sorting pathway for axonally polarized membrane proteins. A small population of VAMP2 arrives in the axon via transcytosis, suggesting that this protein interacts with two different sorting machineries. The sorting machineries and sorting signals that target axonal membrane proteins are as yet undetermined.

P1355/B486

A Novel Labeling Strategy Reveals That Neuronal Myosin V-labeled Vesicles Are Polarized to Dendrites.

M. Frank, M. Bentley; Department of Biological Sciences and the Center for Biotechnology and Interdisciplinary Studies, Rensselaer Polytechnic Institute, Troy, NY.

The maintenance of the eukaryotic endomembrane system requires accurate trafficking of proteins between different cellular compartments by vesicle transport. This is particularly important for neurons, which have numerous subdomains that require specific complements of membrane proteins. Kinesins and dynein mediate long-range microtubule-based transport, while myosins mediate short-range actin-based transport. Myosin V is the primary processive motor that mediates transport towards the barbed end of actin, but little is known about its neuronal functions and its interactions with other motors. Identification of Myosin V cargoes is crucial for determining its neuronal function. One obvious approach to address this is to coexpress fluorescent Myosin V and candidate cargo proteins in the same cell. This is challenging because overexpression of full-length Myosin V results in a bright soluble pool that masks labeled vesicles. We recently developed a strategy to visualize vesicle-bound kinesins by expressing their vesicle-binding tail domains. Here we applied this approach to Myosin V in hippocampal neurons. Live-cell imaging found that Myosin V-labeled vesicles were polarized to the somatodendritic domain and many of these vesicles underwent long-range transport. To determine the identity of these vesicles, we coexpressed Myosin-V tail and important neuronal vesicle trafficking proteins. We found that Myosin V co-transported with the dendritically polarized transferrin receptor, vesicles associated with Kinesin-3 family motors KIF13A and KIF13B. Myosin V also co-transported with a subset of vesicles carrying the dendritically polarized low-density lipoprotein receptor, vesicles associated with the Kinesin-3 motors KIF1A and KIF13B. Unpolarized dense-core granules labeled with brain-derived neurotrophic factor and axonally polarized vesicles labeled with neuron-glia cell adhesion molecule did not colocalize with Myosin V. We systematically measured overlap between Myosin V vesicles and important neuronal cargo proteins. Our results suggest that Myosin V binds to vesicles concurrently with several Kinesin-3 family members. This raises an important question: How are Myosin V and kinesin activity coordinated on the same vesicle? Our findings are also consistent with a previously proposed role for Myosin V in mediating retention of dendritically polarized vesicles in the proximal axon. The novel labeling strategy vastly enhances visualization of Myosin V on vesicles and should be broadly applicable for investigating Myosin V function in many cell types.

P1356/B487

Endocytosis of Dendritic Membrane Proteins in the Axon Initial Segment Is Essential for Neuronal Compartmentalization.

K. Eichel[1], S. Cheng[2], J. Pak[2], C. Taylor[1], E. Özkan[2], K. Shen[1]; [1]Stanford University, Stanford, CA, [2]University of Chicago, Chicago, IL.

How membrane proteins are differentially trafficked to specific domains within a cell is a long-standing question in cell biology. Due to their large size and extreme compartmentalization into axons and dendrites, neurons especially rely on divergent membrane trafficking mechanisms. The axon initial segment (AIS) of the neuron is a specialized boundary zone between the axon and dendrite, and it acts as a selective filter and/or diffusion barrier to achieve protein compartmentalization. We delineate a novel active sorting mechanism in the AIS in which dendritic membrane proteins are endocytosed and degraded to prevent their entry into the axon. We identified this mechanism by studying the dendritic morphology guidance receptor, DMA-1, which is required for the development of the *C. elegans* PVD neuron dendrite, but not its axon. Endogenously labeled DMA-1::GFP is highly polarized to the PVD dendrite and excluded from the axon. We found that DMA-1 undergoes endocytosis in the AIS and localizes to late endosomes. Endogenously labeled clathrin light chain localizes to multiple puncta in the AIS, a region not previously recognized as a site of endocytosis. Together, these results suggest that DMA-1 endocytosis in the AIS is an active removal mechanism to prevent axon entry. Indeed, we found that endocytic inhibition using a temperature sensitive dynamin mutant causes DMA-1 mislocalization to the axon and aberrant axonal branching. We also identify a novel DMA-1 interacting protein called LRP-1 like (LRPL-1), which is essential for DMA-1 endocytosis in the AIS. Therefore, we have delineated a novel mechanism in which the AIS dictates the membrane trafficking and localization of neuronal receptors. Inhibition of this active endocytic sorting mechanism results in the loss of protein compartmentalization and alteration of neuron morphology. These results define a new framework for understanding membrane trafficking mechanisms in the axon initial segment of the neuron.

P1357/B488

Activity Induces Presynaptic Mitochondria Capture and Energy Maintenance Via Syntaphilin-mediated an choring and Ampk Energy Sensing Pathway.

S. Li, G. Xiong, N. Huang, Z. Sheng; Synaptic Function Section, National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MD.

Mitochondria supply ATP essential for supporting high energy-demanding synaptic transmission. Due to their unique polarized structure, neurons face exceptional challenges in maintaining presynaptic energy supply by delivering and anchoring mitochondria at distal synapses. The loss of presynaptic mitochondria inhibits synaptic transmission. Synapses are highly plastic and undergo activity-dependent remodeling; thereby constantly changing mitochondrial re-distribution to meet dynamic energy consumption. Interestingly, sustained synaptic activity is mainly restricted to these mitochondria-containing presynapses during long-term potentiation. Presynaptic mitochondria can be re-mobilized and re-distributed in response to changes in synaptic activity (Sheng 2014). However, the mechanisms recruiting and capturing axonal mitochondria at presynapses in response to changes in synaptic activity and local energy consumption remain largely unknown. Here, we reveal the new energy signaling cascade that controls activity-dependent presynaptic mitochondrial capture and energy maintenance. Syntaphilin plays a crucial role in recruiting and capturing axonal mitochondria at presynaptic terminals

via cytoskeletal track-switch from axonal microtubules to actin filaments that is enriched at synapses. Sustained synaptic activity and thus high ATP consumption activate AMPK signaling, which facilitates mitochondrial recruitment through phosphorylation of downstream anchoring machinery. This pathway allows neurons maintain presynaptic energy supply essential for prolonged and repetitive synaptic transmission. Inhibiting AMPK energy signaling or interfering with the anchoring machinery reduces presynaptic ATP availability, leading to synaptic depression after prolonged stimulation. Thus, our study provides new mechanistic insights into action of cellular energy sensing pathway in the maintenance of presynaptic ATP availability by recruiting axonal mitochondria in response to increased synaptic activity (Supported by the Intramural Program of NINDS, NIH). Reference: Sheng ZH (2014). Mitochondrial trafficking and anchoring in neurons: New insight and implications. J Cell Biol. 204(7):1087-1098.

P1358/B489

Suppression of Axonal Transport of Mitochondria Disrupts Protein Degradation Pathways and Induces Accumulation of Ubiquitinated Proteins in the *Drosophila* Brain.

K. Shinno[1], M. Oka[1], E. Suzuki[2,3], K. M. Iijima[4,5], K. An do[1,6]; [1]Department of Biological Sciences, Graduate School of Science, Tokyo Metropolitan University, Tokyo, JAPAN, [2]Gene Network Laboratory, National Institute of Genetics, Shizuoka, JAPAN, [3]Department of Genetics, School of Life Science, SOKENDAI, Kanagawa, JAPAN, [4]Department of Alzheimer's Disease Research, Center for Development of Advanced Medicine for Dementia, National Center for Geriatrics and Gerontology, Aichi, JAPAN, [5]Graduate School of Pharmaceutical Sciences, Department of Experimental Gerontology, Nagoya City University, Aichi, JAPAN, [6]Division of Biological Sciences, School of Science, Tokyo Metropolitan University, Tokyo, JAPAN.

Mitochondrial transport in the neuronal axon plays critical roles in physiology and pathophysiology. Defects in axonal transport of mitochondria have been suggested in the pathogenesis of a number of neurodegenerative diseases such as Alzheimer's disease and Parkinson's disease. Abnormal accumulation of proteins in neurons are another pathological feature of these diseases and thought to contribute to neuronal death. These observations indicate that disruption of protein homeostasis and intracellular distribution of mitochondria are both play critical roles in neurodegeneration in these disorders. However, the role of mitochondria in protein homeostasis is not well understood. Here we report that disruption of mitochondrial distribution to the axon causes an accumulation of ubiquitinated proteins in the brain in *Drosophila*. Neuronal knockdown of milton or Miro, an adaptor protein for axonal transport of mitochondria, causes depletion of mitochondria from the axon and causes age-dependent neurodegeneration. To ask whether proteostasis is affected in these fly brains, we analyzed the levels of ubiquitinated proteins at different ages. Western blot and immunostaining revealed that milton knockdown causes accumulation of ubiquitinated proteins in young fly brains before the onset of neurodegeneration. Ultrastructural analysis of the photoreceptor neurons with milton knock down detected dense material suggesting protein accumulation. We further analyzed whether protein degradation pathways were disrupted by milton knockdown. Western blot of autophagy markers LC3-I/II and p62 as well as analyses of autophagic fluorescent reporter revealed that autophagic flux is reduced in fly brains with milton knockdown. Finally, to gain insight into the underlying mechanism, we tested whether an overall reduction in mitochondrial functions was sufficient to cause accumulation of ubiquitinated proteins in the brain. We found that overall reduction in mitochondrial function by mutation in mitochondrial ribosomal protein S12 did not cause either accumulation of ubiquitinated proteins or autophagic deficits. These results suggest that accumulation of ubiquitinated proteins observed in milton knockdown flies are due to mislocation of mitochondria rather than a reduction in

mitochondrial function in the axon. Our results suggest that the reduction in the axonal distribution of mitochondria causes disruption in proteostasis and may contribute to the onset and progression of neurodegenerative diseases.

P1359/B490

Four and a Half LIM Domains Protein 2 Mediates Mitochondrial an choring to F-actin.

H. Basu[1,2], G. Pekkurnaz[3,2], W. Wei[4,2], M. Chin[2], T. Schwarz[1,2]; [1]Harvard Medical School, Boston, MA, [2]Boston Children's Hospital, Kirby Neurobiology Center, Boston, MA, [3]Department of Biological Sciences, University of California, San Diego, CA, [4]Department of Biology, Stanford University, Palo Alto, CA.

Mitochondria form distinct pools of stationary and motile organelles. The movement of the motile pool of mitochondria is powered by microtubule based molecular motors. The motors are recruited to the mitochondria by a complex of two proteins on the outer mitochondrial membrane: Miro (also called RHOT 1/2) and Milton (also called TRAK 1/2). Here we report a mechanism by which the Miro/Milton complex, and thereby the mitochondria, are anchored to the F-actin cytoskeleton in response to changes in glucose availability. The immobilized mitochondria retain their molecular motors and can regain their motility when the actin network is disrupted. This pathway of mitochondrial anchoring to F-actin is activated by an acute influx of glucose. This influx triggers the O-GlcNAcylation of Milton by the enzyme O-GlcNAc transferase (OGT). The O-GlcNAcylated Milton binds the actin-binding protein, Four and a half LIM domains protein 2 (FHL2), and thus becomes anchored to the F-actin cytoskeleton. To support this model we demonstrate that: 1) a glucose influx or the over-expression of OGT leads to O-GlcNAcylation of Milton and immobilizes mitochondria; 2) F-actin is responsible for immobilizing the O-GlcNAcylated mitochondria; 3) FHL2 co-immunoprecipitates with Milton under conditions that promote its O-GlcNAcylation; 4) mutation of the O-GlcNAcylation sites on Milton prevents its association with FHL2; 5) knockdown of FHL2 prevents mitochondrial arrest even in the presence of O-GlcNAcylated Milton; 6) artificially targeting FHL2 to the outer mitochondrial membrane is sufficient to drive the association of mitochondria with actin and to stop their movement. Therefore, the recruitment of FHL2 to the mitochondrial surface upon Milton O-GlcNAcylation is both necessary and sufficient to arrest mitochondrial movement by tethering to F-actin. In non-neuronal cells, FHL2 mediated mitochondrial anchoring results in a significant increase of F-actin density around mitochondria. In axons, however, the mitochondria appear to anchor to preexisting actin filaments without any cytoskeletal rearrangement. This mechanism of mitochondrial anchoring to F-actin likely operates in *vivo*. We have previously observed that Milton O-GlcNAcylations are altered by a fasting/feeding protocol (Pekkurnaz et al., 2014). Further, we find that changes in extracellular glucose concentrations, which mimic serum glucose fluctuations post feeding, arrests mitochondria in an F-actin and FHL2 dependent manner. This phenomenon of O-GlcNAcylation mediated mitochondrial arrest appears to be pervasive across multiple cell types and across different species, from *Drosophila to* mammals. Thus, the mechanism is likely conserved and broadly utilized for adapting mitochondrial dynamics to local glucose supply.

P1360/B491

RETROGRADE Transport Is Required for Mitochondrial Health and Function in Neurons.

A. Mandal, K. Pinter, C. M. Drerup; NIH/NICHD, Bethesda, MD.

Maintenance of functional neural circuits is critical for organism survival. To form and maintain the elaborate structure of a neuron, proteins and organelles must be transported to the correct location

throughout the cell. One organelle of particular importance is mitochondria. Mitochondria produce ATP and regulate cytosolic calcium, among perhaps lesser known functions, critical for neuronal maintenance. Abnormalities in mitochondrial transport are associated with neurodegenerative diseases but the mechanisms leading to pathology are largely unknown. While we have a basic understanding of the molecular regulators of anterograde transport of mitochondria (axon terminal directed), the mechanisms regulating retrograde (cell body directed) transport and the actual function of this process were not clear. Furthermore, the dynamics of mitochondrial movement in neurons on timescales longer than minutes were completely unknown. To begin to address these long-standing questions, we used photoconversion and long-term tracking of mitochondria in vivo to assess the frequency of retrograde mitochondrial transport. Our results indicate that mitochondria in mature axons are largely stationary on the order of minutes but move long distances over the course of hours. Strikingly, mitochondria that originate in axon terminals utilize retrograde transport to return to the cell body from the distal axon with complete population turnover from axon terminals within three hours. Our data also illustrates that this process is not just for mitochondrial degradation: inhibition of retrograde mitochondrial movement leads to loss of cell body mitochondrial load. Using various fluorescent reporters, we found that organelles which cannot move back to the cell body show an imbalance of the oxidation/redox system, loss of matrix potential and impaired calcium buffering capacity in neurons. Finally, we provide evidence that retrograde mitochondrial transport back to the cell body is important for maintaining the mitochondrial proteome, likely by bringing the organelle back to the center of protein synthesis for the cell. Altogether, our work has shown the first direct evidence that retrograde transport is essential to maintain mitochondrial homeostasis in neurons.

P1361/B492

Als-associated Mutations in Tbk1 Differentially Disrupt Mitophagy Kinetics.

O. Harding[1], J. Cheung[2], J. Ye[3], E. L. F. Holzbaur[1]; [1]University of Pennsylvania, Philadelphia, PA, [2]New York Structural Biology Center, New York, NY, [3]Columbia University, New York, NY.

TANK-binding kinase-1 (TBK1) has been implicated in several key cellular pathways, including the clearance of damaged mitochondria via mitophagy. The wild-type TBK1 molecule functions as a dimeric kinase that is activated by trans-autophosphorylation to stabilize components of the mitophagy machinery and promote clearance of the damaged organelle. Several mutations of TBK1 are causative for the neurodegenerative disease amyotrophic lateral sclerosis (ALS), but their respective effects on the mitophagic mechanisms are unknown. Interestingly, these mutations occur throughout the structure of TBK1, and are predicted to disrupt a variety of its functions, including kinase activity, dimerization, and overall stability of the molecule. We complemented structural and biochemical analyses of TBK1 mutants with fluorescence microscopy to test whether each mutant could form mitophagy rings after mitochondrial damage. A monomeric TBK1 mutant, R357Q, forms rings around damaged mitochondria. However, TBK1 mutants with abolished auto-phosphorylation activity, G217R (dimeric) and M559R (monomeric), demonstrate significantly less ring formation. Meanwhile, R47H, a mutant with weak autophosphorylation activity does form mitophagy rings, but has poor co-recruitment of TBK1's mitophagy partner, optineurin (OPTN). With live cell timelapse imaging, we can dissect the kinetics of mitophagy components throughout the pathway and compare the findings among TBK1 mutants. M559R never translocates to damaged mitochondria, while G217R can be weakly recruited. Together, these results indicate that the various ALS-associated mutations of TBK1 disrupt mitophagy at a range of

steps, which may be relevant in developing targeted therapies. This project is supported by Project ALS and R37 NS060698.

Misregulation of Mitochondria - Lysosome Contact Sites in Mutant GBA Parkinson's Patient Neurons.

S. Kim, Y. C. Wong, D. Krainc; Northwestern University, chicago, IL.

Parkinson's disease (PD) is the second most common neurodegenerative disorder and has been linked to defects in both mitochondrial and lysosomal function. However, while mitochondria and lysosomes are critical organelles for maintaining neuronal homeostasis, how their dynamics are bidirectionally regulated in neurons is still not well understood. Our lab recently identified the dynamic formation of inter-organelle mitochondria-lysosome contact sites in non-neuronal cells which are essential for regulating the network dynamics of both mitochondria and lysosomes (*Wong et al., Nature 2018*). However, the role of mitochondria-lysosome contact sites in human neurons, as well as their contribution to Parkinson's disease pathogenesis has not been previously studied. Using human iPSC-derived dopaminergic neurons, we found that mitochondria-lysosome contact sites dynamically form in the cell body, axon and dendrites of human neurons. Interestingly, mitochondria-lysosome contact sites are potentially affected by lysosomal enzymes, as reduced activity of the lysosomal enzyme GBA (β-glucocerebrosidase) disrupts lysosomal dynamics contributing to defective mitochondria-lysosome contact site formation. Moreover, heterozygous GBA mutations in familial Parkinson's disease patient neurons exhibit dysfunctional mitochondria-lysosome contact dynamics, resulting in disrupted mitochondrial dynamics in both the axon and cell body. Together, these findings may advance our understanding of fundamental biology underlying the interplay between mitochondria and lysosomes in neurons, and provide important insights into disease pathogenesis in Parkinson's disease.

P1363/B494

Impaired Lysosome Transport to Distal Axons Contributes to Autophagic Stress in the Neurodegenerative Lysosomal Storage Disorder Niemann-Pick Type C.

J. C. Roney[1,2], T. Farfel-Becker[1], X. Cheng[1], F. M. Platt[2], Z. Sheng[1]; [1]Synaptic Function Section, National Institute of Neurological Disorders and Stroke, NIH, Bethesda, MD, [2]Department of Pharmacology, University of Oxford, Oxford, UNITED KINGDOM.

Niemann-Pick Type C (NPC) is a neurodegenerative lysosomal storage disorder characterized by accumulation of multiple lipids in late endosomes and lysosomes. An early pathologic feature of NPC is axonal dystrophy, which consists of bulbous swellings along axons that contain accumulated organelles associated with the autophagy-lysosomal pathway. Such changes occur before symptom-onset and neurodegeneration in NPC mice and suggest that defects in axonal organelle transport contribute to early NPC pathology. However, the mechanisms underlying these pathologic changes remain obscure. Our recent study characterized axon-targeted delivery of degradative lysosomes and demonstrated that the axon is an active compartment for local degradation (Farfel-Becker T et al., ***Cell Reports*** 2019). This work establishes a foundation for our current investigations into axonal lysosome trafficking and functionality in early NPC disease. Here we demonstrate that mature lysosome delivery to distal axons is significantly reduced in cortical neurons from Npc1 null mice, resulting in lower numbers of degradative lysosomes in NPC distal axons. Decreased axonal lysosome density leads to increased axonal autophagic stress that occurs without changes to autophagosome transport in NPC axons. The small GTPase Arl8b is

a limiting factor in coupling lysosomes to the kinesin-1 motor for driving lysosomal transport, and we demonstrate that elevated Arl8b expression facilitates axonal delivery of mature active lysosomes in NPC. Rescuing axonal lysosome density by Arl8b expression reduces autophagic stress in axons from pre-symptomatic NPC mice. Collectively, these observations suggest a new pathological mechanism by which impaired lysosome transport disrupts maturation and progression of the autophagy-lysosomal pathway and contributes to altered axonal homeostasis in NPC. (Supported by the Intramural Research Program of NINDS, NIH) Farfel-Becker T, Roney J C, Cheng X-T, Li S, Cuddy S R, and Sheng Z-H. (2019). Neuronal soma-derived degradative lysosomes are continuously delivered to distal axons to maintain local degradation capacity. ***Cell Reports*** 28, 51-64.

Expression of Wipi2b Counteracts Age-related Decline in Autophagosome Biogenesis in Neurons.

A. K. H. Stavoe, E. L. F. Holzbaur; University of Pennsylvania, Philadelphia, PA.

Autophagy defects are implicated in multiple late-onset neurodegenerative diseases including Amyotrophic Lateral Sclerosis (ALS) and Alzheimer's, Huntington's, and Parkinson's diseases. Since aging is the most common shared risk factor in neurodegeneration, we assessed rates of autophagy in mammalian neurons during aging. We identified a significant decrease in the rate of constitutive autophagosome biogenesis during aging and observed pronounced morphological defects in autophagosomes in neurons from aged mice. While early stages of autophagosome formation were unaffected, we detected the frequent production of stalled LC3B-negative isolation membranes in neurons from aged mice. These stalled structures recruited the majority of the autophagy machinery, but failed to develop into LC3B-positive autophagosomes. Importantly, ectopically expressing WIPI2B effectively restored autophagosome biogenesis in aged neurons. This rescue is dependent on the phosphorylation state of WIPI2B at the isolation membrane, suggesting a novel therapeutic target in age-associated neurodegeneration.

P1365/B496

Defective Axonal Transport of Autophagosomes in *Drosophila* Models of Amyotrophic Lateral Sclerosis (als).

H. Sung, S. Berth, M. Goynatsky, T. Lloyd; Johns Hopkins Univ., Baltimore, MD.

Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disorder characterized by preferential death of motor neurons leading to muscle weakness and atrophy. Although the majority of ALS cases are sporadic, a G_4C_2 hexanucleotide repeat expansion (HRE) in *C9orf72* is the most common inherited cause of ALS (C9-ALS) and frontotemporal dementia (FTD). Since ALS displays selective vulnerability of motor neurons with cytoplasmic protein accumulation and a disruption of fast axonal transport, we hypothesize that dysregulation of axonal trafficking may be a critical step in pathogenesis of motor neuron degeneration in C9-ALS. Here, we performed in *vivo* imaging of *Drosophila* motor neurons expressing 30 G_4C_2 repeats (30R) and investigated the axonal transport of multiple organelles including mitochondria, dense core vesicles (DCVs), late endosomes (LEs), lysosomes and autophagosomes (APs). We found that 30R expression reduces the number of axonal APs, while it causes local accumulation of axonal DCVs, LEs and lysosomes with increased static population of organelles accompanied by alterations in retrograde transport. Since axonal transport of mitochondria was not affected by G_4C_2 HRE, we hypothesize that this preferential alteration in retrograde transport is

due to autolysosomal dysregulation rather than global disruption of axonal transport. Interestingly, 30R expression led to a marked reduction in AP number within motor neuron synaptic boutons, and this deficit was not restored by neuronal excitation with TrpA1. However, the remaining APs in C9-ALS motor neurons underwent normal maturation and development to amphisomes upon successful fusion with LEs during their axonal transport. Collectively, these results suggest that the G_4C_2 HRE causes an impairment in autophagosomal biogenesis in axons in C9-ALS/FTD, and further implicate protein quality control disruption related to autolysosomal degradation process as a critical step in pathogenesis of this disease.

Stimulation of G_{aq}Promotes Stress Granule Formation.

L. Jackson, A. Qifti, A. Singla, O. Garwain, S. Scarlata; Worcester Polytechnic Institute, Worcester, MA.

During adverse conditions, mammalian cells regulate protein production by sequestering the translation machinery in membraneless organelles (i.e. stress granules) whose formation is carefully regulated. Here, we show a direct connection between G protein signaling and stress granule formation through phospholipase Cβ1 (PLCβ1). In cells, PLCβ1, the most prominent isoform of PLCβ in neuronal cells, localizes to both the cytoplasm and plasma membrane. Here, we show that a major population of cytosolic PLCβ1 binds to stress granule proteins, such as PABPC1, eIF5A and Ago2. PLCβ1 is activated by $G_{\alpha q}$ in response to hormones and neurotransmitters and we find that activation of $G_{\alpha q}$ shifts the cytosolic population of PLCβ1 to the plasma membrane, releasing stress granule proteins. This release is accompanied by the formation of intracellular particles containing Ago2 aggregates, an increase in the size and number of particles containing PABPC1 and Ago2, and a shift of cytosolic RNAs to larger sizes consistent with cessation of transcription. These particles are seen when the cytosolic level of PLCβ1 is lowered by siRNA, osmotic stress or $G_{\alpha q}$ stimulation by carbachol. These stresses, in addition to cold, heat, oxidative and arsenite stress produces particles that appear to have different molecular compositions. Our results fit a simple thermodynamic model in which cytosolic PLCβ1 solubilizes stress granule proteins and its movement to $G_{\alpha q}$ upon stimulation releases these particles to allow the formation of stress granules. Taken together, our studies show a link between $G_{\alpha q}$-coupled signals and transcription through stress granule formation.

P1367/B498

Intracellular Trafficking and Secretory Defects in *Progranulin*-deficient Microglia.

Y. Huang[1,2], A. Urisman[1,2], A. Tankka[1,2], A. Leidal[1,2], A. Burlingame[1,3], J. Debnath[1,2], E. Huang[1,2]; [1]University of California San Francisco, San Francisco, CA, [2]Departments of Pathology, University of California San Francisco, San Francisco, CA, [3]Pharmaceutical Chemistry, University of California San Francisco, San Francisco, CA.

Microglia activation is a prominent feature in neurodegenerative diseases. However, there are many critical barriers in our knowledge regarding the cellular and molecular mechanisms that how the microglia are being activated and how these microglia interact with neurons to further promote neurodegeneration. Our previous work showed that deficiency in a common frontotemporal dementia (FTD) gene Progranulin (*GRN*) leads to age-dependent expansion in reactive microglia that promote excessive synaptic pruning in the thalamo-cortical circuit. To characterize the mechanism that promotes aberrant activation of microglia in the absence of progranulin deficiency, we performed stable isotope

labeling by amino acid in cell culture (SILAC) in *Grn*$^{+/+}$ and *Grn*$^{-/-}$ microglia and identified a number of proteins that were differentially expressed in *Grn*$^{-/-}$ microglia. An notations using KEGG pathways showed that most differentially expressed proteins in *Grn*$^{-/-}$ microglia were involved in the phagosome, AGE-RAGE signaling pathway, glutamatergic synapse, and cell adhesion molecules. Consistent with these results, *Grn*$^{-/-}$ microglia showed an increase in phagocytic activity of the zymosan particles and synaptic vesicles. In addition, *Grn*$^{-/-}$ microglia exhibited significant deficiency in cell adhesion properties to several extracellular matrix proteins, including collagens, laminin, fibronectin and fibrinogen. Since microglia is a secretory cell type, we asked how intracellular trafficking defects in *Grn*$^{-/-}$ microglia affected its secretory properties. To this end, we used ultracentrifugation to isolate extracellular vesicles from from *Grn*$^{+/+}$ and *Grn*$^{-/-}$ microglia. Nanosight analyses showed that loss of progranulin significantly reduced the secretion of exososmes in *Grn*$^{-/-}$ microglia. To further characterize how changes in secretion affected the cytotoxic properties in *Grn*$^{-/-}$ microglia, we collected serum-free conditioned media from *Grn*$^{+/+}$ and *Grn*$^{-/-}$ microglia and showed that *Grn*$^{-/-}$ microglia conditioned media were much more toxic to *Grn*$^{-/-}$ neurons. Using SILAC and quantitative proteomics, we showed that *Grn*$^{-/-}$ microglia conditioned media contained elevated amount of complements and lysosomal proteins. Together, these results provide critical insights into how progranulin deficiency alters a number of important cell biological properties in microglia, including endolysosomal trafficking, phagocytosis, cell adhesion and vesicle-mediated secretion. Changes in these properties most likely contribute to neurodegeneration in FTD caused by *GRN* mutations.

P1368/B499

Development of a *LYST*-deficient Glutamatergic Neuronal Model of Chediak-Higashi Syndrome.

J. Serra-Vinardell, M. Morimoto, P. Sharma, M. B. Sandler, K. Keyvanfar, W. J. Introne, M. E. Ward, W. A. Gahl, M. C. V. Malicdan; National Institutes of Health, Bethesda, MD.

Chediak-Higashi Syndrome (CHS) is a lysosome-related organelle (LRO) disorder caused by bi-allelic mutations in the lysosomal trafficking regulator gene (*LYST*), which has 53 exons and encodes a 429 kDa protein (LYST). The clinical characteristics of CHS include oculocutaneous albinism, primary immunodeficiency, coagulation problems, risk for development of hemophagocytic lymphohistiocytosis and high risk of progressive neurological problems such as tremors, ataxia, weakness and intellectual disability. To date, several animal models of CHS have been investigated, but none of them consistently recapitulates the neurological phenotype seen in patients. Additionally, the role of LYST in lysosomal biology is poorly understood and likely a cell type-dependent. For these reasons, we aim to investigate the functions of LYST in a neuronal cell model. Here we describe the generation of a *LYST*-deficient neuronal cell model system using clustered regularly interspaced short palindromic repeats (CRISPR) and CRISPR interference technologies to respectively knock-out and knock-down the expression of endogenous *LYST* in induced pluripotent stem cells (iPSCs). These iPSCs were also engineered to facilitate an inducible expression of the transcription factor Neurogenin 2 to enforce their differentiation into glutamatergic neurons. With this approach, we have successfully established a *LYST*-deficient glutamatergic neuronal system to study the role of LYST in lysosomal biogenesis and trafficking through the endo-lysosomal pathway. Additionally, the homogenous population of neuronal cells obtained by this approach could potentially be utilized for global proteome, transcriptome and metabolome studies.

Egfr Sorting Defects Cause Reduced Neural Stem Cell Proliferation and Microcephaly.

J. Carpentieri[1], A. Di Cicco[1], D. An dreau[1], J. Brault[1], L. Del Maestro[2], L. Coquand[1], N. Bahi-Buisson[3], A. Baffet[1]; [1]Institut Curie, Paris, FRANCE, [2]Universite Paris Diderot, Paris, FRANCE, [3]Hopital Necker-Enfant Malade, Paris, FRANCE.

The development of the neocortex is a highly regulated process whereby each cell type must be correctly specified and positioned. Alterations in this process can lead to a variety of cortical malformations, including microcephaly (small brain). This latter pathology has been recently related to mutations in the WD repeat domain 81 (*WDR81*) gene. WDR81 is a poorly characterized transmembrane protein that has been involved in endosomal maturation as well as aggrephagy. It remains unknown how mutations in WDR81 alters the growth of the neocortex. To address this question, we have generated a CRISPR/Cas9 WDR81 knock-out mouse. Mutant animals die perinatally and recapitulate the human microcephaly phenotype. We demonstrate that the reduced brain size is not due to increased apoptosis or altered cell fate, but to reduced neural stem cell proliferation rates. Importantly, patient-derived fibroblasts also display reduced proliferation, indicating that this may be a general feature of WDR81 loss of function. We identify alterations in the MAP kinase signalling pathway, which shows reduced ERK phosphorylation in mutant cells following EGF stimulation. We further demonstrate that this defect is due to a strong reduction of the EGR receptor (EGFR) expression levels. EGFR levels can be rescued following EGF starvation, indicating that this downregulation is due to altered EGFR downstream signalling. Indeed, we observe EGFR intracellular clearance delays following its internalization after EGF binding. We demonstrate that EGFR accumulates in aberrant swollen early endosomes in WDR81 patient mutant cells, which we also observe in mutant mouse neural stem cells in vivo. Together, this work identifies endosomal EGFR sorting defects as the cause of reduced neural stem cell proliferation and WDR81-linked microcephaly.

P1370/B501

The Ataxia-associated Gene Vps13d Is Required for Mitochondrial Fission and Mitophagic Progression in *Drosophila* Neurons.

R. Insolera[1], P. Lőrincz[2], A. Wishnie[1], M. Burmeister[1], G. Juhász[2], C. Collins[1]; [1]University of Michigan, an n Arbor, MI, [2]Eotvos Lorand University, Budapest, HUNGARY.

In order to support a healthy pool of mitochondria, neurons must sustain a balance of mitochondrial fission and fusion, along with the degradation of damaged mitochondria. Disrupting this balance, and consequently compromising mitochondrial function is a common theme in neurological and neurodegenerative diseases. Recent genetic studies in humans have associated mutations in *VPS13D* with ataxia and childhood-onset movement disorders, and uncovered an essential role for Vps13D in the regulation of mitochondrial morphology. While little is known about the function or cellular localization of Vps13D, its parental yeast protein (vps13) and metazoan family members (Vps13A and C) localize to inter-organelle contacts sites. Human mutations in all members of the Vps13 family (VPS13A-D) are associated with neurological disorders, sparking growing interest in understanding their function and mechanism. In order to better comprehend the vital role of Vps13 proteins in the nervous system, we examined the cell biological consequences associated with loss of Vps13D in *Drosophila melanogaster* neurons. We have found that targeted knockdown of Vps13D in larval motoneurons induces the formation of oversized mitochondria, and a subpopulation of these abnormal mitochondria are being

targeted for degradation through mitophagy. This subpopulation represents intermediates stuck in the late stages of the mitophagy pathway: post-polyubiquitination of damaged mitochondria, but prior to targeting to the lysosome. To understand this novel defect, we asked whether enlarged mitochondria generated via other mechanisms similarly initiate and stall in the mitophagy pathway. Knockdown of the mitochondrial fission protein Drp1 resulted in enlarged mitochondria; however, highly abundant mitophagy intermediates similar to Vps13D loss are only observed when Drp1 was removed in a null mutant background for core autophagy gene Atg5. These observations suggest that inhibition of fission alone induces active and complete mitophagy in neurons. In contrast, mitophagy intermediates in neurons lacking Vps13D stall at the stage of mito-phagophore elongation. Ultrastructural and IHC studies indicate that these intermediates rupture and lose matrix components to the cytoplasm. We conclude that Vps13D loss results in two progressive defects: first in mitochondrial fission, which induces mitophagy, and reveals a second defect in mitophagic progression. Both of these processes are critical to general mitochondrial health, likely contributing to the pathophysiology of the neurological diseases associated with mutations in Vps13D.

P1371/B502

***Hot* Gene Expression and Function in *Caenorhabditis ELegans*.**

K. Mali, R. Sung, J. Wolff; Carleton College, Department of Biology, Northfield, MN.

The Ly6 protein family is structurally characterized by the 4 highly conserved disulfide bonds, giving its members a “three-fingered” shape similar to that of alpha-neurotoxins found in snake venom. Despite these structural similarities, very little is known about the function of the Ly6 proteins. Studies of Ly6 function in mammalian systems are made difficult by the large size of the family, which contains 40 members. In *C. elegans*, however, there are only 10 members of this protein family, making it an apt model organism for establishing an understanding of the function of these proteins. As a first step to deducing the function Ly6 proteins, we hoped to learn their cellular location by generating transcriptional GFP reporters followed by fluorescence microscopy for each of the *hot* genes, as the genes that encode members of the protein family in *C. elegans* are called. In addition, we utilized RNAi knockdown in an attempt to study function. Thus far, we have successfully cloned GFP reporters for *hot* 4 and *hot* 7. Images of these strains show that these proteins are located near the pharynx, alluding to a potentially neuronal role for these proteins. Moving forward, we hope to determine the specific cell, or set of cells, where each hot gene is being expressed as well as gather more conclusive data regarding function using gene deletion analysis.

P1372/B503

Characterization of the HOPS/CORVET Complex in Axon Development.

S. R. Wisner, A. Mandal, C. M. Drerup; NIH/NICHD, Bethesda, MD.

The transport of cargos along neuronal processes is important for maintaining neuronal health and function. This transport occurs in two directions; anterograde (towards axon terminals) and retrograde (towards the cell body). An terograde transport is accomplished by a super family of kinesin motor proteins while retrograde transport is accomplished by a single motor protein complex, Cytoplasmic dynein. While we know that dynein is responsible for all retrograde transport, how it attaches to specific cargos and moves them to the right place at the right time is largely unknown. This process is critical for neurons as disruption to retrograde transport is causal in many neurodegenerative diseases. To address

this gap in our knowledge, our lab uses forward genetics to identify novel modulators of dynein activity. In our forward genetic screen, we identified a mutant *vps18* zebrafish line. This mutant has axon terminal swellings, a sign of disrupted retrograde transport, and hypopigmentation along the body. Further tests show our *vps18* mutants have a loss of function mutation in the Vps18 protein. VPS18 (Vacular protein sorting-associated protein18) is a core component of the HOPS and CORVET complexes in yeast. The HOPS and CORVET complexes are important for membrane fusion in the endolysomal pathway. These two complexes share four proteins as part of the Class C Core subunits consisting of VPS18 along with VPS16, VPS33, VPS11. Each complex also has two complex specific proteins; VPS41 and VPS39 for HOPS, and VPS8 and Tgfbrap1 (VPS3) for CORVET. To determine if Vps18 defects were due to loss of the HOPS and/or CORVET complexes, we used a G0 crispant screen. Guide RNAs against individual HOPS components resulted in axon terminal swellings and hypopigmentation as seen in our *vps18* mutants. Conversely, knockout of CORVET-specific proteins Tgfbrap1 and Vps8 had no pigment or axonal phenotype. This indicates that HOPS, rather than CORVET, has a role in axonal physiology. Additionally, transport of various cargos such as autophagosomes, early and late endosomes and dynein was disrupted and their localization also altered compared to wild type fish, suggesting an additional role for the HOPS complex beyond vesicle fusion. As part of our future studies, we hope to discern the exact role of the HOPS with respect to transport of cargos in neurons and how this transport is important for maintaining neuronal health.

3r:4r Tau Splicing Isoform Ratio Functions as a Leading Indicator for Tdp43 Proteinopathy.

N. Pyles, 15208, J. Mann, C. Donnelly; University of Pittsburgh School of Medicine, Pittsburgh, PA.

3R:4R Tau Isoform Ratio Functions as a Leading Indicator for TDP43 Proteinopathy Amyotrophic Lateral Sclerosis (ALS) is an upper and lower motor neuron disease characterized by progressive motor neuron degeneration. One common pathological hallmark in both familial and sporadic ALS is the presence of cytoplasmic inclusions of TAR DNA Binding Protein 43 (TDP43)—a highly conserved, predominantly nuclear protein that facilitates alternative splicing. Interestingly, these inclusions are also be found in frontotemporal dementia, Alzheimer's disease and chronic traumatic encephalopathy patient pathology. In order to better understand this pathology, the Donnelly lab has established an optogenetic system for rapidly inducing TDP43 inclusion formation with blue light that involves the coupling of a photo-active protein, Cryptochrome 2 (Cry2), to TDP43. The Cry-2 protein rapidly homo-oligomerizes when stimulated with blue light and quickly disaggregates when the stimulus is removed. This platform allows for spatiotemporal control by way of rapid inclusion formation and disaggregation at physiologically relevant translational levels. Furthermore, the platform induces the recruitment of endogenous TDP43 protein into the artificial inclusions thus sequestering TDP43 to the cytoplasm. Our lab has optimized this "OptoTDP43" construct in numerous cell lines and demonstrated that the induced inclusions recapitulate the biochemical markers characteristic of those observed in patient pathology. While our model permits the unparalleled control of insoluble inclusion formation, we have yet to characterize the etiology and pathway of cell death in our model. I hypothesize that the cell toxicity we observe in our model after chronic stimulation is not due to the insoluble cytoplasmic inclusions, but rather, the functional depletion of nuclear TDP43 and subsequent changes in the RNA splicing as a result. One target of TDP43 mediated splicing that is of interest is tau—a microtubule associated protein linked to numerous neurodegenerative pathologies. In recent years, researchers have identified that certain ratios of tau splice-isoforms are associated with a neurotoxic phenotype, particularly imbalances

in the ratio of 3R to 4R tau. It is the objective my research to translate the optoTDP43 model into a new neuronal cell line with GFP tagged TDP43 to demonstrate that cytoplasmic sequestration of TDP3 alters the 3R:4R tau isoform ratio to recapitulate an established tau pathological phenotype. Furthermore, using an oligonucleotide therapy designed to disaggregate cytoplasmic inclusions of TDP43, I wish to demonstrate that the neurotoxic tau isoform ratio can manifest independent of cytoplasmic TDP43 inclusion formation.

P1374/B505

Metabolic Regulation of Neuronal Mitochondria Via O-GlcNAcylation.

S. B. Yu, N. Al-Azzam, G. Pekkurnaz; UC San Diego, La Jolla, CA.

The brain has an exceptionally high energy demand. Metabolic requirements vary greatly among brain regions, classes of neurons, individual neurons, and even neuronal sub-compartments. It is the job of mitochondria to provide 95% of the energy exactly when and where it is needed. The brain consumes glucose as the primary source of energy, therefore neurons are particularly sensitive to spatio-temporal glucose fluctuations. Our previous work showed that the metabolic sensor enzyme O-GlcNAc transferase (OGT) regulates mitochondrial positioning in neurons by sensing glucose availability. This OGT-mediated response is an adaptation that would allow mitochondria to concentrate in regions of high glucose. However, little is known about how O-GlcNAcylation affects neuronal metabolism and mitochondrial bioenergetics. Here, we demonstrate that high O-GlcNAcylation enhances mitochondrial bioenergetics by modifying key mitochondrial proteins in neurons. First, we observed changes in mitochondrial functions with maximal O-GlcNAcylation by inhibiting O-GlcNAcase (OGA) activity. Then, we utilized quantitative mass spectrometry to determine proteome that undergo O-GlcNAc regulation from isolated neuronal mitochondria. Total mitochondrial O-GlcNAcome and specific modification sites were mapped using higher energy collision dissociation (HCD) and electron transfer dissociation (ETD) fragmentation, respectively. Functional annotation on these proteins revealed key metabolic proteins including electron transport chain subunits, mitochondrial transmembrane transporters, and ketone body metabolizing proteins. These results suggest OGT alters mitochondrial function in adaptation to metabolic environment. We conclude that O-GlcNAcylation fine-tunes these subsets of proteins differentially, which eventually leads to higher glucose utilization. This study will lay a groundwork for how O-GlcNAcylation regulates metabolic homeostasis in neurons.

P1375/B506

Axonal Transport of an Insulin-like Peptide Mrna Promotes Stress Recovery In*C. Elegans*.

R. Chandra; University of California, San Francisco, San Francisco, CA.

Aberrations in insulin or insulin-like peptide (ILP) signaling in the brain causes many neurological diseases. Here we report that mRNAs of specific ILPs are surprisingly mobilized to the axons of C. elegans during stress. Transport of the ILP ins-6 mRNA to axons facilitates recovery from stress, whereas loss of axonal mRNA delays recovery. In addition, the axonal traffic of ins-6 mRNA is regulated by at least two opposing signals: one that depends on the insulin receptor DAF-2 and a kinesin-2 motor; and a second signal that is independent of DAF-2, but involves a kinesin-3 motor. While Golgi bodies that package nascent peptides, like ILPs, have not been previously found in C. elegans axons, we show that axons of stressed C. elegans have increased Golgi ready to package peptides for secretion. Thus, our

findings present a mechanism that facilitates an animal's rapid recovery from stress through axonal ILP mRNA mobilization.

Caspase-independent Structural Plasticity of the Actin-spectrin-based Membrane-associated Periodic Skeleton (MPS) Underlies the Initiation of Sensory Axon Degeneration.

G. Wang[1,2], D. J. Simon[3,4], Z. Wu[3], D. M. Belsky[4], E. Heller[1,2], M. K. O'Rourke[4], N. T. Hertz[3,4], H. Molina[5], G. Zhong[1,2], M. Tessier-Lavigne[3,4], X. Zhuang[1,2]; [1]Department of Chemistry and Chemical Biology, Howard Hughes Medical Institute, Harvard University, Cambridge, MA, [2]Department of Physics, Howard Hughes Medical Institute, Harvard University, Cambridge, MA, [3]Laboratory of Brain Development and Repair, the Rockefeller University, New York, NY, [4]Department of Biology, Stanford University, Stanford, CA, [5]Proteomics Resource Center, the Rockefeller University, New York, NY.

Axon degeneration shapes neuronal connectivity patterns during development and is an early hallmark of several adult-onset neurodegenerative disorders. Despite the substantial progress in identifying effector mechanisms driving axon fragmentation, much less is known about the upstream signaling pathways that initiate this process. Here, we investigate the caspase-independent structural plasticity of the actin-spectrin-based Membrane-associated Periodic Skeleton (MPS) in response to neurotrophin deprivation and the spectrin-dependent retrograde signaling in axon degeneration. We find that trophic deprivation (TD) of mouse sensory neurons causes a rapid disassembly of the axonal MPS, which occurs prior to protein loss and caspase activation. Besides, we show that actin destabilization initiates TD-related retrograde signaling needed for degeneration; actin stabilization prevents MPS disassembly and the retrograde signaling. Interestingly we also find that depletion of bII-spectrin, a key component of the MPS, suppresses retrograde signaling and strongly protects axons against degeneration. Our data demonstrate importance of structural plasticity of the MPS on initiation of axon degeneration. eLife, 8, p.e38730 (2019)

P1377/B508

Age-dependent Autophagy Induction After Injury Promotes Axon Regeneration Via Limiting Notch.

S. KO, Z. Liu, L. Chen; UT Health SA, San an tonio, TX.

Autophagy is essential for maintaining cellular homeostasis by the degradation of organelles or proteins. It also has a prominent role in modulating aging. But the role of Autophagy in the neuronal response to axon injury and subsequent axon regeneration, particularly in the context of aging, remains largely unknown. Our candidate genetic screen for axon regeneration regulators has identified genes in the autophagy pathway. Using a reporter that monitors autophagosomes and autolysosomes, we were able to monitor the dynamics of autophagy during axon regeneration. In response to axon injury, there was a significant increase in the number of autophagic vesicles. The injury-triggered autophagy activation and the capacity of axon regeneration undergo an age-dependent decline, and both of the declines were partially rescued by autophagy-activating agents. We found that DLK-1 was both required and sufficient for injury-induced autophagy activation. Autophagic vesicles were co-localized with Notch receptor LIN-12, a previously identified inhibitor of axon regeneration. Epistasis analyses indicate that LIN-12 might be a target of autophagy in axon regeneration. Taken together, our data suggest that DLK-mediated

injury signaling can activate autophagy, which might limit the level of LIN-12/Notch to promote axon regeneration. Our findings reveal that autophagy activation can promote axon regeneration in neurons that lack the maximal regrowth capacity, providing a promising therapeutic strategy for axon injury.

Ubiquitin Proteasome Dysfunction as a Biomarker for Neurodegenerative Disease.

D. Ouazia, 19355, K. Kadimisetty, 19355, K. Sheets, 19355, J. Dhillon, 19355; LifeSensors, Inc., Malvern, PA.

The ubiquitin-proteasome system (UPS), chaperone mediated-autophagy (CMA), and mitophagy constitute the protein quality control system of the cell. Since damaged proteins are rarely repaired, the failure of protein quality control is particularly difficult to overcome in terminally differentiated cells (e.g., neurons). UPS dysfunction likely plays a key causative role in Alzheimer's disease (AD) and Parkinson's disease (PD); for example, mutations in the ubiquitin ligase parkin lead to loss of mitophagy, destruction of dopaminergic neurons and, thus, to Parkinson's Disease. Numerous developmental neuronal defects and neuromuscular pathologies are attributed to mutations in UPS genes. LifeSensors has studied the consequences of these mutations by screening brain tissues, serum, and CSF of healthy individuals (postmortem) and age-matched AD patients. Because antibodies against ubiquitin or target proteins are ineffective due to low affinity, epitope masking, and an inability to discriminate among various poly-ubiquitin chains, LifeSensors developed high-affinity chain selective polyubiquitin binding tools called TUBEs (Tandem Ubiquitin Binding Entities) to isolate ubiquitylated proteins. These enriched ubiquitylated protein fractions were analyzed by mass spectrometry-based proteomics to identify candidate markers for UPS dysfunction in neurons; comparing brain tissues from healthy individuals and AD patients, we uncovered numerous proteins with altered ubiquitylation patterns in the disease state. For example, the Tau protein is heavily ubiquitylated at multiple sites in AD, while Tau from normal brain is essentially ubiquitin-free; other unique ubiquitylated biomarkers were identified for AD. We are currently investigating CSF and plasma samples from AD and PD patients to establish a panel of unique ubiquitylated markers with reference to control samples. The goal of this study is to develop a diagnostic panel of ubiquitylation signatures using pan-selective and linkage-selective TUBEs for blood-based early diagnosis of AD/PD.

P1379/B510

Role of Aurora Kinase a and Endolysosomes in Alzheimer's Disease.

Z. Afghah, M. Bordak, X. Chen, J. D. Geiger; University of North Dakota, Grand Forks, ND.

Endolysosome dysfunction plays an important role in the pathogenesis of Alzheimer's disease (AD), the most common cause of dementia. The acidic pH of endolysosomes is not only critical for the activity of pH-sensitive enzymes involved in amyloidogenic processing of amyloid-β (Aβ) precursor protein but also is critical for endolysosome degradation of Aβ and aggregated Tau; even subtle de-acidification of endolysosomes accelerates amyloidogenesis and tauopathy. Because endolysosome acidification decreases amyloidogenesis and p-Tau, re-acidifying endolysosomes might represent a promising therapeutic strategy against AD. Recently, the activity of aurora kinase a (AURKA); a kinase that regulates vital neuronal functions including microtubule organization, synaptic plasticity, and neuronal migration was reported to be decreased in postmortem brain tissues of AD patients. However, virtually nothing is known about the expression levels and distribution patterns of AURKA in brain as well as the

role of AURKA in AD pathogenesis. Here, we tested the hypothesis that decreased AURKA activity results in endolysosome de-acidification and contributes to the pathogenesis of AD. Using immunofluorescence staining we showed that AURKA phosphorylation, which correlates positively with its activity, was significantly decreased in hippocampus of AD patients and in 3xTg-AD mice. Using immunoblotting and immunostaining methods, we demonstrated that AURKA was expressed in primary cultured rat neurons, in adult mouse brain, and in human brain tissues. Furthermore, using ratiometric measurements of endolysosome pH and ELISA measurements of Aβ, we demonstrated that activation of AURKA with anacardic acid resulted in endolysosome acidification and decreased levels of Aβ, whereas inhibiting AURKA with MLN8237 decreased AURKA phosphorylation, and increased levels of Aβ. Decreased AURKA activity may contribute to the pathogenesis of AD in part because of endolysosome de-acidification and re-acidifying endolysosomes using AURKA activators may provide for a new therapeutic strategy against AD. P1380/B511

Late-breaking News: Autophagy Goes on Strike! - Rampant Immune Response Kills Neurons!.

A. K. Shukla[1], J. Spurrier[2], E. Giniger[1]; [1]National Institutes of Health, Bethesda, MD, [2]Yale University, New Haven, CT.

Autophagy and innate immunity are two homeostatic processes highly debated for their role in neurodegeneration (ND). How these two homeostatic processes plays role in age related neurodegenerative diseases are currently murky and in the focus of intense investigation. Here we examine the role of these two processes in cyclin dependent kinase (Cdk5) mediated neurodegeneration. Cdk5, an unusual cyclin-dependent-kinase, plays no role in cell cycle progression, but acts exclusively in postmitotic neurons, where its deregulated activity is linked to Alzheimer's and Parkinson's in humans. First, we observed hyperactivated innate immune response, particularly anti-microbial peptides (AMPs) in the brain of Cdk5-altered animal, using microarray profiling. We further examined the expression of AMPs in 3d-, 10d-, 30d- and 45d-old using qPCR and simultaneously counted dopaminergic (DA) neurons. We observe that Cdk5-associated upregulation of AMPs is accompanied by ND in age dependent manner. Conversely, targeted overexpression of individual AMP in DA neurons results in DA neuron loss in 30d-old normal flies. Finally, genetically reducing AMPs expression using a NFκB (Relish) mutant suppresses DA neuron loss in Cdk5-altered *Drosophila*. These data argue strongly that innate immune activation is necessary and sufficient for DA neuron loss in Cdk5-altered animals. Next, we asked why altered Cdk5 activity stimulates AMPs expression. The first clue in this regards come from our microaaray data, where we observed downregulation of components of autophagy, alongside the overactivation of innate immunity. Futher observation revealed high levels of Ref(2)P, the *Drosophila* p62, autophagosome accumulation, reduced level of cysteine protease-1 (Cp1) and vacuolar ATPase (Vha-13), confirming compromised autophagy in Cdk5-altered brain. Moreover, we found overexpression of AMPs in a mutant that blocks autophagy (*Atg8a*) strengthening the argument that reducing autophagy may overactivate innate immunity. Finally, we restored autophagy by moderate expression of the canonical autophagy regulator, TFEB (Mitf), in p35-null *Drosophila* brain and observed decreased AMP expression and rescue of DA neuron loss. These data suggest that it was reduced autophagy that stimulates AMPs overexpression in Cdk5-altered Drosophila. Our study recasts our picture or neurodegeneration by revealing a linear relationship between autophagy, innate immunity and neuron loss. Considering the conservation of genes and signaling pathways between flies and

mammals, these data open a new avenue for further exploration of the relationship between these two core processes in human neurodegenerative disease.

P1381/B512

The Role of Optineurin in Neuronal Mitophagy.

C. S. Evans, E. L. F. Holzbaur; University of Pennsylvania, Philadelphia, PA.

Mitophagy, the selective removal of damaged mitochondria, is thought to be critical to maintain neuronal homeostasis. Mutations in proteins implicated in mitophagy, including PINK1, Parkin, OPTN, and TBK1, cause Parkinson's disease or ALS, suggesting defective mitochondrial turnover contributes to neurodegeneration. To test this hypothesis, we used mild oxidative stress to induce low levels of mitochondrial damage in hippocampal neurons. We observed the sequential recruitment of Parkin, TBK1, and OPTN to depolarized mitochondria followed by their sequestration into autophagosomes, and determined this pathway was compartmentally restricted to the soma. Further, acidification of mitophagosomes was remarkably slow in neurons and overall was a rate-limiting step in the mitophagy pathway. Expression of an ALS-linked OPTN mutation disrupted the integrity of the mitochondrial network and this effect was exacerbated by oxidative stress. We propose that the slow kinetics of mitophagy enhance neuronal susceptibility to disease-associated mutations in the pathway, leading to neurodegeneration.

Neuronal Traffic Jams: Mechanistic Insights into Mutant Mammalian Prion Aggregate-mediated Intracellular Transport Impairments.

T. Chaiamarit, A. Verhelle, R. Chassefeyre, S. E. Encalada; the Scripps Research Institute, La Jolla, CA.

A ubiquitous hallmark of neurodegeneration is the accumulation of misfolded protein aggregates inside axons. Intracellular aggregates can impair or block the proper transport of cellular components from the soma to the synapse, but the mechanisms of transport impairment remain unclear. Using an in *cellulo* neuronal system expressing a mutant prion protein (PrP^{PG14}) that forms aggregates inside axons and causes prion diseases in humans, we tested the hypothesis that PrP^{PG14} aggregates poison neurons by creating traffic jams to intracellular transport. Using high-resolution quantitative imaging approaches, we showed that PrP^{PG14} aggregates selectively interfere with the anterograde axonal transport of pre-synaptic vesicles and mitochondria by sequestering kinesin-1 away from cargoes, and thus disrupting the association between kinesin-1 and cargo adaptors as these complexes move through the aggregates. Our findings reveal a novel mechanism by which intracellular protein aggregates selectively disrupt axonal function and transport through sequestration of molecular motors. This study suggests potential targets for the development of strategies to combat intracellular prion aggregation, as well as the aggregation of misfolding-prone proteins involved in other neurodegenerative diseases.

Evaluating Adc Related Peripheral Neuropathy with Human Ipsc-derived Neuronal Models.

R. Ciurlionis, L. Loberg, P. Mahalingaiah, T. Van Vleet; Abbvie, North Chicago, IL.

Antibody-drug conjugates (ADCs) are novel chemotherapeutics designed for more selective delivery of cytotoxic agents to cancer cells. However, toxicity of ADCs in normal cells has been reported in multiple

pre-clinical studies and clinical trials, leading to significantly narrowed safety margins. Peripheral neuropathy is a frequent adverse event with microtubule inhibitor (MTI) ADCs that can be challenging to assess in short term preclinical studies. For example, peripheral neuropathy was not predicted based on nonclinical toxicology studies in monkeys or rats treated with vcMMAE ADCs. MTI payloads MMAF and MMAE were tested alone and as ADCs linked to AB-095, an antibody against the non-mammalian tetanus toxoid protein, in two in *vitro* iPSC-derived neuronal models: 1) a 2D model from PhenoVista Biosciences in which test articles were administered to cells during neurite outgrowth and 2) a 3D model from Mimetas that examines test article effects on a pre-formed neurite network. Multi-parametric evaluation of imaging data resulted in ranking each test article's peripheral neuropathy potential as MMAE > AB095-MMAE > AB095-MMAF ≥ 2 (MMAF). This ranking is consistent with what can be expected based on clinical experience. Both 2D and 3D Human iPSC-derived neuronal models produced essentially the same test article ranking. Results indicated that the effect on neurite outgrowth formation and pre-formed neurite network integrity appear to provide the same outcome. Specifically, payload permeability appears to be important in ADC-mediated neurotoxicity in *vitro* and target-independent (non-specific) ADC uptake is unlikely to contribute significantly to neurodegeneration. Further testing of MTI ADCs/payloads in co-culture systems (sensory neurons and Schwan cells) and DRG sensory nerves (e.g.,Nerve on a Chip platform) may provide additional insight. All authors are employees of AbbVie and may own AbbVie stock. AbbVie sponsored and funded the study; contributed to the design; participated in the collection, analysis, and interpretation of data, and in writing, reviewing, and approval of the final publication.

Parp1 Promotes Oligodendrocyte Remyelination in Cuprizone-induced Mouse Model of Multiple Sclerosis.

Y. WANG[1,2], S. Zhang[1,2], B. Kim[1,2], Z. Lan[1,2], E. Ma[1], P. Prabhu[1], F. Guo[1]; [1]UC Davis, Sacramento, CA, [2]Shriners Hospitals for Children, Northern California, Sacramento, CA.

Multiple sclerosis (MS) is a chronic inflammatory demyelinating disease of the central nervous system (CNS) in which oligodendrocytes and myelin are primary targets. Promoting oligodendrocyte regeneration and myelin repair remains a major challenge in treating MS patients. Poly (ADP-ribose) polymerase 1 (PARP1) is a nuclear protein whose enzymatic activity plays an important role in DNA damage and repair. Previous studies reported that PARP1 and its activity are upregulated in demyelination lesion in MS brains. However, the role of PARP1 in myelin pathogenesis and repair remains elusive. We employ the cuprizone model to study the expression and function of PARP1 in oligodendrocyte regeneration and myelin repair. Our results showed that PARP1 and its enzymatic activity were increased in newly regenerated oligodendrocyte during myelin repair after cuprizone-induced oligodendrocyte damage and demyelination. Inhibiting PARP1's activity by small inhibitors decreased the rate of oligodendrocyte regeneration from oligodendrocyte progenitor cells and impaired timely myelin repair. Our study reveals that PARP1 activity is required for oligodendrocyte generation from oligodendrocyte progenitor cells and promotes remyelination in a toxin-induced demyelination animal model of MS. Our study also points to the potential of increasing PARP1's activity to promote oligodendrocytes regeneration and remyelination in treating MS patients.

P1385/B516

Knockdown of CTDSP1 as a Novel Strategy to Boost Neurotrophin Synthesis and Enhance Peripheral Nerve Regeneration After Traumatic Injury.

N. M. Gervasi[1,2], A. Dimtchev[1,2], A. Pisarchik[3], M. Dingle[1,4], D. Clark[1,4], A. Piscoya[1,4], L. J. Nesti[1,4]; [1]USUHS, Bethesda, MD, [2]HJF, Bethesda, MD, [3]Alcamena Stem Cell Therapeutics, Halethorpe, MD, [4]Walter Reed National Military Medical Center, Bethesda, MD.

Peripheral nerve injury (PNI) is a frequent complication of musculoskeletal trauma. Unfortunately, current treatments rarely restore complete motor and sensory function, with patients often experiencing long term deficits, such as motor dysfunction and chronic pain. Nerve regeneration and accurate reinnervation depend in part on the neurotrophic support received from surrounding cells at the zone of injury. We have previously identified a population of musculoskeletal trauma-induced mesenchymal progenitor cells (MPCs) that are found at high concentration at the site of injury, and exhibit neurotrophic properties. The expression of neurotrophins such as brain-derived neurotrophic factor (BDNF), nerve growth factor (NGF) and neurotrophin-3 (NT-3), is repressed by a single transcriptional repressor known as RE1 silencing transcription factor (REST), which is protected from degradation by C-terminal domain small phosphatase 1 (CTDSP1). As direct targeting of transcription factors is challenging, we investigated whether modulating CTDSP1 activity is sufficient to promote REST degradation and stimulate the expression of neurotrophins. To characterize the expression profiles of REST, CTDSP1 and neurotrophins after musculoskeletal trauma, we quantified RNA and protein in traumatized muscle tissue and trauma-derived MPCs. qRT-PCR and Western Blot analysis showed that REST, CTDSP1 and neurotrophin expression is altered in a time-dependent manner following traumatic injury. Consistent with CTDSP1 role in stabilizing REST, an increase in CTDSP1 levels is associated with a decrease in neurotrophin levels. To investigate whether decreasing CTDSP1 activity increases neurotrophin production, we transfected cultured MPCs and dorsal root ganglion neurons with CTDSP1-targeting siRNA. qRT-PCR analysis of neurotrophin mRNA and ELISA quantification of secreted BDNF in cell culture supernatants showed that knockdown of CTDSP1 results in higher expression of neurotrophins and increased secretion of BDNF. Taken together, our results suggest that modulating CTDSP1 activity may represent a novel strategy to promote nerve regeneration and muscle reinnervation by increasing neurotrophin expression both proximally in the cell bodies of the injured nerves and distally in neuronal support cells at the site of injury.

Major Histocompatibility Complex of Class I (MHC-I) Expression in Human Brain and Cultivated Astrocytes.

R. Silvestre Ignarro[1], A. Luis Bombeiro[1], L. de Oliveira Coser[1], L. Politti Cartarozzi[1], E. Ghizoni[2], H. Tedeschi[2], F. Cendes[2], I. Lopes-Cendes[3], F. Rogerio[4], A. Leite Rodrigues de Oliveira[1]; [1]Laboratory of Nerve Regeneration, Department of Structural and Functional Biology, Institute of Biology (IB), University of Campinas (UNICAMP), Campinas, BRAZIL, [2]Department of Neurology, School of Medical Sciences, University of Campinas (UNICAMP), Campinas, BRAZIL, [3]Department of Medical Genetics, School of Medical Sciences, University of Campinas (UNICAMP), Campinas, BRAZIL, [4]Department of Pathology, School of Medical Sciences, University of Campinas (UNICAMP), Campinas, BRAZIL.

Major histocompatibility complex of class I (MHC-I) plays a pivotal role in the adaptative immune response. It has also been implicated in neuroplasticity during development and after lesion. Indeed,

interferon beta-1b (IFN-beta) increases MHC-I expression by motoneurons after sciatic nerve crush in mice improving axonal growth and functional recovery. IFN-beta induces glial hypertrophy associated with upregulation of fibrillary acidic protein (GFAP) and MHC-I in astrocytes in *vitro*. Silencing of beta-2 microglobulin (β2M), a component of the MHC-I, decreases GFAP gene expression and downregulates astrogliosis in co-cultured astrocytes and spinal cord neurons, suggesting that MHC-I is associated with astrocyte activation. Even though MHC-I expression has been reported and functionally confirmed in murine nervous tissue, less is known regarding such expression and function in the adult human nervous tissue. Thus, we investigated MHC-I expression in the human brain, by using samples of non-epileptogenic anterior temporal lobe obtained as part of the surgical approach to treat hippocampal sclerosis (n=5). The cortical MHC-I expression was studied in histological sections and primary cultures of astrocytes derived from the same specimens. MHC-I in *vitro* expression was evaluated after exposing astrocytes to IFN-beta (100, 500 and 1000 IU/ml) for 5 days. MHC-I was mainly detected (β2M immunolabeling) in blood vessels, and in cortical neurons to a lesser extent. In *vitro* analysis showed expression of β2M in the control group (not exposed to IFN-beta), with consequent increase after IFN-beta stimulation. Flow cytometry quantitative data showed β2M upregulation ranging from 63% to 243%, in comparison to control. In *vitro* astrocyte activation was also investigated by the expression of vimentin, which presented up to 44% upregulation (100 IU/ml of IFN-beta), as compared to the control. Moreover, GFAP showed 34% upregulation (500 IU/ml of IFN-beta). In accordance with previous studies in rodents, our data show that IFN-beta is capable of increasing MHC-I expression, stimulating reactivity of human astrocytes. Considering that MHC-I and astrocytic activation may be protective after peripheral nerve damage and in neurodegenerative conditions, the current study opens perspectives for further research on the pathophysiological roles of MHC-I in the human nervous system in health and disease. Response of SH-SY5Y Cells to N-(3-oxododecanoyl)-l-homoserine LactoneResponse of SH-SY5Y Cells to N-(3-oxododecanoyl)-l-homoserine Lactone.

B. J. Greene, M. C. Raya; Bristol Community College, Fall River, MA.

Inflammation is a pivotal mechanism in an organism’s response to physical or pathogenic stressors. The inflammatory process aids in the response of the immune system and the subsequent release of healing factors. Bacteria utilize hormone-like signaling molecules, known as quormones, to coordinate growth and increase their chances of successfully colonizing a host. There is growing evidence connecting these quormones to an inflammatory response. The purpose of our study was to determine if quormone n-(3-oxododecanoyl)-L-homoserine lactone (ODHL) could induce an inflammatory state capable of affecting the normal function of cellular model SH-SY5Y. After exposing retinoic acid-induced SH-SY5Y to low concentrations of ODHL, we found that their neurite connections weakened, their population numbers decreased, and inflammatory signals cyclooxygenase-2 and tumor necrosis factor alpha were expressed shortly after the exposure began. We believe that our data provides evidence to conclude that ODHL has the potential to cause a detrimental effect to nervous tissue in vivo.

P1388/B519

The Effects of Crispr Cas-9 System on Progeny of Hereditary Parkinson'S Disease in *C. Elegans*.

M. M. Rutter, S. J. Steinley, J. C. Mitchell; Northern State University, Aberdeen, SD.

We have studied the effects of gene editing on *Caenorhabditis elegans* expressing the mutation responsible for heritable Parkinson's disease. To do this, a strain of *C. elegans*, a nematode often used as a model organism, was acquired. This strain possessed a mutation in its lrk-1 gene which is a homologue for the LLRK-2 gene found in humans and is responsible for the development of hereditary Parkinson's disease. The clustered, regularly interspaced short palindromic repeats (CRISPR) Cas-9 system and RNA interface (RNAi) were applied to the Parkinson's disease strain of *C. elegans*. By doing this, the effects of the CRISPR Cas-9 system on the progeny of the nematodes were studied. The CRISPR Cas-9 system targets specific stretches along the genome and turns the desired gene on or off. This allows for permanent changes of the genes to occur. RNAi is a precise way to target specific genes in the genome. Once targeted, the RNAi is able to "fix" the genes of the individual. Combining the RNAi and CRISPR allows the "fixed" genes to pass down to the offspring of each generation. Some of the progeny of the Parkinson's strain of *C. elegans* did not express the lrk-1 gene, and therefore are free of hereditary Parkinson's disease. During the initial trial, 50 worms containing the Parkinson's disease gene were given the CRISPR and RNAi combination and they were scored for presence or absence of agglutination indicating a functional lrk-1 gene. In the long term, this method could be applied to humans that suffer from hereditary Parkinson's disease, and prevent the genes from being passed down to their successive generations.

P1389/B520

Neuronal Regeneration with Recelularized Nerve Allografts in Peripheral Nerve Injuries.

Y. Tamez-Mata, A. Soto-Dominguez, F. Pedroza-Montoya, A. Rios-Cantu, R. Gonzalez-Flores, M. Garcia-Perez, V. Peña-Martinez, R. Montes-De-Oca-Luna, H. Martinez-Rodriguez, F. Vilchez-Cavazos; UANL, School of Medicine, Monterrey, MEXICO.

INTRODUCTION. Peripheral nerve injuries (PNI) are one of the most frequent causes of motor and sensitive deficits in adults. The gold standard graft material is autograft. Nevertheless, certain disadvantages have been associated (limited length, donor site morbidity, and neuroma formation). Thus, alternatives such as decellularized and recelularized nerve allografts have been under development. The objective was to assess the regenerative capacity of a recelularized allograft (RA) with allogeneic mesenchymal stem cells derived from adipose tissue (AMSC-AT), pre-differentiated in vitro to Schwann-like cells (S-lC) in a PNI of an ovine model, compared to an autograft (AU). **MATERIALS and METHODS**. Ovine were randomly included in two groups of seven. At the operating room and under generalized anesthesia, a 3 cm resection in the left peroneal nerve (PN) was performed. In group AU, the PN was reversed, while in group RA, the allograft was previously treated within a fast decellularization method (FDM) based on sulfobetaines and chondroitinase and subsequently enriched with infiltrated S-lC. In both experimental groups, microsurgical neurorraphy technique was performed. Right PN was used as Sham group, the nerves were surgical identified and untreated. All surgical wounds were closed by planes. The nerve regeneration analysis was through histological stains: Hematoxylin and Eosin (H&E) for general evaluation, and Masson's Trichrome (MTC), to identify connective tissue nerve components. In addition, histochemistry with: Periodic Acid of Schiff (PAS), Klüver-Barrier (KB), and Marsland-Glees-Erikson (MGE) silver impregnation stains were performed; they selectively identify external lamina (EL),

myelin, and axons, respectively. All right PN were also procured as Control (C) group purpose. **RESULTS.** One year after surgery, morphological analysis revealed that AU group had better nerve fibers organization than RA group. Densitometric analysis on connective tissue revealed no statistically differences ($p>0.05$) between both experimental groups. Also, no differences were observed on EL in all groups. Furthermore, a significant ($p<0.05$) myelin increased densitomety in both experimental was identified, compared with C. Axons were significantly decreased in both experimental groups. **CONCLUSIONS.** Recelularized allografts proved to be a successful treatment for PNI, with comparable results as gold standard. Despite the less organization degree of nerve fibers, the recelularized allograft is capable of regenerate. Recelularized allografts are a therapeutic option in PNI since, unlike autograft, the need for a second surgery and nerve donor site morbidity are avoided. In addition, using S-lC in the acellular scaffold might decrease pre-surgical time in patients.

Establishing and Maintaining an Organelle 2

P1390/B522

Multiple C2 Domain Containing Proteins, Mctp1 and Mctp2, Regulate Lipid Droplet Biogenesis.

A. Joshi; University of North Carolina, Chapel Hill, NC.

Lipid droplets (LDs) are ubiquitous, dynamic organelles that serve as cellular storage sites for lipids. Nascent LDs form at specialized sites in the ER membrane, though little information is available about these subdomains. Previously, we showed that, in yeasts, both Pex30p and Pex31p have a reticulon-like transmembrane domain and Pex30p can tubulate liposomes in *vitro*. We found that Pex30p ER subdomains are sites of nascent LDs formation. In the absence of Pex30p, LDs are smaller and form clusters and exhibit decreased TAG levels. Also, deletion of *PEX30* and*SEI1* (which encodes the yeast homologue of the LD biogenesis factor Seipin) results in a severe growth defect, strongly suggesting that Pex30p plays an important role in LD biogenesis. Using a homology prediction program (HHpred), we found that the transmembrane region of mammalian proteins MCTP1 and MCTP2 exhibits homology to Pex30p. The MCTP proteins localizes to ER subdomains in a manner similar to Pex30p. Depletion of MCTP2 causes a decrease in the number and size of LDs in Hela cells and worms whereas overexpression leads to increase in the number of LDs. MCTP proteins are uniformly distributed in the ER when overexpressed. However, upon addition of oleic acid these proteins are re-distributed to ER-LD contact sites. We are currently determining the role of MCTP proteins in LD biogenesis.

P1391/B523

Investigating the Role of Lipid Droplet Sub-populations through Proteomic Landscape an alysis.

N. O. Speer, H. Hariri, M. Henne; UT Southwestern Medical Center, Dallas, TX.

Eukaryotic cells store fatty acids in the form of esterified lipids, triacylglycerol (TG) and sterol esters (SE), in cytoplasmic organelles called lipid droplets (LD). These organelles are of crucial importance to cellular metabolic homeostasis as they can serve as neutral lipid reservoirs for future energy utilization, and also sequester toxic fatty acids, preventing lipotoxicity. Previous mammalian and yeast studies have shown that LDs can exist in subpopulations with unique proteomes that heavily influence their function in maintaining cellular metabolic homeostasis (Schott et al., *JCB*, 2019; Eisenberg-Bord et al., *JCB*, 2018; Teixeira et al., *JCB*, 2018). Published work from our lab showed that, in yeast, a hallmark of nutrient scarcity is formation of a subpopulation of LDs at the Nucleus-Vacuole Junction (NVJ), a phenomenon

known as LD clustering (Hariri et al., *JCB*, 2018). Furthermore, we find that NVJ-associated LDs interact with the NVJ tether protein Mdm1, which we hypothesize helps to facilitate LD turnover. To investigate the function of this distinct LD subpopulation at the NVJ, I performed a proteomics screen of LDs constitutively clustered at the NVJ via Mdm1 overexpression. From this proteomic data, I selected several candidates that enrich on Mdm1-associated LDs at the NVJ. Currently, I am investigating the relationship between these candidate proteins and the extent to which they regulate LD homeostasis and spatial positioning, as well as how the contribute to metabolic homeostasis within the cell.

P1392/B524

Opa-1 Deficiency in Skeletal Muscle Increases Lipid Droplet Formation.

M. Mungai[1], I. Hicsasmaz[1], B. Kirk[1], P. Katti[2], B. Glancy[2], A. Hinton[1], R. Pereira[1], E. D. Abel[1]; [1]University of Iowa, Iowa, IA, [2]National Institutes of Health, Bethesda, MD.

Defective mitochondria-associated membranes (MAMs) or mitochondria and endoplasmic reticulum (ER) contact sites (MERCs), have been associated with Insulin-Resistant Type 2 Diabetes Mellitus (T2DM). MERCs are enriched with specific proteins and lipids that are believed to mediate inter-organellar communication such as calcium transfer and lipid transfer. T2DM subjects have miscommunication of lipid transfer inside of the cell and MAMs have been implicated in controlling these changes. MERCs dysfunction has also been implicated in fat accumulation in skeletal muscle, which has been shown to occur in insulin resistance. We have previously demonstrated that Optic Atrophy 1 (OPA-1) deficiency in skeletal muscle induces ER stress, which correlates with upregulation of Mitofusin-2 (MFN-2), a known tethering protein in MERCs. MFN-2 ablation has been shown to alter phospholipid metabolism and MERC tethering in murine skeletal muscle cells. Therefore, we hypothesized that OPA-1 deficiency increases the number of lipid droplets in skeletal muscle cells through an MFN-2 MERC related mechanism. To test this hypothesis, we surveyed for lipid droplets in primary OPA-1-deficient myotubes and lipid metabolites in OPA-1- deficient skeletal muscle. Primary myotubes were generated by isolating satellite cells from OPA-1 floxed mice, differentiating, and subsequently deleting OPA-1 by infecting the cells with adenoviral CRE recombinase. TEM image analysis of OPA-1-deficient myoblasts and myotubes confirmed an increase in the number of lipid droplets in cells. Conversely, ablation of MFN-2 in myotubes showed a decrease in the number of lipid droplets, as did the OPA-1/MFN-2 double-knockout. In addition, TEM image analysis of OPA-1 knockout cells showed an increase in smooth MERCs, and MFN-2 deletion increased rough MERCs distance in cells. Lastly, statistical analysis of lipid metabolites revealed that metabolite peak intensities were higher in OPA-1 knockout tissue than in wildtype tissue. Collectively, these data suggest that loss of OPA-1 in skeletal muscle cells results in an increase in lipid droplet formation and may result in an increase in lipid metabolite transfer in the MERC space. Notably, this increase may be due to the reduced smooth MERCs distance, as smooth ER has been shown to be more involved than rough ER in lipid transfer.

P1393/B525

Architecture of Interfaces between Lipid Droplets Revealed by Electron Cryo-tomography.

I. Ganeva[1], K. Lim[2], J. Boulanger[1], P. Hoffmann[1], D. Savage[2], W. Kukulski[1]; [1]MRC LMB, Cambridge, UNITED KINGDOM, [2]Institute of Metabolic Sciences, Addenbrooke's Hospital, Cambridge, UNITED KINGDOM.

Lipid droplets (LDs) are responsible for regulated storage and release of neutral lipids. LDs feature a neutral lipid core enclosed by a phospholipid monolayer and surface proteins involved in lipid metabolism. CIDE proteins govern the number and size of LDs in cells. CIDEC is crucial for fat storage in white adipocytes where it mediates fusion between LDs. This process is fundamentally different from fusion of bilayer-surrounded compartments. CIDEC accumulates at interfaces between LDs and facilitates directional neutral lipid transfer from the smaller to the larger LD. Deciphering the structure of the LD-LD interface is key in understanding the molecular mechanism of lipid transfer. Here, we use live cell imaging and electron cryo-tomography of vitrified human cells, thinned by focussed-ion beam milling. By live cell imaging we reveal that LD interface formation is a highly dynamic process. LDs contact each other repeatedly before eventually merging. Lipid transfer is completed within minutes. Our electron cryo-tomography shows that at the interface between LDs, the two monolayers are intact and in close apposition. LDs exhibit large-scale shape deformations and adjacent monolayers get as close as 5 nm. Depending on the size difference between the LDs, the interface morphology varies: i) minimal deformation, ii) flattening of LDs similar in size, or iii) smaller LD locally imposing curvature to larger LD. These differences possibly reflect distinct stages of interface formation. The interfaces contain a dense protein layer and apposing monolayers display waviness, indicating local packing disturbances. Currently, we use in *vitro* reconstitution to test if CIDEC is required and sufficient to establish the LD-LD interface architecture we observe in *situ*. Our results suggest that CIDEC-mediated neutral lipid transfer does not occur through a fusion pore formed between two LDs, but through close apposition of two intact monolayers. How the dynamics of contact formation exactly relate to the interface architecture remains to be seen. While the interface organization is conceptionally similar to known organelle contact sites involved in lipid transfer, the distance between the two monolayers is significantly shorter. Local disturbances in phospholipid packing possibly lower the energy barrier and allow neutral lipids to cross from one LD to the other.

Drosophila Adipocytes Maintain Spatially Distinct Lipid Droplet Sub-populations.

M. Henne, R. Ugrankar, J. Bowerman; UT Southwestern Medical Center, Dallas, TX.

Adipocytes store nutrients as lipid droplets (LDs), but how they organize their LD stores to balance lipid uptake, storage, and mobilization remains poorly understood. Here, using *Drosophila* fat body (FB) adipocytes we characterize spatially distinct LD populations that are maintained by different lipid pools. We identify peripheral LDs (pLDs) that make close contact with the plasma membrane (PM) and are maintained by lipophorin-dependent lipid trafficking. pLDs are distinct from larger cytoplasmic medial LDs (mLDs), which are maintained by FASN1-dependent *de novo* lipogenesis. We find that sorting nexin CG1514/Snazarus (Snz) associates with pLDs and regulates LD homeostasis at ER-PM contact sites. Loss of *SNZ* perturbs pLD organization whereas Snz over-expression drives LD expansion, triacylglyceride production, starvation resistance, and lifespan extension through a DESAT1-dependent pathway. We

propose that *Drosophila* adipocytes maintain spatially distinct LD populations, and identify Snz as a regulator of LD organization and inter-organelle crosstalk.

Cdc42 Negatively Regulates Endocytosis during Lumen Maintenance in Live Mice.

A. Shitara[1], C. K. E. Bleck[2], R. Weigert[3]; [1]ASAHI University, Gifu, JAPAN, [2]National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD, [3]National Cancer institute, National Institutes of Health, Bethesda, MD.

Appropriate regulation of lumen establishment and maintenance are fundamental for tubular organs physiology. Cell culture model or small organism model have shown the detailed mechanisms regulating these processes, although little work has been done in mammalian model systems in *vivo*. In this study, we used the mouse salivary gland as a model system to investigate the role of the small GTPase Cdc42 to regulate the homeostasis of the intercellular canaliculi, which is a luminal structure of the acinar cells where saliva secretion occur. Cdc42 depletion in adult mice altered the morphology of canaliculi, whereas depletion at late embryonic stages inhibited the canaliculi formation. In addition, intravital subcellular microscopy revealed that Cdc42 depletion altered membrane trafficking from and towards the plasma membrane. In conclusions, we highlighted a novel role for Cdc42 to remodel the plasma membrane through the negative regulation of selected endocytic pathways.

Endophilin A2-dependent Tubular Endocytosis Sustains Plasma Membrane Repair in the Absence of Caveolae and Promotes Cell Invasion by *Trypanosoma Cruzi*.

M. Corrotte, M. Cerasoli, **N. An drews, 20742**; University of Maryland-College Park, College Park, MD.

Plasma membrane (PM) repair requires Ca^{2+}-triggered exocytosis of lysosomes, followed by lesion endocytosis[1]. Caveolae, PM invaginations that are abundant in injury-susceptible cells, participate in toxin pore (SLO) removal from the PM [2]. In B lymphocytes lacking detectable caveolin 1 (Cav1) or caveolae, SLO pore repair is mediated by Ca^{2+}-triggered lysosomal exocytosis and tubular endocytosis [3]. In this study we examined how Cav1-deficient cells process SLO wounds in the absence of caveolae, by comparing wild type (WT) and Cav1 knockout mouse embryonic fibroblasts (Cav1 KO MEFs). Cav1 KO MEFs were able to repair SLO wounds, but not as effectively as WT MEFs. Transmission electron microscopy (TEM) of cells treated or not with SLO in the presence of cholera toxin B (CTxB) showed an increase in CTxB-positive tubular endosomes in Cav1 KO MEFs. siRNA-mediated knockdown excluded the involvement of Galectin 3-dependent, clathrin independent carriers (CLICs) [4] in PM repair. The BAR-domain protein Endophilin A2 (but not A1 or A3), another regulator of tubular endocytosis [5], was essential for PM repair in Cav1 KO MEFs but not in WT MEFs. Knockdown of Endophilin A2 increased the number of open tubular endosomes observed by TEM, consistent with the proposed role for Endophilin A2 in membrane fission [6]. Since Endophilin A2 colocalized partially with endocytosed CTxB, we investigated its involvement in the PM deformation events that occur during cell entry by the parasite *Trypanosoma cruzi*, which subverts the PM repair machinery to invade host cells [7]. *T. cruzi* infection was partially inhibited in Cav1 KO MEFs when compared to WT, but Endophilin A2 silencing markedly decreased infection in both WT and Cav1 KO MEFs. Endophilin A2 was gradually recruited to nascent intracellular vacuoles containing *T. cruzi,* but was no longer associated with the parasites at later stages of infection. These results identify Endophilin A2 as a key component of the machinery for PM repair

that is subverted by *T. cruzi* for cell invasion ,and reveal a role for this BAR-domain protein in the tubular and clathrin-independent endocytic pathway that sustains PM repair in the absence of caveolae. 1 Idone, V. *et al. Membrane Dynamics and Regulators during Endosomal Tubulation.

R. Jani[1], A. Di Cicco[1], K. Kaplan[2], Y. Zhu[3], F. Tsai[1], J. Bonifacino[2], G. Raposo[1], M. S. Marks[3], P. Bassereau[1], D. Levy[1], **C. Delevoye**[1]; [1]Institut Curie, Paris, FRANCE, [2]NIH, Bethesda, MD, [3]Children's Hospital of Philadelphia, Philadelphia, PA.

The endosomal system is a major sorting station consisting of various membrane compartments controlling many intracellular transport and signaling events. At early endosomes, the dynamic formation and release of narrow and highly curved tubular network, called recycling endosomes, enable the sorting and delivery of specific cargoes to target membranes. How the limiting membrane of endosomes is locally remodeled to ensure the generation of recycling tubules is still poorly understood. Here, we address how protein and lipids could coordinate the biogenesis of the recycling network by focusing on the 8-subunit protein complex BLOC-1 and endosomal phospholipids. By manipulating the phospholipids abundance or localization through various in vitro approaches from cryo-EM to live cell imaging and biochemical analyses in cells, we demonstrate that the formation, shape and release of recycling tubules rely on a BLOC-1/Phospholipid couple. We thereby elucidate crucial sequence of events during the biogenesis of recycling endosomes with potential consequences in some genetic disorders.

P1398/B530

Lipid Scramblase Tmem16k Is an Interorganelle Regulator of Endosomal Sorting.

M. Petkovic, J. Oses-Prieto, A. Burlingame, L. Jan, Y. Jan; University of California, San Francisco, San Francisco, CA.

It is emerging that essential cellular processes can be coordinated via interorganelle communication at membrane contact sites (MCS) between distinct organelles. However, the identity and function of such membrane contact sites in maintaining cellular physiology remain an open scientific question. Here, we report that TMEM16K, an endoplasmic reticulum lipid scramblase linked to spinocerebellar ataxia (SCAR10), is a critical interorganelle regulator of the endolysosomal pathway. We identify endosomal transport as a major functional cluster of TMEM16K in proximity biotinylation proteomics analyses. TMEM16K forms contact sites with endosomes, interacting with the small GTPase RAB7 and phosphatidylinositol 3-phosphate (PtdIns(3)P). Our study further implicates TMEM16K lipid scrambling activity in endosomal sorting at these sites. Absence of TMEM16K leads to dysfunction of the endolysosomal pathway, which human disease point mutants cannot rescue, and progressive neuromuscular impairment in mouse models, consistent with observed human pathology. Thus,

TMEM16K-containing ER-endosome contact sites represent clinically relevant platforms for regulating endosomal sorting.

P1399/B531

The Pattern of Vacuole Inheritance and Biogenesis in *S. Cerevisiae*.

A. Chemel, M. Chan; San Francisco State University, San Francisco, CA.

In short, organelles are compartments found in all eukaryotic cells and carry out fundamental processes such as synthesizing, transporting, and degrading proteins, molecules, and lipids. In particular, the lysosome is responsible for storing and degrading proteins. However, in individuals affected by Tay-Sachs disease, the lysosomes found in the neurons are unable to degrade proteins properly. In turn, this leads the lysosomes to be filled with waste, swell and increase in size. This phenotype impairs the central and peripheral nervous system leading to symptoms such as neurodegeneration, loss of motor skills, and seizures. In addition, the ratio of the lysosome size to the cell size is perturbed. This suggests that maintaining proper organelle size is vital for the cell's overall health. A widely used model to study lysosomes are the yeast vacuoles. Previous research has shown that vacuoles maintain a vacuole size to cell size ratio as the cell increases in size, however this ratio is lost in individuals with Tay Sachs disease. In budding yeast, organelles are physically dragged from the mother cell to its daughter cell in a process called inheritance, thus it is necessary that the daughter cell receives the proper amount of organelles. Since the mother cell is losing its organelles to its daughter, it must make up for that loss through organelle biogenesis (the synthesis of new organelles). It is interesting to note that the vacuole size in the mother cell remains intact even as it is losing vacuoles to its daughter cell. This implies that vacuole inheritance and biogenesis are highly regulated processes, yet the regulation of vacuole size scaling remains poorly understood. I hypothesize that there is a pattern in which the cell regulates vacuole inheritance and vacuole biogenesis. Using a combination of fluorescence with 3-D microscopy and image analysis software, I will measure organelle (vacuole and peroxisome) inheritance and biogenesis in live yeast cells to determine the timing of the two processes. As hypothesized, current data is suggesting that vacuole inheritance occurs in a steady progressive pattern over time. Understanding vacuole inheritance may shed light onto elucidating the role organelles play in overall cell health, thus providing insight into lysosomal storage disorders such as Tay-Sachs disease.

P1400/B532

Intersectin-1 Interacts with the Golgin, GCC88, to Couple the Actin Network and Golgi Architecture.

C. Makhoul, P. Gosavi, R. Duffield, N. A. Williamson, P. A. Gleeson; University of Melbourne, Melbourne, AUSTRALIA.

The Golgi apparatus is a dynamic organelle and, in vertebrate cells consists of individual Golgi stacks laterally fused together in a continuous ribbon-like structure. The modulation of the Golgi ribbon architecture has recently been shown to be associated with the regulation of cellular signaling pathways, and our ongoing studies are investigating how the architecture of the Golgi ribbon contributes to cellular processes. The conversion of individual Golgi stacks into a ribbon structure is a highly regulated process which relies on a balance between the actin and microtubule network. While the involvement of the microtubule network has been well defined, the role of the actin network is poorly characterized. Our previous studies have shown that a membrane tether/golgin known as GCC88, located at the trans-Golgi network (TGN), modulates the architecture of the Golgi ribbon in a dose-

dependent manner. Increased levels of GCC88 led to the loss of the Golgi ribbon whereas GCC88 depletion resulted in the formation of longer Golgi ribbons[1]. The aim of the current study was to identify the underlying mechanism for GCC88-mediated re-organization of the Golgi ribbon. We have shown that GCC88-mediated dispersal of the Golgi ribbon is an actin-dependent process and involves non-muscle myosin-IIA[2]. To further understand the role of GCC88 in this process, candidate interactors were identified through an in vivo enzymatic labelling approach known as BioID. We have identified the long isoform of Intersectin-1 (ITSN-1), which has GEF activity for the Rho GTPase Cdc42, as a novel interaction partner of GCC88; demonstrated its localization at the TGN; and its involvement in linking the TGN to the actin cytoskeleton. Golgi ribbon fragmentation has been reported in various neurodegenerative diseases and we have demonstrated the potential relevance of our findings in neuronal cells using a model of neurodegeneration. 1. The Exocyst Complex Is a Component of Cytoplasmic Rods and Rings.

B. K. Dean[1], L. E. Adams[1], I. Jourdain[2], H. R. Dawe[1]; [1]University of Exeter, Exeter, UNITED KINGDOM, [2]MoA-Technology, Oxford, UNITED KINGDOM.

Inosine monophosphate dehydrogenase (IMPDH) and cytidine triphosphate synthase (CTPS) are two rate-limiting enzymes involved in the catalysis of GTP and CTP, that in humans form into filamentous structures termed cytoplasmic rods and rings throughout the cytoplasm. Although cytoplasmic rods and rings have been described in multiple cell types, neither their formation nor their composition are well understood. Here we identify a novel localisation for the exocyst complex. Both antibody labelled and GFP-tagged EXOC8 localise to prominent rod and ring-shaped structures throughout the cytoplasm that are distinct from previously described localisations for the exocyst. Upon closer inspection, these structures resemble beads on a string, similar to the structure of IMPDH2-containing cytoplasmic rods and rings previously observed by cryo-EM. Mutations in the closely related enzyme IMPHD1 are a cause of inherited retinal degeneration, and mutation in EXOC8 is a candidate for pleiotropic syndromes where retinitis pigmentosa is part of the clinical presentation. Therefore, we tested whether EXOC8 and IMPDH2 have a physical association. GFP-Trap analysis identified the two proteins as putative novel binding partners, and this interaction was lost in a disease-linked EXOC8 variant. We propose that exocyst function at cytoplasmic rods and rings plays a role in regulating cyclic nucleotide metabolism, and that dysregulation may contribute to the molecular pathology of retinal degeneration.

RASSF4 Functions at the Interface between Actin and Intracellular Vesicles to Regulate PI(4,5)P_2 Synthesis.

Y. Chen, D. Ryskamp, I. Bezprozvanny, J. Liou; UT southwestern at Dallas, Department of Physiology, TX.

The tumor suppressor RAS association domain family 4 (RASSF4) interacts with the small G protein ARF6 to regulate the level of phosphatidylinositol 4,5-bisphosphate (PI[4,5]P_2) important for a wide array of cellular functions. Nevertheless, the biological context of this RASSF4-ARF6-PI(4,5)P_2 pathway is not well understood. We found that actin dynamics controls RASSF4-ARF6 association at F-actin-associated intracellular vesicles, where RASSF4 activates ARF6 to stimulate PI(4,5)P_2 synthesis. Disruption of the

SARAH domain of RASSF4 resulted in an enhanced association with ARF6 at intracellular vesicles and an increased level PI(4,5)P_2 at the plasma membrane (PM). Additional data derived from acute manipulation and live-cell imaging experiments indicate that PI(4,5)P_2 produced at intracellular vesicles by the RASSF4-ARF6 pathway is delivered to the PM in an actin-dependent manner. Disruption of this intracellular PI(4,5)P_2 synthesis pathway in RASSF4 knockout cells resulted in reduced PM PI(4,5)P_2, enlarged cell size, disrupted actin cytoskeleton, and abnormal lysosomes. Consistently, knockdown of RASSF4 greatly suppressed neurite outgrowth in hippocampal neurons. Together, our study reveals a novel PI(4,5)P_2 synthesis pathway mediated by actin-regulated association of RASSF4 and ARF6 at intracellular vesicles. This RASSF4-mediated pathway is important for actin cytoskeletal integrity, lysosome homeostasis, and numerous PI(4,5)P_2-dependent physiological functions.

A Conserved Lysosomal Switch Regulates Male Meiosis in *Drosophila melanogaster*.

T. Butsch, O. Dubuisson, A. Johnson, A. Bohnert; LOUISIANA STATE UNIV A&M COL BATON ROUGE, Baton Rouge, LA.

Gametogenesis involves a series of well-orchestrated events that ultimately produces viable reproductive cells. Recently, we found that lysosome activation is required for the meiotic maturation of oocytes (female gametes), suggesting that lysosome activity may be developmentally linked to meiotic progression during oogenesis. It is currently unclear whether lysosomes would be similarly regulated during the development of sperm (male gametes). Using the fruit fly *Drosophila melanogaster*, we have found that lysosomes are robustly activated in meiotic spermatocytes. Inhibition of lysosome activation results in the accumulation of early meiotic cells, which are often multinucleate and display abnormally large lysosomes. Interestingly, the multinucleate germ cells we observe upon loss of lysosome function resemble those seen in aged and diseased testes, highlighting lysosomes as likely points of control. We have evidence that a known lysosome regulator, Mitf/TFEB, is expressed in the testis only as spermatocytes enter meiosis. This observation hints at a potential signaling mechanism that could entrain lysosome activity to early sperm development. Collectively, these findings indicate that lysosomes play a critical role in spermatogenesis. They also support the conclusion that lysosome activation is tightly linked to meiotic progression in both male and female germ cells. Accordingly, these studies begin to describe a fundamental aspect of gametogenesis that is common to both sexes. Further analysis of lysosome activation during spermatogenesis will likely shed light on developmental events central to germline biology, while also providing relevant information on lysosome regulation and modes of action.

Heterogeneity of Organelle Morphology in 2D Breast Cancer Cell Culture and 3D Bioprinted Breast Tumor Systems.

L. Wang[1], J. Ward[1], M. Bouyea[1], N. Maharjan[2], A. ELADDADI[2], C. Roberge[3], D. Corr[3], M. M. Barroso[1]; [1]Albany Med Coll, Albany, NY, [2]College of Saint Rose, Albany, NY, [3]Rensselaer Polytechnic Institute, Troy, NY.

Early endosomes function as a nexus between mitochondria and plasma membrane to regulate a wide variety of cancer-associated cellular processes, including receptor-mediated endosomal trafficking, signaling and iron homeostasis. Unravelling the complex relationships between these organelles and

breast cancer progression will provide new tools for cancer therapy and diagnosis. Since, 3D cell growth has been shown to affect organelle morphology, the analysis of the morphology and function of organelles in 3D tumor systems is the new frontier of cancer cell biology. Here, we tackled this challenge by studying early endosomes, a complex and dynamic organelle, and their interaction with mitochondria, in a comparative manner across a wide variety of 2D-culture cancer cells and 3D tumor systems. We combined laser-direct write (LDW) bioprinted 3D tumor systems with novel quantitative 3D imaging approaches to define and quantify the role of 3D tumor heterogeneity in endosome and mitochondria morphology as well as endosome-mitochondria contact regions. Several different breast cancer cell lines were grown in 2D cell culture, 3D spheroid systems using liquid overlay and size- and shape-controlled LDW bioprinted 3D tumor systems. Cells were subjected to immunostaining using anti-Tom20, a mitochondrial marker, and anti-EEA1, an endosomal marker, Airyscan high-resolution microscopy and image analysis using Imaris 3D visualization software coupled with statistical measures. Ten morphometric parameters were integrated to define the organelle diversity index (ODI), which is derived from clustering analysis based on Shannon diversity index for those different morphometric parameters. MDA-MB-231, an aggressive breast cancer cell line, showed high morphology heterogeneity of endosomes and their interaction with mitochondria when grown in 3D tumor systems in comparison to 2D cultured cells. 2D MDA-MB-231 cells displayed a similar endosomal and mitochondrial morphology only to some of the cells in the 3D systems. Thus, 2D MDA-MB-231 cells showed a more homogenous organelle morphology, whereas 3D MDA-MB-231 presented alternate organelle morphology, in which endosomes and mitochondria colocalized strongly in perinuclear circular rings. This morphology may indicate the initial steps of autophagy and/or mitochondria uncoupling. These results make evident the importance of determining subcellular organelle morphology in cancer cells grown in 3D culture systems. Altogether, our results demonstrate that LDW generates size- and shape-controlled 3D breast tumor systems that can be used to specifically evaluate the role of 3D growth in the morphology of early endosomes and their interaction with mitochondria.

P1405/B537

Identifying Novel Proteins That Mediate Very-Low-Density Lipoprotein (vldl) Biogenesis and Trafficking in Liver Cells.

J. Kim, W. Prinz; National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, MD.

Lipoproteins deliver lipids to organs and tissues through the blood stream. They play critical roles in lipid metabolism and homeostasis. The regulation of the lipoprotein biogenesis is critical because uncontrolled production is associated with diseases such as atherosclerosis and obesity. Lipoproteins are primarily generated in the liver, which produces VLDL, and the intestine, which generates chylomicrons. VLDL and chylomicrons are assembled in the ER lumen and mature as they traffic through the cell. They are structurally similar to lipid droplets, containing a core of neutral lipids surrounded by phospholipids and proteins. The major protein on VLDL and chylomicrons is apolipoprotein B (apoB), which is thought to be co-translationally lipidated, forming pre-VLDL particles that mature into VLDL particles before secretion out of cells. Lipidation requires microsomal triglyceride transfer protein (MTP) but is not well understood and probably requires other unknown proteins. To follow VLDL formation and trafficking in hepatocytes and to undertake a screen for proteins required for VLDL biogenesis, I have tagged endogenous apoB with GFP using CRISPR/Cas9. Because adding the gene encoding GFP can be challenging for the relatively large size of apoB, I used the recently devised strategy of tagging proteins

with a fragment of GFP that can form fluorescent GFP when it encounters the rest of the protein. I tagged apoB at the N-terminus with the 11th β strand of GFP (GFP11). The remainder of GFP, β strands 1 to 10 (GFP1-10), was expressed in the ER lumen by a lentivirus. When GFP11-apoB encounters GFP1-10 in the ER lumen, a fluorescent GFP-tagged apoB is formed. I have confirmed that apoB was successfully tagged with GFP using this scheme and the cells with the GFP-apoB were sorted and amplified. An additional advantage of this approach is that only ApoB outside the cytoplasm is visualized, allowing us to better track ApoB trafficking. We are going to use this cell line for CRISPR screening and diverse biochemical assays to find novel factors affecting the VLDL biogenesis and trafficking in the liver cells. We also successfully GFP-tagged apoE, another protein on VLDL, using the same method. These cell lines will allow us to study the lipoprotein biogenesis and screen for new proteins required for formation and trafficking of VLDL. Long-term, my hope is that these studies will open new targets for therapies or medicines to control lipoprotein production to lower the risk of the cardiovascular disease, which is the leading cause of death globally.

P1406/B538

Structural Basis of Curvature Generation by Dynamin-related Protein 1.

P. V. Thomas, A. S. Frost; University of California, San Francisco, San Francisco, CA.

Fission dynamin proteins are large GTPases that polymerize to remodel membranes. Their association with membranes and their propensity to polymerize have challenged efforts to understand the mechanism of their action. Specifically, the mechano-chemical details of how nucleotide binding, hydrolysis, and release are coupled to dynamin polymerization and membrane fission remain poorly understood. Using a disease allele of a fission dynamin family member, DRP1, which polymerizes to constrict and divide mitochondria, we stabilized a potential reaction intermediate of the DRP1 fission process. Here we report a 3D cryo-EM structure of a 12-membered ring of DRP1 with dimensions consistent with inner mitochondrial membrane fission and outer mitochondrial membrane “super-constriction”. Notably, we observe a previously undescribed interface between the nucleotide-bound GTPase domain and bundle-signalling element of one ring protomer and the stalk domain of the next protomer. This interface is blocked by a DRP1 receptor, MiD49, in a previously published structure of a linear DRP1-MiD49 copolymer. Compared to the linear copolymer, we document a sliding motion between protomers about interface 3, causing significant rearrangement of interface 1. Together, these changes describe how DRP1 can transition from a metastable, linear oligomer to a preferred, high-curvature oligomer in the absence of GTPase domain dimerization.

P1407/B539

Three-dimensional Live Imaging of Keratinocytes during Cornification Using Epidermal Equivalent Model.

S. Ipponjima[1], Y. Umino[2], M. Nagayama[1], M. Denda[2]; [1]Research Institute for Electronic Science, Hokkaido University, Sapporo, JAPAN, [2]Shiseido Global Innovation Center, Yokohama, JAPAN.

The stratum corneum plays an important role for water-impermeable barrier function. The process of cornification which granular cells transit to corneocytes requires for formation of the functional stratum corneum. Since corneocytes are quite different from granular cells, changes on the cells during cornification would be dynamic. However, the spatiotemporal details of these changes were still unclear. Here, we performed three-dimensional live imaging during cornification in an epidermal

equivalent model using a two-photon microscope with various fluorescent probes labeling intracellular structures. Our observation revealed that the granular cells during cornification not just simply flattened but temporally expanded before flattening. The morphological change from the expansion to the complete flattening took about 20 minutes. We also found that acidic vesicles which had been moving before cornification abruptly stopped just before the morphological change started. Focusing on mitochondrial morphology and amount, the granular cells with lower quantity of mitochondria, which were mostly punctate, tended to transit to corneocytes. Time-lapse imaging during cornification showed that remaining fragmented mitochondria were depolarized at the same time as the acidic vesicles stopped. After flattening, DNA signals were leaked from the nuclear region and gradually faded out. Furthermore, we also experimented using an epidermal equivalent model with impairment of filaggrin expression. The results of imaging suggested that filaggrin affected on a certain step of the morphological change. Our study would contribute to elucidate the mechanism of the cornification and skin diseases such as vulgar ichthyosis or atopic dermatitis.

P1408/B540

Optimizing Cell Factories: Uncovering the Role of Vacuolar Size in Biochemicals Yield.

G. L. Alvarez Azanedo, Y. M. Chan; San Francisco State University, San Francisco, CA.

The organelles of eukaryotic cells house molecules involved in specialized biochemical reactions and thus, may be used as bioreactors. In this study, we focus on the vacuoles of *Saccharomyces cerevisiae* since they are dynamic organelles that serve crucial functions including pH and ion homeostasis, protein and organelle degradation, and storage. In addition, vacuoles have been suggested to hold the potential to manufacture compounds that can be converted to liquid fuels such as gasoline. However, it remains unknown if the size of an organelle can determine the quantity of biochemicals stored within them in addition to how vacuolar size could impact the quantity of compounds vacuoles can store. Therefore, the aim of this study is to examine if vacuolar size influences the quantity of compounds stored, which can provide insights on its capacity to yield compounds. Our compound of interest is 5-Aminoimidazole ribonucleotide (AIR), an intermediate molecule in the '*de novo*' Purine Biosynthesis (DNPB) pathway. AIR accumulates in the vacuoles of *S. cerevisiae* mutants defective in the *ADE2* gene (also involved in the DNPB pathway) when grown in adenine-deprived medium. Interestingly, AIR emits red fluorescence naturally when exposed to oxygen, thus, allowing us to visualize the content of the vacuoles and draw a relationship against vacuolar volume using fluorescent microscopy. Therefore, to study the capacity of different vacuole sizes to store AIR, we imaged *ade2* mutants via confocal, fluorescent microscopy. These images were used to reveal three-dimensional information of the vacuoles and AIR content from fluorescent signatures. The fluorescence intensities from the vacuolar membrane (GFP-tagged) and AIR were analyzed with two softwares, ImageJ and MatLab, and used to determine whether a correlation exists between vacuole size and AIR accumulation. Preliminary results suggest a positive correlation between vacuolar size and the amount of AIR accumulated. Understanding how vacuolar size affects the amount of a compound accumulated within the vacuoles could shed light on finding effective ways to enhance yeast vacuoles as bioreactors to manufacture other compounds of interest in larger scales.

P1409/B541

Proposed Plasma Membrane Sphingolipid Sensor Nce102 Regulates Ergosterol-dependent Processes of the Vacuolar Membrane in Yeast.

J. Zahumensky[1], K. Vaskovicova[1], J. B. Konopka[2], J. Malinsky[1]; [1]Institute of Experimental Medicine CAS, Prague, CZECH REPUBLIC, [2]Department of Microbiology and Immunology, Stony Brook, NY.

Biomembranes are segmented into lateral microdomains of specific composition and function. This enables spatio-temporal segregation of not only diverse cellular processes, but also distinct biological functions executed by individual membranes. One of the best characterised microdomains of the yeast plasma membrane is the ergosterol-rich MCC (membrane compartment of Can1). It is stabilized by the eisosome, a cytoplasmic protein scaffold, which gives the microdomain its typical furrow-like shape. Chief among the core MCC constituents is the tetraspan protein Nce102. Its absence causes a decrease in number of MCC microdomains in the plasma membrane and renders them flat. While the exact function of Nce102 remains unknown, the protein has been proposed to act as a sensor of plasma membrane level of sphingolipids, and to be involved in regulation of their biosynthesis. We demonstrate that as the yeast culture ages, and the sphingolipid content of cellular membranes increases, a subpopulation of Nce102 migrates from the plasma membrane to the vacuole. In contrast to other plasma membrane proteins, this transition does not trigger degradation of Nce102. Instead, the protein is stably localized to ergosterol-rich domains of the vacuolar membrane, including the nucleus-vacuole junction, suggesting functional relevance. Indeed, deletion of *NCE102* and/or its functional homologue *FHN1* leads to several vacuolar phenotypes, prime examples being delayed vacuolar fusion (a hallmark of both cell ageing and filamentous growth) and less efficient formation of ergosterol-rich domains in the vacuolar membrane. Our data further suggest that the deletion strains might have a defect in lipophagy, a process directly dependent on pre-existence of ergosterol-rich domains in the vacuolar membrane, and vital for ergosterol recycling. Interestingly, both vacuolar fusion and lipophagy involve close apposition of membranes enriched either in ergosterol or sterol esters. The nucleus-vacuole junction is also an ergosterol-rich membrane contact site, as is the inside of the MCC furrow. All of these membrane domains are strongly favoured by Nce102. We therefore speculate that Nce102 might play a role in stabilization of membrane contact sites of ergosterol-rich membranes, which would explain why there are fewer eisosomes and flat MCC microdomains in *nce102*Δ strains. In this respect, Nce102 may function analogous to claudins and occludins, which are major stabilizers of tight junctions in animal cells. Consistently, Nce102 is structurally similar to claudins and occludins in that they all have four membrane spanning domains. Studies on Nce102 are hence expected to bring new insights into the roles of tetraspan proteins in the organization of eukaryotic membranes.

Peroxisomes and Chloroplasts

Peroxisomes Contain Internal Membrane Compartments in Arabidopsis.

Z. J. Wright, B. Bartel; Rice University, Houston, TX.

Peroxisomes, which house vital and often oxidative metabolic reactions in eukaryotes, are typically described as small spherical organelles with a single delimiting membrane. Although occasional peroxisomal membrane complexity has been observed in yeast, mammals, and plants, technical challenges have limited the recognition and understanding of this complexity. We developed fluorescent

reporters to simultaneously label Arabidopsis peroxisomal membranes and lumen, and we examined these lines using live-cell imaging. Exploiting the unusually large size of Arabidopsis seedling peroxisomes, we discovered extensive and pervasive peroxisomal inner membranes. We found that peroxisomal internal vesicles accumulate over time, can harbor distinct proteins, use ESCRT (endosomal sorting complexes required for transport) machinery for formation, and are likely derived from the outer peroxisomal membrane. This unanticipated structural complexity necessitates revisiting the classical view of peroxisomes as simple, single-membrane bound organelles.

P1411/B543

Misdirection of Miro to Peroxisomes Reveals That the GTP-bound State of the N-terminal Domain Is Required for Motor/ Adaptor Complex Assembly.

K. J. Davis[1,2], H. Basu[1,2], E. Shurberg[3], T. L. Schwarz[2,4]; [1]Harvard Medical School, Harvard University, Boston, MA, [2]F. M. Kirby Neurobiology Center, Boston Children's Hospital, Boston, MA, [3]Brandeis Universtiy, Boston, MA, [4]Department of Neurobiology, Harvard Medical School, Boston, MA.

Mitochondria are actively transported in all somatic cells, including neurons and their proper distribution is essential for cellular function. Disrupted mitochondrial trafficking is linked to axon degeneration and dysfunctional synapses. Mitochondrial transport relies on microtubules and a highly regulated motor/adaptor complex that consists of four critical components: Miro, a mitochondrial outer membrane protein; Milton/TRAK1/2, the adaptor protein; and kinesin-1, and dynein, the molecular motors. Miro comprises a C-terminal transmembrane anchor in the outer mitochondrial membrane and two GTPase domains (N-GTPase and C-GTPase) that are separated by EF hands. Although the GTPase domains of Miro are a prominent feature, their functional significance is controversial. Overexpressing GTP and GDP-locked versions of Miro have been confounded by the presence of endogenous Miro and detrimental consequences of gross reorganization of the mitochondria. To circumvent these confounding factors, we have misdirected Miro1 to peroxisomes with the transmembrane domain of PEX3 and have expressed this construct in both COS7 cells and hippocampal neurons. This construct recruits to peroxisomes both coexpressed TRAK and kinesin-1. Using the peroxisome-directed Miro1, we find that the Miro1 N- GTPase regulates the ability of Miro1 to interact with the rest of the motor adaptor complex: neither TRAK1/2 nor kinesin colocalize on peroxisomes with the GDP-locked T18N mutation and the motility and distribution of the peroxisomes in COS7 cells and hippocampal neurons are correspondingly affected. The complex assembles correctly with the GTP-locked N-GTPase (P13V). In contrast, neither the GTP-locked nor GDP-locked C-GTPase mutations substantially altered Miro1 recruitment of TRAK1/2 or kinesin to peroxisomes. In hippocampal neurons peroxisomes bearing the P13V Miro1 or wildtype Miro1 are transported out of the soma into axons and dendrites, but those bearing T18N Miro1 remain in the soma. Thus, N-GTPase of Miro1 is critical for regulating Miro1's interaction with the other components of the motor/adaptor complex and thereby for regulating mitochondrial motility.

P1412/B544

Characterization of a Novel Peroxin in *Trypanosoma Brucei*.

E. Knight, A. Gianos, L. Crowe, M. Morris; Clemson University, Clemson, SC.

Peroxisomes are ubiquitous membrane bound organelles with multiple functions including the degradation of hydrogen peroxide and the oxidation of fatty acids. Kinetoplastids, a group of flagellated

protozoans, have specialized peroxisomes called glycosomes that are essential. Glycosomes are unique in that they compartmentalize the first seven steps of glycolysis and are indispensable. Despite their importance, we know little about the processes that regulate these organelles. Proteins known as peroxins (Pexs) coordinate peroxisome and glycosome biogenesis. While their function is often conserved across species, their sequences usually are not. Pexs regulate many processes including peroxisome/glycosome formation and proliferation, and the import of membrane and matrix proteins. In kinetoplastids, homologs for only a small number of known Pexs have been characterized, suggesting that there are more Pexs to be discovered. We are interested in identifying and characterizing additional Pexs. Pex19 is a soluble chaperone that delivers peroxisome membrane proteins, many of which are Pexs, to the peroxisome via interactions with the glycosome membrane protein Pex3. We queried the trypanosome genome for open reading frames that contain a Pex19 binding domain that is present yeast, mammal, and plant in Pex3. We found a single ORF (Tb927.9.11350) containing a putative Pex19 binding domain (P19BD; SNKLEIWEDLKIISFTR), which is conserved in all kinetoplastids. In pursuit of resolving the function of this putative Pex19 binding protein, Pex19BP, we have defined its cellular localization, purified organelles using epitope-tagged Pex19BP, and identified putative Pex19BP binding proteins via co-immunoprecipitation (co-IP). In the kinetoplastid parasite, *Trypanosoma brucei*, immunofluorescence assays revealed that staining for hemagglutinin antigen-tagged TbP19BP (HA-TbP19BP) overlapped with the glycosome protein aldolase. Western analysis of organelles isolated via immunoaffinity using HA-TbP19BP revealed the presence of multiple glycosome proteins and co-IP experiments demonstrated that TbP19BP interacts with proteins involved in glycosome protein import. Phenotypic characterization of Pex19BP-deficient cells is ongoing and will provide insight into the role this protein plays in glycosome biogenesis. Inhibition of glycosome protein import is lethal to trypanosomes. The identification of additional Pexs in these parasites provides a foothold into future investigations into the pathways that coordinate glycosome biogenesis, which may be exploited for pragmatic gain.

P1413/B545

Functional Peroxisomes Are Necessary to Maintain Regulatory Pathways of Cholesterol Homeostasis and Efficient Cholesterol Synthesis in CHO Cells.

K. N. Charles[1], J. E. Shackelford[1], P. L. Faust[2], S. J. Fliesler[3], H. Stangl[4], **W. J. Kovacs**[5]; [1]Department of Biology, San Diego State University, San Diego, CA, [2]Department of Pathology and Cell Biology, Columbia University, New York, NY, [3]Departments of Ophthalmology and Biochemistry, University at Buffalo - the State University of New York (SUNY); and Research Service, Veterans Administration Western New York Healthcare System, Buffalo, NY, [4]Department of Medical Chemistry, Medical University of Vienna, Vienna, AUSTRIA, [5]Institute of Molecular Health Sciences, ETH Zurich, Zurich, SWITZERLAND.

Cholesterol biosynthesis is a multi-step process involving more than 20 enzymes in several subcellular compartments. The pre-squalene segment of the cholesterol/isoprenoid biosynthetic pathway is localized in peroxisomes. Cellular cholesterol homeostasis involves the sensing of sterol levels and an appropriate response by altering the balance between dietary uptake, endogenous *de novo* synthesis, efflux, and (in liver) conversion to bile acids. Cells adjust their sterol content by both transcriptional and post-transcriptional feedback regulation of sterol metabolism, and the sterol regulatory element-binding protein (SREBP) family of transcription factors is central for this regulatory system. Using the peroxisome-deficient *Pex2* knockout mouse we have defined the importance of peroxisomes in maintaining normal cholesterol homeostasis. We showed that peroxisome deficiency activates ER stress

pathways in the liver, especially the integrated stress response, leading to dysregulation of the endogenous sterol response mechanism and SREBP-2 pathway induction. In this study, we compared the transcriptional regulation of cholesterol biosynthesis in wild-type Chinese hamster ovary (CHO-K1) cells and in three isogenic peroxisome-deficient CHO cell lines harboring *Pex2* gene mutations. Peroxisome deficiency activated expression of cholesterogenic genes; however, cholesterol levels were unchanged compared to wild-type CHO-K1 cells. HMG-CoA reductase (HMGCR) activity was significantly decreased in the mutant cells, whereas the protein levels of HMGCR, mevalonate kinase, and IPP isomerase (IDI1) were significantly increased. The rate of cholesterol synthesis was significantly reduced in peroxisome-deficient cells. U18666A, which inhibits cholesterol export from lysosomes, induced the mRNA and protein levels of cholesterol biosynthetic enzymes in peroxisome-deficient cells; however, cholesterol synthesis rates were significantly lower than in CHO-K1 cells. ER stress, mTORC1 and MAPK pathways were not involved in the SREBP-2 pathway activation in peroxisome-deficient CHO cells. Interestingly, peroxisome deficiency promoted SCAP trafficking from the ER to the Golgi even when cells were cultured in medium containing 10% FCS. Restoration of functional peroxisomes in peroxisome-deficient CHO mutants upon complementation with *Pex2* cDNA normalized the transcriptional regulation of the cholesterol biosynthetic pathway, the rate of cholesterol synthesis, and SCAP trafficking. These results highlight the importance of functional peroxisomes for maintaining regulatory pathways of cholesterol homeostasis and efficient cholesterol synthesis in CHO cells.

P1414/B546

Characterization of the Kinesin KSE2 in Stromule Formation and Function.

K. Seward[1], N. Meier[2], A. Alqarni[1], A. Nedo[1], A. Kolagunda[1], W. Treible[1], C. Kambhamettu[1], S. Dinesh-Kumar[2], J. Caplan[1]; [1]University of Delaware, Newark, DE, [2]University of California, Davis, Davis, CA.

Chloroplasts play an important role during plant immunity and are the source for many cellular signals during the defense response. During the immune response chloroplasts send out stroma-filled tubular extensions called stromules. Stromules are induced during both PAMP-triggered immunity (PTI) and effector-triggered immunity (ETI). Stromules extend along microtubules, and since kinesins are the only MT motors in plants, we hypothesized that a kinesin provides the motive force for stromule extension and stromule-driven movement. Our lab took a candidate approach to identify the kinesin for stromule extension by overexpressing kinesins belonging to kinesin family 14. One of the candidates resulted in increased stromule length and faster chloroplast movement, which we named kinesin for stromule extension 2 (KSE2). We are currently characterizing KSE2 to understand its role in stromule formation and function. To do this, we overexpressed 9 deletion mutants in *N. benthamiana in* which we deleted various domains of KSE2. These deletions include the actin-binding calponin domain (ΔCH), the coiled-coiled 1 domain (ΔCC1), both the ΔCH and ΔCC1 (ΔCH-CC1), only the motor (motor), no motor (Δmotor), the coiled-coiled 2 domain (ΔCC2), the C-terminal tail (Δtail), both the CC2 and tail (ΔCC2-Tail). The full length and ΔCC1 showed significant changes in stromule branching. The Δmotor showed no significant differences in stromules per chloroplast and branches per stromule. The full length KSE2, only the motor, ΔCC1 showed significant differences in stromules per chloroplast. All 6 deletion mutants tested showed significant differences in average stromule length. We are currently in the process of examining changes in stromule morphology for ΔCH, ΔCC2, and ΔCC2-Tail, and analyzing movement dynamics, such as extension velocity, for all KSE2 overexpression deletion mutants. This data suggests that KSE2 may be the motor required for stromule extension and future experiments will focus on examining knockdown and knockout mutants during plant innate immunity.

P1415/B547

The Study of Stromule Dynamics during Reactive Oxygen Species Regulation of Intra- and Inter-cellular Defense Signaling.

A. Nedo; University of Delaware, Newark, DE.

Stromules, are stroma-filled tubular extensions of the chloroplast that appear to play a major role in cellular signaling. Specifically, they appear to impact the movement and localization of chloroplast as part of the regulation of immune response signals such a hydrogen peroxide (H_2O_2). However, the exact mechanics behind their function and precise role in signal transmission remains unclear. Chloroplast and stromule movement dynamics are dependent on the plant cytoskeletal networks. Stromule tips move along microtubules during extension, while chloroplast moment itself is dependent on the actin microfilament network. By utilizing viral induced gene silencing (VIGS) in *Nicotiana benthamiana,* it is possible *to* disrupt chloroplast movement by silencing a gene called Chloroplast Unusual Positioning 1 (*CHUP1*), which has been observed playing a major role in blue light mediated avoidance. An alysis of *CHUP1*-silenced *N. benthamiana* indicate that CHUP1 plays a regulatory role in the movement of chloroplast bodies, influencing the rate of chloroplast movement, as well as influencing the movement dynamics of stromules. While stromules have a vital role in intracellular communication, they may also function to send signals intercellularly via plasmodesmata (PD). The regulation of PD permeability limits the region of cell death as part of the hypersensitive response programed cell death (HR-PCD). In order to understand the role of signal transmission during HR-PCD it is necessary to understand the contribution chloroplasts and stromules play in the transmission of H_2O_2 as it relates to (PD) permeability. Preliminary data shows that during HR-PCD induction, there is an increased association of PD with both stromules and chloroplast bodies. This suggests that chloroplast generated signals are necessary for the regulation of PD permeability during HR-PCD. Determining the means of stromule and chloroplast movement regulation and their role in signal transmission will help elucidate the mechanics of the plant innate immune response. By understanding this, our ability to combat pathogens will only increase, as we will better be able to target the pathways involved in plant defense and disease resistance.

P1416/B548

Non-canonical Interactions in Intracellular Transport: Investigating the Physical Mechanisms of Hitchhiking and Tethering.

S. S. Mogre[1], J. R. Christensen[2], S. L. Reck-Peterson[2,3,4], E. F. Koslover[1]; [1]Department of Physics, University of California San Diego, La Jolla, CA, [2]Department of Cellular and Molecular Medicine, University of California San Diego, La Jolla, CA, [3]Division of Biological Sciences, Cell and Developmental Biology Section, University of California San Diego, La Jolla, CA, [4]Investigator, Howard Hughes Medical Institute, Chevy Chase, MD.

Intracellular transport plays an important role in metabolism, signaling, cell growth, and development. The traditional picture of transport in cells involves the bidirectional movement of cargo attaching directly to cytoskeletal motor proteins such as kinesin and dynein, which move along microtubule tracks. In contrast to this canonical model, recent evidence shows that cargos such as peroxisomes, lipid droplets, mRNPs, and the endoplasmic reticulum can also move by attaching to other motor-driven organelles, navigating the cytoplasm through “hitchhiking”. A molecular component of hitchhiking has

been identified for peroxisome transport in *A. nidulans* fungal hyphae, where PxdA proteins on the surface of early endosomes are required for hitchhiking. However, the physical principles underlying this transport mechanism remain unexplored. We describe a quantitative model of hitchhiking, focusing on the interplay between the carrier organelle, linker protein and the transported cargo to obtain the rate at which hitchhiking can be initiated. Our work shows that transport initiation rates depend on the distribution of the cytoskeletal tracks and the carrier organelle, as well as linker protein stiffness. In mammalian cells, there is evidence that peroxisomes are tethered to microtubule tracks when not being actively transported. We have imaged peroxisomes in the hyphae of live *A. nidulans* cells and analyzed their motion to identify signatures of tethering to microtubules. Using an analytical model of fluctuating semiflexible polymers, we compared tethered peroxisome motion in live cells to the mechanical properties of the intracellular environment. Our computational model of hitchhiking predicts that tethering to microtubules results in a ten-fold enhancement of the hitchhiking initiation rate in geometries similar to fungal hyphae. This enhancement is expected to substantially increase the overall transport rate of hitchhiking organelles, lead to a more uniform distribution, and reduce the time required for hitchhiking cargo to encounter different cellular regions. Our results leverage a quantitative physical model to highlight the importance of organelle interactions in non-canonical intracellular transport and provide new experimental directions that will allow us to further elucidate this under-appreciated transport mechanism.

P1417/B549

Targeting of the Membrane-anchored Rab GAP (GTPase Accelerating Protein) Gyp8 to Peroxisomes Is Regulated by the AAA ATPase Msp1.

M. A. Quinn, A. Lin, A. Mora, C. Vuong, S. Connolly, B. Delgado, **D. P. Nickerson**; California State University, San Bernardino, CA.

Eukaryotic cells use vesicular transport to build and maintain membrane-bound organelles housing specific biochemical functions. Rab GTPase signaling proteins (Rabs) are key regulators of vesicular transport, controlling where and when membranes dock and fuse, ensuring lipid and protein cargoes are delivered to appropriate destinations. Rabs adopt their signaling active conformation when bound to GTP, allowing Rab interactions with tethering and membrane fusion proteins. Rabs depend upon GTPase accelerating proteins (GAPs) to trigger GTP hydrolysis and return the Rab to its GDP-bound, inactive state. Rab GAPs contribute to the efficiency and fidelity of transport pathways, and defective Rab GAPs are implicated in a variety of human diseases. Rab GAPs tend to be cytosolic proteins that transiently localize at membranes to survey for their client Rab. We report that the yeast Rab GAP Gyp8 is an atypical transmembrane (TM) GAP whose association with peroxisomes is regulated by the AAA ATPase Msp1, a chaperone that functions to remove tail-anchored proteins from peroxisomes and mitochondria. Computational analysis of Gyp8 predicted a single-pass TM domain near the carboxy terminus, characteristic of a tail-anchored protein. Fluoresence microscopy indicated that GFP-tagged Gyp8 co-localized with endoplasmic reticulum (ER) and peroxisomal markers in wild type cells. In the absence of peroxisomes, GFP-Gyp8 redistributed to the ER. Loss of Msp1 chaperone function resulted in mislocalization of GFP-Gyp8 to mitochondrial membranes. Subcellular fractionation biochemically demonstrated that Gyp8 localized exclusively to a membrane fraction containing peroxisomes. Truncation analysis of Gyp8 indicated that the TM and luminal domains are necessary and sufficient to direct localization to peroxisomes. These data represent the first report in any experimental system of a

Rab GAP that localizes to peroxisomes. Ongoing studies continue to explore the physiological significance of Gyp8 in regulating peroxisome dynamics.

P1418/B550

Ypk9, a Homolog of Parkinson'S Associated Park9, Has a Role in Peroxisomal Proliferation.

F. Joseph, W. Chirico; SUNY-Downstate Medical Ctr, Brooklyn, NY.

Yeast PARK9, a homolog of human ATP13A2, was previously identified as a suppressor of alpha synuclein toxicity. Mutations in ATP13A2, a putative divalent cation transporter located in lysosomes, have been implicated in the aging disorder, Parkinson's disease. Because oxidative damage accumulates during aging, we speculated that loss of YPK9 may compromise growth and oxidants, such as hydrogen peroxide, may exacerbate it. We found the growth rates of *ypk9* and a wildtype strain to be nearly identical. However, growth of *ypk9* was severely impaired in the presence of hydrogen peroxide. When treated with hydrogen peroxide, the number of peroxisomes remained unchanged in wildtype cells but increased as much as 6-fold in YPK9 deletion strains suggesting that YPK9 plays a role in peroxisomal proliferation. DNM1, FIS1, and VPS1 were previously shown to regulate peroxisomal proliferation (fission). To test the hypothesis that YPK9 genetically interacts with DNM1, FIS1, and VPS1, we created a series of single and double deletions and monitored growth and the number of peroxisomes. The growth of *dnm1*, *fis1*, and *vps1* strains was modesty slower than the wildtype. Growing the strains in the presence of hydrogen peroxide further hampered growth. The *dnm1 ypk9* strain grew slightly faster and the *fis1 ypk9* strain grew slightly slower than the wildtype. The growth of *vps1 ypk9* strain was dramatically impaired. The *dnm1* and *fis1* strains had about the same number of peroxisomes as the wildtype, whereas the *vps1* strain had 25% fewer peroxisomes. Hydrogen peroxide increased the number of peroxisomes in *fis1*, *dnm1*, and *vps1* relative to untreated cultures. Although the number of peroxisomes in the *vps1 ypk9* strain was ~60% greater than the wildtype, the number in *dnm1 ypk9* and *fis1 ypk9* strains was about the same as the wildtype. Treating *fis1 ypk9* and *vps1 ypk9* with hydrogen peroxide increased the number of peroxisomes by more than 30%, whereas the number of peroxisomes in the *dnm1 ypk9* strain remained essentially unchanged suggesting that peroxisomal proliferation resulting from the loss of YPK9 is dependent on DNM1. Together, these results suggest that YPK9 negatively regulates peroxisomal proliferation and plays an important role in hydrogen peroxide detoxification.

P1419/B551

Investigating the Role of Peroxisomes in Hutchinson-Gilford Progeria Syndrome.

X. Mao[1], P. Bharti[1], A. Thaivalappil[1], J. Hacia[2], K. Cao[1]; [1]University of Maryland, College Park, College Park, MD, [2]University of Southern California, Los an geles, CA.

Peroxisomes are small, membrane-enclosed organelles that house various enzymes with metabolic functions. One important feature in both Hutchinson-Gilford Progeria Syndrome (HGPS) and normal aging is the elevated levels of Reactive Oxygen Species (ROS), which are generated from metabolic pathways with the capacity to cause oxidative damage to macromolecules within the cells. Although peroxisomal bioreactions can generate free radicals as their byproducts, many metabolic enzymes within the peroxisomes play critical roles as ROS scavengers, in particular catalase. Preliminary data from our group showed multiple peroxisomal defects in HGPS fibroblasts. First, we observed impaired peroxisomes-targeting proteins trafficking, which suggested that the poorly assembled peroxisomes

might cause high oxidative stress, contributing to the premature senescent phenotype in HGPS. We then investigated the ROS clearance efficiency by peroxisomal enzymes, and found significantly decreased expression of catalase in HGPS. Furthermore, we evaluated the effects of two promising HGPS-treatment drugs Methylene Blue and Rad001 on peroxisomes in HGPS fibroblasts. We found that comparing to Rad001, Methylene Blue reduces cellular ROS with less peroxisomal toxicity. Our findings will bring new insights on the cellular aspects of HGPS as well as normal aging.

P1420/B552

Structural Investigation of *Arabidopsis Thaliana* Peroxins: Purifying PEX4 and PEX22 for Crystallization.

S. E. Bradford, Z. J. Wright, J. L. Olmos, Jr., G. N. Phillips, Jr., B. Bartel; Rice University, Houston, TX.

Peroxisomes are essential organelles that host metabolic reactions such as the breakdown of fatty acids. Peroxisome function and biogenesis are controlled by proteins called peroxins (PEX). Structural data exist for several peroxins from organisms such as *Saccharomyces cerevisiae* and *Homo sapiens*, but no structures for *Arabidopsis thaliana* peroxins have been solved. PEX4 is an E2 ubiquitin conjugating enzyme that ubiquitinates peroxisomal membrane proteins. PEX22 anchors PEX4 to peroxisomes with a transmembrane domain. Interestingly, PEX22 is necessary for the function of PEX4 beyond its role as a membrane anchor, but this relationship is incompletely understood. *Arabidopsis* PEX4 has high sequence similarity to homologs in other organisms, but *Arabidopsis* PEX22 has virtually no sequence similarity to PEX22 proteins in other organisms. We are investigating the structure of *Arabidopsis* PEX4 in complex with PEX22. We have generated a construct of PEX4 linked to a soluble portion of PEX22 with a protease cleavage site. We have expressed these constructs in *E. coli* with a 6xHis tag and an MBP tag and have purified the proteins for crystallization. This research will further our understanding of peroxin structure in *Arabidopsis* and elucidate the role of PEX22 in PEX4 function.

The Lon Protease Promotes Mitochondrial Homeostasis in Lysosome Impaired Cells.

T. Coody, C. Hughes, A. Lever, A. Hughes; University of Utah, Salt Lake City, UT.

Communication between organelles is crucial for cells to sense, respond, and adapt to environmental changes. Amongst organelle interactions, the mitochondria-lysosome connection is uniquely important due to the role of these organelles in regulating energy metabolism, nutrient sensing, and protein and metabolite recycling. Disruption of mitochondria-lysosome communication contributes to numerous diseases, including heart failure, neurodegeneration, diabetes, and inborn errors of metabolism. Working in budding yeast, we recently found that lysosomes promote mitochondrial respiration by spatially compartmentalizing amino acids. This sequestration is necessary to prevent amino acids from interfering with iron homeostasis, which is critically important for maintaining mitochondrial respiration. Here, we sought to identify pathways that operate to maintain mitochondrial homeostasis during amino acid-induced iron limitation. To do this, we performed genetic screens in yeast to identify genes that become conditionally essential in the absence of a functioning lysosome. These screens uncovered numerous genes important for maintaining mitochondrial homeostasis during lysosome impairment, including several mitochondrial localized proteases. Amongst mitochondrial proteases, we found that

the LON protease, a mitochondrial matrix-localized protease conserved from bacteria to mammals, becomes critically important during times of lysosome failure. Indeed, we found that both well-characterized and previously unknown LON substrates are degraded upon lysosome impairment, and demonstrate that degradation of these substrates during lysosome dysfunction is triggered by amino acid-induced iron limitation. We are currently working to determine how LON-dependent degradation of mitochondrial matrix proteins promotes mitochondrial health. Interestingly, many LON targets under these conditions are iron containing proteins. Based on this observation and the fact that their degradation is triggered by amino-acid induced iron limitation, our current model is that LON is required to prevent deleterious accumulation of apo, iron-less containing misfolded protein during times of lysosome impairment.

P1422/B554

Molecular Mechanism of Ubiquitin-dependent Mitophagy.

K. Yamano, N. Matsuda; Tokyo Metropolitan Institute of Medical Scinence, Tokyo, JAPAN.

Parkin and PINK1, two gene products mutated in a familial Parkinson's disease, have been identified as essential proteins for ubiquitin-dependent degradation of damaged mitochondria through autophagy machinery called mitophagy. Parkin is a member of the RBR E3 ligase harboring a RING1 domain for interaction with E2 enzymes and a RING2 domain for conjugation to ubiquitin molecule. However among 40 different E2 enzymes encoded in the human genome, E2 enzymes, which are recruited to the damaged mitochondria with Parkin during mitophagy, remain largely unknown. Here we developed a method in which interactions between E2 and activated Parkin on the damaged mitochondria are captured in cells, and identified many E2 enzymes required for Parkin-dependent mitochondrial ubiquitylation.

P1423/B555

Bridging the Gap between Energy Sensing and Mitophagy: Characterization of the Regulation of Mitophagy Receptors by Ulk1 and Tbk1.

A. S. H. Tung[1,2], C. Hung[1], R. J. Shaw[1]; [1]Molecular and Cell Biology Laboratory, Salk Institute for Biological Studies, La Jolla, CA, [2]Division of Biological Sciences, University of California, San Diego, La Jolla, CA.

AMPK is a highly-conserved energy sensor, the master regulator of cellular metabolism, and has been shown to regulate mitochondrial autophagy via activation of its substrate, ULK1. However, the precise mechanism of AMPK-regulated mitophagy remains to be elucidated. The LC3-Interacting Region (LIR) is a conserved amino acid sequence present in some proteins that allows their binding to Atg8 family proteins, critical proteins for autophagosome formation. A subgroup of LIR-containing proteins called mitophagy receptors function to tether damaged mitochondria to the Atg8-decorted autophagosome. Previous studies have shown that phosphorylation at the serine before the conserved LIR sequence in some LIR-domain containing proteins increases the affinity of the LIR motif to LC3B and alters the function of the LIR-containing protein. For example, ULK1 has been reported to phosphorylate the mitophagy receptor FUNDC1 at one such serine, increasing FUNDC1 and LC3B binding affinity and promoting mitophagy. Interestingly, TBK1 has been reported to phosphorylate other LIR-domain containing proteins. Here we have investigated more broadly whether individual LIR-domain containing autophagy/mitophagy receptors are regulated by ULK1 or TBK1, or both, and the role that AMPK-dependent energy sensing plays in the regulation.

P1424/B556

Trpm2/ca^{2+}/camkii Pathway Leads to Impairment of Mitophagy to Mediate Neuron Cell Death in Models of Stroke.

F. Li; Zhejiang University, Hangzhou, CHINA.

Ischemia neuronal injury has been demonstrated to induce mitochondrial dysfunction and mitochondrial reactive oxygen species (ROS) production, and mitophagy in turn is activated to repair dysfunctional mitochondrial and relieve mitochondrial ROS. Yet, whether and how ROS-sensitive TRPM2 channel (transient receptor potential cation channel subfamily M membrane 2) regulates mitophagy remains unknown. Here, we mechanistically studied the role of TRPM2 in oxygen and glucose deprivation-reperfusion induced mitophagy regulation. We find that TRPM2-mediated Ca^{2+} influx leads to mitophagy inhibition, which leads to death of primary neuron. Genetically knockout of TRPM2 channel or Chemically chelation of Ca^{2+} induces mitophagy and reduces cell death. Moreover, in response to OGD-Rep, TRPM2-mediated Ca^{2+} influx induces phosphorylation of CAMK2, and the activated CAMK2 subsequently reduces the translocation of parkin to mitochondria. Chemically inhibition of CAMK2 increases mitophagy and improves mitochondrial functions. Therefore, our results demonstrate that ROS activates the TRPM2/ Ca^{2+}/CAMKII/ cascade to decrease parkin translocation to mitochondrial leading to mitophagy impairment in models of stroke.

P1425/B557

A Close-up View of Mitophagy Using Mt-Keima and Fluorescence Lifetime Microscopy.

D. Malide[1], N. Sun[2,1], T. Finkel[3,1]; [1]National Institutes of Health, Bethesda, MD, [2]Ohio State University Wexner Medical Center, Columbus, OH, [3]Aging Institute, University of Pittsburgh Medical Center, Pittsburgh, PA.

Mitophagy is a cellular process that selectively removes damaged, old or dysfunctional mitochondria. Defective mitophagy is thought to contribute to normal aging and to various neurodegenerative and cardiovascular diseases. Previous methods used to detect mitophagy in vivo were cumbersome, insensitive and difficult to quantify. We created a transgenic mouse model that expresses the pH-dependent fluorescent protein mt-Keima in order to more readily assess mitophagy. Keima is a pH-sensitive, dual-excitation ratiometric fluorescent protein that also exhibits resistance to lysosomal proteases. At the physiological pH of the mitochondria (pH 8.0), the shorter-wavelength excitation predominates. Within the acidic lysosome (pH 4.5) after mitophagy, mt-Keima undergoes a gradual shift to longer-wavelength excitation. In addition to intensity imaging we describe here how to apply mt-Keima fluorescence lifetime microscopy (FLIM) to visualize mitophagy in live cells as well as various tissues including skeletal muscle, heart, liver, and kidney, obtained from mt-Keima transgenic mice. We observed that in control live cells mt-Keima fluorescence exhibits two components a short (0.4ns) lifetime corresponding to the mitophagic compartment and a longer (2.6ns) lifetime corresponding to normal mitochondria, in good correspondence to the intensity images. Interestingly, in the tissues the lifetime measurements reveal a heterogeneous mitophagic compartment containing in addition to the short (0.5ns) lifetime mt-Keima species an intermediary (1.2ns) longer lifetime component. Whether these 2 components correspond to different folding states, digestion products of the mt-Keima in the acidic environment remains to be elucidated. In conclusion FLIM provide a complementary approach to

asses mitophagy in normal cells and tissues as well as in disease situations, or altered under environmental, genetic perturbations, or in aging.

Neuronal Mul1-Mfn2 Nexus Protects Stressed Mitochondria from Parkin-mediated Mitophagy through ER-Mitochondria Contacts.

R. Puri, X. Cheng, M. Lin, N. Huang, Z. Sheng; Synaptic Function Section, National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MD.

Chronic mitochondrial stress associates with major neurodegenerative diseases. As neurons are post-mitotic cells, recovering stressed mitochondria, rather than acute degradation via mitophagy, constitutes a critical step for mitochondrial quality control and thus energy maintenance in early stages of neurodegeneration. Our previous studies in mature cortical neurons revealed that mitophagy is observed in a small proportion of neurons following mitochondrial depolarization and that Parkin translocation to depolarized mitochondria occurs much more slowly than in non-neuronal cells (Cai et al., ***Current Biology*** 2012; Lin et al., ***Neuron*** 2017). These findings argue for intrinsic neuronal mechanisms that can maintain mitochondrial integrity before Parkin-mediated mitophagy is activated. To support this assumption, we address two fundamental questions: (1) Do distinct mechanisms are in place in neurons to act as a checkpoint for recovery versus rapid degradation of chronically stressed mitochondria? (2) Is mitophagy the second resort for neuronal mitochondrial quality control after recovery mechanisms have failed? by addressing these questions, we reveal a new mechanism through Mul1-Mfn2 pathway that acts as a checkpoint to maintain neuronal mitochondrial health under mild stress conditions (Puri et al., ***Nature Communications*** in press). Deficiency in mitochondrial Mul1 E3 ubiquitin ligase increases Mfn2 activity that triggers the first phasic mitochondrial hyperfusion and also acts as an ER-mitochondria (ER-Mito) tethering antagonist. Reduced ER-Mito coupling leads to increased cytoplasmic Ca^{2+} load that activates calcineurin and induces the second phasic Drp1-dependent mitochondrial fragmentation and mitophagy. Overexpressing Mfn2, but not Mfn1, mimics Mul1-deficient phenotypes, while expressing PTPIP51, an ER-Mito anchoring protein, suppresses Parkin-mediated mitophagy. Consistently, expressing Drp1 mutant or blocking calcineurin activity locks mitochondria in hyperfusion status in Mul1-deficient neurons. Thus, by regulating mitochondrial morphology and ER-Mito contacts, Mul1-Mfn2 pathway plays an early checkpoint role in maintaining mitochondrial integrity. Our study provides new mechanistic insights into neuronal mitochondrial maintenance under stress conditions, which is relevant to major neurodegenerative diseases associated with chronic mitochondrial dysfunction and altered ER-Mito interplay *(Supported by the Intramural Research Program of NINDS, NIH). Dysfunction of Hepatic Mitochondria in Alpha-1 Antitrypsin Deficiency Mediated Liver Disease.

N. Khodayari, R. Wang, R. Oshins, Y. Lu, A. Aranyos, Y. Scindia, C. Gould, A. Bryant, M. Brantly; University of Florida, Gainesville, FL.

Alpha-1-antitrypsin deficiency (AATD) is an inherited disease characterized by emphysema and liver disease. AATD is most often caused by a single amino acid substitution at amino acid 342 in the mature protein, results in Z mutation of the AAT gene (ZAAT). This substitution is associated with misfolding and the accumulation of ZAAT in the Endoplasmic reticulum of hepatocytes and monocytes, causing a toxic gain of function. Mitochondrial injury in AATD mediated liver disease has been shown by altered morphology of mitochondria as well as mitochondrial autophagy in the liver of AATD individuals and in a transgenic mouse model ofAATD. In this the main objective of this study is to determine the role of mitochondrial dysfunction in the pathogenesis of AATD-mediated liver disease. Pi*M (normal variant) and Pi*Z (mutant variant) human AAT transgenic mice and PiMM and PiZZ hepatocyte cell lines were used to isolate mitochondria and cytoplasm fractions. The presence of AAT within the mitochondria was determined by western blot analysis, electron and immunofluorescence microscopy.The expression of genes and proteins related to glucose and lipid metabolism pathways were investigated by qPCR, western blot and immunofluorescent microscopy. Live cell metabolic assays were performed using a Seahorse XF analyzer.Pi*Z transgenic mice and PiZZ hepatocyte contain misfolded ZAAT in the hepatic mitochondria as well glucose and lipid metabolism dysregulation.We demonstrate that misfoldedZAAT is imported into mitochondria in our model systems. As a consequence of this transport the is an overabundance of misfolded proteins inside mitochondria that disrupts mitochondrial biosynthetic activities leading to organelle dysfunction. This novel mechanism has the potential to lead to novel interventions to prevent liver disease in AATD.

P1428/B560

A Mitochondrial Presequence That Drives Sorting to the Cell Surface in a Regulated Manner.

J. Catalán[1], A. Negrete[1], B. Vásquez[1,2], C. Retamal[1], A. González[1], **C. Oyanadel**[1]; [1]CEBICEM Facultad Medicina y Ciencia Universidad San Sebastián, Santiago, CHILE, [2]Centro de Envejecimiento y Regeneración (CARE), Facultad de Ciencias Biológicas, Pontificia Universidad Católica de Chile, Santiago, CHILE.

Most of mitochondrial proteins are synthesized in the cytosol as precursors bearing an N-terminal presequence that acts as targeting signal. The hydroxyacyl-CoA deshydrogenase trifunctional multienzyme complex α-subunit (HADHA), involved in β-oxidation, has also been found at the cell surface, known there as gastrin binding protein (GBP). GBP binds gastrin with low affinity and mediates autocrine mitogenic effects in normal gastric and colon carcinoma cells. The mechanism addressing HADHA/GBP from the cytosol to either the mitochondria or the cell surface remains unknown. Interestingly, cytosolic HADHA has recently been described to interact with LC3, a protein crucial in the macroautophagic processes that remove cytosolic components and are increased during starvation conditions. Here, we study whether the presequence of HADHA has sorting information to target the protein to the cell surface and whether this process is regulated by starvation. We raised an antibody against a synthetic peptide of GBP detected variable levels of this protein at the surface of different tumoral cell lines by biotinylation assays. HADHA/GBP is an integral membrane protein as revealed by its resistance to sodium carbonate extraction. This antibody also showed the expected mitochondrial

localization and co-immunoprecipitation of HADHA/GBP with LC3. A construct consisting of the first 36 residues of HADHA fused to green fluorescent protein (GFP) as reporter (N36-MTS-GFP) allowed to analyse the role of the mitochondrial presequence in determining subcellular localization and secretion. We observed N36-MTS-GFP sorted into mitochondria and also to the medium. Strikingly, both GBP cell surface distribution and N36-MTS-GFP secretion increased upon 24 h of starvation. These results reveal that the presequence of HADHA/GBP contains sorting information to target the mitochondria or the plasma membrane depending on yet unknown regulated processes, in which the cell surface pathway is at least activated by starvation. Proteomic an alysis Identifies Membrane Proteins Dependent on the ER Membrane Protein Complex.

S. Tian; Boston Children's Hospital, Boston, MA.

The endoplasmic reticulum (ER) membrane protein complex (EMC) is a key contributor to biogenesis and membrane integration of transmembrane proteins, but our understanding of its mechanisms and the range of EMC-dependent proteins remains incomplete. Here we carried out an unbiased mass spectrometry (MS)-based quantitative proteomic analysis comparing membrane proteins in EMC-deficient cells versus wild-type (WT) cells, and identified 36 EMC-dependent membrane proteins and 171 EMC-independent membrane proteins. Of these, six EMC-dependent and six EMC-independent proteins were further independently validated. We found that a common feature among EMC-dependent proteins is that they contain transmembrane domains (TMDs) with polar/charged residues. Mutagenesis studies demonstrate that EMC-dependency can be converted in cells by removing or introducing polar/charged residues within TMDs. Our studies expand the list of validated EMC-dependent and -independent proteins, and suggest that EMC is involved in handling TMDs with residues challenging for membrane integration.

P1430/B562

TRPM2-mediated Ca^{2+} Entry Promotes Neurotoxin-induced Oxidative Stress, Mitochondrial Fragmentation and Neuronal Cell Death.

M. Al-Ahmad[1,2], D. Hamade[1], A. Sivaprasadarao[1]; [1]School of Biomedical Sciences, Faculty of Biological Sciences, University of Leeds, Leeds, LS2 9JT, UNITED KINGDOM, [2]Department of Biological Sciences, Faculty of Science, Kuwait University, Khaldiya, KUWAIT.

The Transient receptor potential melastatin 2 (TRPM2) is a Ca^{2+} permeable ion channel. It is activated during oxidative stress, affecting cellular homeostasis of both Ca^{2+} and Zn^{2+}. TRPM2 is associated with a number of degenerative diseases including diabetes, Alzheimer's and Parkinson's diseases (PD). A defining feature of these diseases is a rise in the intracellular levels of reactive oxygen species (ROS) and increased mitochondrial fragmentation. We have previously demonstrated that TRPM2 activation underlies mitochondrial fragmentation and pancreatic β-cell death. In this study, we asked whether TRPM2 channels play a similar role in neuronal cell death seen in PD, and whether TRPM2 channels regulate ROS, a key driver of mitochondrial fission. To address these questions, we have used the neurotoxin, 1-methy-4-phenylpyridinium (MPP^+) to induce PD-associated changes in the SH-SY5Y neuroblastoma cell line. We have used fluorescent probes to detect changes in ROS (total and

mitochondrial) production, intracellular distribution of Ca^{2+} and Zn^{2+}, mitochondrial morphology, and cell death. Chemical inhibitors of NADPH oxidase (NOX) and TRPM2, and Ca^{2+} and Zn^{2+} chelators, were used to determine the mechanistic role of TRPM2 channels in MPP^+-induced cellular events. We found MPP^+ to induce Ca^{2+} entry, leading to NOX activation and that NOX-derived ROS, in turn, triggered mitochondrial ROS production. Notably, MPP^+ caused a rise in mitochondrial Zn^{2+}, suggesting that rise in mitochondrial Zn^{2+} could stimulate ROS generation by inhibiting mitochondrial electron transport. TRPM2 inhibition attenuated MPP^+-induced Ca^{2+} influx, and the subsequent rise in mitochondrial Zn^{2+}, ROS production, as well as mitochondrial fission and cell death. Inhibition of rise in mitochondrial Zn^{2+} with TPEN, a Zn^{2+} chelator, attenuated ROS production, mitochondrial fission and neuronal cell death. To determine the potential interplay between Ca^{2+} and Zn^{2+}, we used ionophores in conjunction with chelators. A23187-induced rise in cytosolic Ca^{2+} triggered mitochondrial fission and cell death; these changes were prevented by Zn^{2+} chelation, indicating a critical role for Zn^{2+}downstream of Ca^{2+}. Rising mitochondrial Zn^{2+} with the Zn^{2+}-ionophore, pyrithione, alone was sufficient to cause mitochondrial ROS generation, fragmentation and cell death. Taken together, our results suggest that TRPM2 channels play a key role in upregulating ROS production and subsequent neuronal cell death by causing Ca^{2+}-induced rise in mitochondrial Zn^{2+} and subsequent mitochondrial fragmentation.

Live Imaging in Liver Cells to Study Virus-ca^{2+} Interactions and ER-mitochondria Junctions-regulated Ca^{2+} Homeostasis.

Y. Lin[1], P. Tsai[1], F. Tsai[1,2]; [1]Department of Pharmacology, College of Medicine, National Taiwan University, Taipei city, TAIWAN, [2]Department of Internal Medicine, National Taiwan University Hospital, Taipei city, TAIWAN.

Hepatitis B virus (HBV) is the leading cause of hepatocellular carcinoma (HCC), but how HBV induces HCC remains unknown. HBx, one of the HBV proteins, was reported to be responsible for HCC initiation, and that oncogenic effect of HBx might require Ca^{2+} signaling in hepatocytes. Recent study also implied that HBx disturbed Ca^{2+} signaling in HCC cells. However, the mechanistic link between HBx, Ca^{2+} signaling and HCC initiation remain elusive. We therefore using live-cell Ca^{2+} imaging to explore how HBx affected Ca^{2+} signaling, and how Ca^{2+} affected the tumorigenic effect of HBx in HCC cells. We established a real-time Ca^{2+} monitoring platforms, which can simultaneously demonstrate local Ca^{2+} dynamics in cytosol, mitochondria and/or endoplasmic reticulum (ER), by stably expressed genetic-encoded Ca^{2+} indicators (GECIs) in HCC and primary hepatocyte cell lines. Assays to measure Ca^{2+} flow between organelles were also designed to elucidate the Ca^{2+} dynamics between those compartments. Using this platform we first discovered that (1) HBx may not directly disturb the intracellular Ca^{2+} dynamics in hepatocytes, but HBx effects on hepatocyte signaling require proper Ca^{2+} dynamics, (2) There exist distinct statuses of mitochondrial Ca^{2+} dynamics, and (3) Local Ca^{2+} oscillations occur in the mitochondria. These findings about mitochondrial Ca^{2+} may be belated to the connectivity statues of ER and mitochondria. To further elucidate the role of ER-mitochondria junctions (EMJs) in whole cell Ca^{2+} homeostasis, we break EMJs by knocking down the tethering proteins, mitofusin2 (MFN2) and PDZD8 in our platform. Indeed, EMJ breakdown increased Ca^{2+} stores in ER and reduced mitochondria Ca^{2+} levels. Surprisingly, knockdown of MFN2 or PDZD8 also suppressed store-operated Ca^{2+} entry (SOCE). Double knockdown of the EMJ tethering proteins MFN2 or PDZD8 and the SOCE components STIM1 and/or ORAI1 eliminated the effects of MFN2 or PDZD8 knockdown. Thus, mitochondria may contribute to STIM1/ORAI1-mediated SOCE via EMJs. We are currently investigating the molecular mechanisms and physiological/pathological

significance of the above phenomena, which will not only revolutionize our understanding of virus-Ca^{2+} interactions and mitochondrial Ca^{2+}-SOCE regulation, but also inspire our potential to develop novel strategies against HBV-induced HCC.

Alteration in Intracellular Ca^{2+} Levels through Ion Chennels in Human Endometrial Stromal Cells.

K. Park[1], J. Sohn[1], H. Kim[2], S. Seong[1], J. Lim[1]; [1]Seoul National University, Seoul, KOREA, REPUBLIC OF, [2]Sungkyunkwan University School of Medicine, Suwon, KOREA, REPUBLIC OF.

Calcium (Ca^{2+}) is an important element for many physiological functions of the uterus, including embryo implantation. Here, we investigated the possible involvement of altered intracellular Ca^{2+} levels in decidualization in human endometrial stromal cells (hEMSCs). hEMSCs showed high levels of mesenchymal stem cell marker expression (CD73, CD90, and CD105) and did not express markers of hematopoietic progenitor cells (CD31, CD34, CD45, and HLA-DR). Decidualization is a process of ovarian steroid-induced endometrial stromal cell proliferation and differentiation. Several types of ion channels, which are regulated by the ovarian hormones progesterone and estradiol, as well as growth factors, are important for endometrial receptivity and embryo implantation. The combined application of progesterone (1 μM medroxyprogesterone acetate) and cyclic AMP (0.5 mM) for 6 days not only elevated inositol 1,4,5-triphosphate receptor (IP_3R)-mediated Ca^{2+} release and *IP_3R* expression, it also promoted *ORAI* and *STIM* expression as well as cyclopiazonic acid-induced Ca^{2+} release. Finally, intracellular Ca^{2+} levels and ion channel gene expression influenced hEMSC proliferation. These results suggest that cytosolic Ca^{2+} dynamics, mediated by specific ion channels, serve as an important step in the decidualization of hEMSCs.

The Ca^{2+} Channel TRPML3 Regulates Autophagy by Interaction with VTI1B and ATG16L1.

J. Shin, Y. Park, S. Choi, S. Hong, S. Kim, **H. Kim**; Sungkyunkwan University School of Medicine, Suwon, KOREA, REPUBLIC OF.

TRPML3 is a Ca^{2+}-permeable cation channel that is expressed in multiple subcellular compartments, including the plasma membrane, endocytosis and autophagy pathways. We have previously shown that upon induction of autophagy, TRPML3 traffics to the phagophore by palmitoylation and Ca^{2+} release via TRPML3 is crucial for autophagosome formation. However, it is still not clear from which compartment TRPML3 originates to function in autophagy. To search interacting partners with TRPML3 in autophagy, we performed split-ubiquitin membrane yeast two-hybrid screening and identified VTI1B, a SNARE protien that is required for ATG16L1 precursor homotypic fusion. Since ATG16L1 vesicles are formed by endocytosis and associated into the phagophore, we hypothesized that TRPML3 may move along the same path with ATG16L1 by interaction with VTI1B. Indeed, TRPML3 was also internalized upon autophagy stimulation by mTOR inhibition, while accumulated at the plasma membrane by mTOR activation. Inhibition of TRPML3-VTI1B interaction altered TRPML3 internalization, leading to increased surface expression. Interestingly, the retention of TRPML3 at the plasma membrane caused by any reason was accompanied by suppressed autophagy, suggesting that like in ATG16L1, proper endocytosis of TRPML3 is necessary for autophagy. We found that TRPML3 not only localized in ATG16L1-positive vesicles but also interacted with ATG16L1. Moreover, the interaction between TRPML3 and ATG16L1 was increased by autophagy stimulation but decreased by autophagy suppression. Collectively, our data

suggest that the Ca^{2+} channel TRPML3 is recruited from the plasma membrane to the early autophagic structures by interaction with VTI1B and ATG16L1 to regulate autophagy.

P1434/B566

Orp3 Phosphorylation Regulates Phosphatidylinositol 4-phosphate and Ca^{2+}Dynamics at Plasma Membrane - Endoplasmic Reticulum Contact Sites.

G. Gulyas[1], M. Sohn[1], Y. Kim[1], P. Varnai[2], T. Balla[1]; [1]NIH/NICHD, Bethesda, MD, [2]Department of Physiology, Faculty of Medicine, Semmelweis University, Budapest, HUNGARY.

Oxysterol-binding protein (OSBP)-related proteins (ORPs) mediate non-vesicular lipid-transfer between intracellular membranes. Previous studies revealed the role of phosphoinositide (PPIn) gradients in the ability of OSBP and some ORPs to transfer cholesterol and phosphatidylserine (PS) between the ER and other organelle membranes. Our recent work focused on a less characterized ORP family member, ORP3, as a potential regulator of lipid homeostasis at contact sites between the plasma membrane (PM) and the ER. ORP3 associates with the ER via interaction with vesicle-associated membrane protein-associated proteins (VAPs) and binds to the PM only after activation of protein kinase C (PKC). However, it remains unclear what lipids are specifically transported by ORP3 and what determines its PM localization. Previous studies have suggested that 3-phosphorylated PPIns are recognized by the isolated pleckstrin homology domain of ORP3. Here we usedGFP-tagged forms of ORP3 to investigate in living cells whether PM PPIns contribute to the interaction of ORP3 with the PM. A chemically-inducible heterodimerization approach was used to selectively reduce PM PPIns levels by recruiting PPIn phosphatases directed against either the 4- or 5-phosphate of phosphatidylinositol 4-phosphate (PI4P) and/or phosphatidylinositol 4,5-bisphosphate ($PI(4,5)P_2$) to the PM. PM attachment of ORP3 was monitored with TIRF microscopy, while changes in PPIn lipids were measured by BRET-based biosensors in living cells. Our results showed that ORP3 PM association was mainly determined by $PI(4,5)P_2$and to a lesser degree, by PI4P levels of the PM. Furthermore, full activation of ORP3 achieved by a combination of PMA and thapsigargin treatment, robustly decreased PM PI4P levels. Acute artificial establishment of PM association of ORP3 using the chemically-inducible heterodimerization approachled to a small reduction in PM phosphatidic acid (PA) levels and a slightly increase in PM cholesterol level in addition to the massive depletion of PM PI4P. Lastly, ORP3 activation inhibited Ca^{2+}entry via the store-operated Ca^{2+}entry pathway by a mechanism that required the C-terminal segment of the ORP3 protein.

P1435/B567

Store-operated Ca^{2+} Channels Are Involved in Erythropoiesis.

Y. Lee[1], j. Lee[2], K. Kim[1], A. Lee[1], Y. Kweon[1], C. Park[1]; [1]UNIST, Ulsan, KOREA, REPUBLIC OF, [2]KRIBB, Cheongju, KOREA, REPUBLIC OF.

Erythropoiesis is the process which produces red blood cells from erythropoietic stem cells. Ca^{2+} is a fundamental second messenger which regulates dynamic cellular processes, such as, cell differentiation, proliferation, cytoskeletal rearrangement, and cell cycle. Ca^{2+} signaling is also known to involve in erythropoiesis. However, underlying mechanisms and specific function of Ca^{2+} channels in erythropoiesis remain elusive. Here, we identified the effects of Store-Operated Ca^{2+} channels (SOCs) inhibitors in erythroid lineage determination and proliferation of CD34+ hematopoietic stem cells (HSCs) with colony-forming unit (CFU) assay. SOCs inhibitors reduced the proportion of erythroid lineage and proliferation rate. Next, we demonstrated that the mRNA expression level of SOCs modulators, STIM1

and STIM2, increased during erythropoiesis. Besides, we observed two different patterns of cytosolic Ca^{2+} fluctuation in the maturation stage of RBC formation by doing Fluo-4 Ca^{2+} imaging. In conclusion, this study suggests a novel role of SOCs during erythropoiesis, red blood cell formation.

P1436/B568

The Intramolcular Interaction of IDstim within STIM1 Prevents a Spontaneous Ca^{2+} Entry.

S. Lee[1], M. Lee[2], S. Jeong[1], X. Qin[2], A. Lee[1], H. Park[2], C. Park[1]; [1]Ulsan National Institute of Science and Technology, Ulsan, KOREA, REPUBLIC OF, [2]The Hong Kong University of Science and Technology, Kowloon, HONG KONG.

SOCE (store-operated calcium entry) is a major calcium ion influx pathway and abnormal SOCE activation causes severe diseases such as Stormorken syndrome, York platelet syndrome, and tubular aggregate myopathy. To control SOCE, STIM1 undergoes a conformational change in its cytosolic domains. STIM1 was known to maintain an inactive state through hydrophobic interaction between CC1 (coiled-coil domain 1) and CAD (CRAC activating domain). However, the CC1-CAD fragment showed constitutive activation despite maintaining the hydrophobic interaction. This conflicting observation implies that an additional mechanism is required to maintain the inactive state of STIM1. Here, we show that IDstim (inactivation domain of STIM1) binds to and inhibits CC1-CAD and this inhibitory effect of IDstim is abolished by either CC1α1 deletion or leucine substitution. The conserved short linker between CC1-CAD and IDstim facilitates the IDstim-mediated STIM1 inhibition. Our findings expand our understanding how the unintended activation of SOCE is prevented under resting conditions.

P1437/B569

***Disease-associated Mutations in Niemann-Pick Type C1 Alter ER*Ca^{2+}*and IP_3R Mediated Signaling Pathways*.**

S. A. Tiscione, E. J. Dickson; University of California Davis, Davis, CA.

NPC1 is a transmembrane lysosomal protein involved in transporting free cholesterol from lysosomes to other cellular membranes, including the endoplasmic reticulum (ER). This transfer of cholesterol to the ER regulates the activity of the sterol-response element binding protein (SREBP), a transcription factor governing the genes involved in cholesterol homeostasis. The importance of cholesterol regulation by NPC1 and SREBP is underscored by the fatal neurodegenerative disease: Niemann Pick Type C1 (NPC1 disease), where loss of function mutations in NPC1 lead to significant accumulation of free cholesterol within lysosomes and activation of the SREBP pathway due to the loss of cholesterol transfer to the ER. We have determined that in NPC1 disease, ER Ca^{2+} signaling pathways are significantly impaired with patient cells having reduced luminal ER Ca^{2+}, potentiated IP_3R Ca^{2+} release, and enhanced store-operated calcium entry (SOCE) compared to healthy controls. A combination of super-resolution imaging, qPCR, western blot, and pharmacology, reveals that SREBP is upstream of many expressional changes of Ca^{2+} handling proteins in NPC1 disease, including an increase in expression of presenilin 1 (PS1); a purported Ca^{2+} leak channel at the ER. Using a genetically encoded Ca^{2+} sensor targeted to the ER lumen we have measured a significant increase in ER Ca^{2+} leak in NPC1 disease. Treating NPC1 disease fibroblasts with siRNA targeting PS1 rescues this ER Ca^{2+} phenotype. Moreover, an inhibitor of NPC1 (U18666A), which recapitulates the Ca^{2+} phenotypes of NPC1 disease in multiple cell types, elicits no Ca^{2+} change in $PS1^{-/-}$ cells. Treatment of NPC1 disease fibroblasts with SREBP inhibitor, PF-429242, rescues PS1 expression as well as ER Ca^{2+} and SOCE, suggesting a close relationship between SREBP and

PS1. Given PS1 has been proposed to interact with IP_3R to regulate IP_3R-Ca^{2+} signaling in neurons, we investigated if GqPCR Ca^{2+} signaling is altered in NPC1 disease. Western blot analysis, super-resolution microscopy and Ca^{2+} imaging revealed a 3-fold increase in IP_3R protein with increases in puncta size, density, and IP_3R mediated Ca^{2+} release. Overexpression of the PS1 catalytically-dead holoprotein (PS1-D257A) results in larger clustering of IP_3R and enhanced Ca^{2+} release following activation of Gq-coupled receptors. Conversely, overexpression of the wild-type form of PS1 does not alter IP_3R-mediated Ca^{2+} release, suggesting the holoprotein form of PS1 specifically mediates these cellular changes. Together, these data suggest that the holoprotein form of PS1 at the ER is able to decrease ER Ca^{2+} levels leading to constitutive SOCE, and promote clustering of IP_3R to augment Gq-coupled receptor activation.

The Role of Voltage-gated Ion Channels in Phagocytosis of Photoreceptor Outer Segments.

S. Nymark[1], J. K. Johansson[1], I. Korkka[1], V. I. Karema-Jokinen[1], S. Hakanen[2], A. Jylha[1], H. Uusitalo[1], M. Vihinen-Ranta[2], H. Skottman[1], T. O. Ihalainen[1]; [1]Tampere University, Tampere, FINLAND, [2]University of Jyvaskyla, Jyvaskyla, FINLAND.

Background: Retinal pigment epithelium (RPE), important retina maintenance tissue in the back of the the eye, has a critical role in photoreceptor renewal where phagocytosis of photoreceptor outer segments (POSs) occurs in a diurnally synchronized process. This process is precisely regulated, however, the regulation is not yet completely understood. Earlier work on macrophages have raised the question about the involvement of ion channels in phagocytosis. Interestingly, changes in intracellular Ca^{2+} concentration have been indicated to affect the phagocytic activity of RPE. In addition, recent work suggests the contribution of Ca^{2+}-dependent ion channels to POS phagocytosis. Despite the existing knowledge, we have only a limited understanding on the influence of ion channels on phagocytosis. Our aim was to investigate the role of voltage-gated Ca^{2+} (Ca_v) and Na^+ (Na_v) channels that we have recently identified in RPE, to POS phagocytosis. Methods: the work was performed on human embryonic stem cell-derived RPE (hESC-RPE) and mouse RPE. Ion channel expression was studied by mass spectrometry analysis and functionality by whole-cell patch clamp recordings. Ion channel localization was determined by immunostainings and immunogold electron microscopy (EM). Phagocytosis was assayed by feeding porcine POS to RPE and incubating the samples either at room temperature (binding phase) or at 37°C (processing phase) with or without the pharmacological ion channel modulators. Results: Our patch clamp recordings showed the presence of functional L- and T-type Ca_v channels together with several Na_v channel subtypes in RPE. These channels participated in POS phagocytosis: pharmacological modulation of their activity affected phagocytosis by increasing or decreasing the amount of bound and ingested POS particles, depending on the modulator. Specifically, inhibition of Na_v channels by pharmacology or shRNA silencing affected phagocytosis by decreasing the amount of ingested POS particles while not affecting their binding. Immunolabeling results showed that in both hESC-derived and mouse RPE, these channels concentrated on the phagosomes, and immuno-EM confirmed this finding. Conclusions: Our results indicate that Na_v and Ca_v channels are an integral part of RPE physiology, and that they contribute to POS phagocytosis. The role of Na_v channels is to co-regulate the processing phase of bound photoreceptor outer segments. Further studies are needed in order to fully evaluate the concerted functioning of these ion channels in phagocytosis. Towards Structure of the Human Spt-ORMDL Sphingolipid Regulatory Complex.

M. Kannan; Virginia Commonwealth University, Richmond, VA.

Towards structure of the human SPT-ORMDL sphingolipid regulatory complex. Muthukumar Kannan[1], Weihua Qiu[2], Youzhong Guo[2 and] Binks Wattenberg[1] [1]Department of Biochemistry and Molecular Biology, Virginia Commonwealth University, Richmond, VA 23298. [2]Department of Medicinal Chemistry, Virginia Commonwealth University, Richmond, VA. **Abstract** Sphingolipids are a group of lipids which are found in abundance in all eukaryotic cell membranes as well as acting as critical signaling molecules. The cellular level of sphingolipid is maintained by the first and rate–limiting enzyme in the *de novo* synthesis pathway, serine palmitoyltranferase (SPT). SPT is a multi-subunit enzyme localized to endoplasmic reticulum (ER) in yeast and mammals. The activity of SPT is homeostatically regulated by another ER resident protein, ORMDL, which is crucial for regulating the *de novo* biosynthesis of ceramide. SPT forms a stable complex with ORMDL to precisely maintain the cellular ceramide level. Increased levels of cellular ceramide inhibits SPT activity in an ORMDL-dependent manner. The mechanism behind the regulation of SPT activity by ORMDLs is largely unknown. To address these critical gaps in our knowledge, currently we are studying the structure of SPT-ORMDL complex. We expressed the human SPT and ORMDL in yeast cells. We believe this will be the excellent tool to understand the structural basis of ORMDL dependent SPT regulation. Our initial experiments suggest that both human SPT and ORMDL are expressed in functionally active form in yeast and in yeast, human ORMDL regulates SPT activity in response to elevated levels of sphingolipids.

P1440/B572

Sphingolipid Biosynthesis during Myelination in the Developing Rat Brain.

U. Mahawar; Virginia Commonwealth University, Richmond, VA.

Myelin is a specialized extension of plasma membrane produced by oligodendrocytes in the central nervous system (CNS). It consists of specific lipids and proteins produced in a coordinated process. As compared to other biological membranes, lipid content is very high. Sphingolipids comprise a major portion of myelin lipids. Previous studies have shown that sulfatides, cerebrosides and sphingomyelin are the major constituents of myelin sphingolipids and the timing of their production has also been reported to some extent. Understanding how individual lipid and protein components are regulated to produce optimal lipid composition is essential for understanding the basics of production of this highly specialized membrane and how dysregulation of its production contributes to devastating demyelinating diseases. To address above question, we utilized the well characterized myelination program in neo-natal rats. Rat pups were sacrificed from postnatal day 2 to 30. In addition, we isolated oligodendrocytes, the CNS cell type that produces myelin. Comprehensive sphingolipid profiling was performed in total brain and oligodendrocytes. Using mass spectrometry, we measured the levels of d18:sulfatides (3-O-sulfogalactosylceramide, a sulfated sphingolipid) and found that sulfatide starts rising from day 5 to day 25 where it plateaus. Similarly, levels of d18:monohexosalceramides (cerebrosides) rises at day 9 and plateau at day 25. The d:18ceramide and sphingomyelin levels were

found to be constant throughout the myelination. Next we measured d18:sphingosine and d18:dihydrosphingosine, upstream metabolites in sphingolipid pathway. We found that sphingosine levels rise gradually during myelination process but dihydrosphingosine levels rise more dramatically late in process. We also found that the molecular species of sphingolipids, i.e. The length of the fatty acyl component of sphingolipid, undergo dramatic changes during onset of myelination. Moreover, there were marked increase in the levels of non-canonical sphingolipid backbones, particularly the d:20 species. To gain an understanding of the molecular basis of these changes we measured the protein, mRNA and activity of the rate limiting enzyme complex in sphingolipid biosynthesis, serine palmitoyltranferase (SPT). We found dramatic changes in the composition of the SPT complex, including changes in levels of the regulator of SPT, the ORMDLs. These studies will form the basis for understanding the coordination of the lipid and protein components of myelin and how these might be manipulated for the treatment of demyelinating diseases.

Mammalian Ormdl Proteins Respond Stereospecifically to Ceramide Species to Regulate *De Novo* Sphingolipid Biosynthesis.

J. Suemitsu, D. Davis, B. Wattenberg; Virginia Commonwealth University, Richmond, VA.

Sphingolipids are a diverse class of lipids built on a sphingosine backbone which have important functions in cell signaling and membrane structure. Serine palmitoyl transferase (SPT) serves as the initiating and rate-limiting enzyme of the *de novo* biosynthesis of sphingolipids. SPT is homeostatically regulated by a mechanism which requires the ORMDL proteins in mammalian cells and ORM proteins in yeast. ORMDLs and ORMs, which are membrane-bound proteins in the endoplasmic reticulum, function to reduce SPT activity in response to elevated cellular sphingolipid levels. Previous studies have shown that ORMDLs mainly sense ceramide. However, for technical reasons, the ceramides used in those studies had chain lengths that were much shorter than natural ceramides. Here we attempt to recapitulate the inhibition of ORMDL-dependent inhibition of SPT by endogenous ceramides using ceramide synthase (CerS) to generate ceramides with natural chain lengths. CerS uses Acyl-Coenzyme as (Acyl-CoA) and either sphingosine or dihydrosphingosine to generate ceramide or dihydroceramide, respectively. To recapitulate the sphingolipid-dependent regulation of SPT by ORMDLs, we recently developed a cell-free system in which membranes were isolated and used to test SPT activity. To generate ceramides with native chain lengths within those membranes using the activity of the endogenous CerS, we pre-incubated membranes with the 24:1 CoA and sphingosine or dihydrosphingosine either separately or together. We demonstrate that SPT activity is inhibited in an ORMDL-dependent process only under conditions in which ceramide is generated. Moreover, we find that both ceramide and its immediate precursor, dihydroceramide, are sensed by this system. Using the CerS inhibitor, Fumonisin B1, we have established that the ORMDLs do not respond to sphingosine or dihydrosphingosine. Furthermore, we tested the four stereoisomers of ceramide and find that only the native stereoisomer of ceramide is able to trigger SPT inhibition. This strongly suggests that the ORMDL/SPT complex senses ceramide levels by a direct binding interaction. These results establish ORMDL as a negative regulator of SPT that directly senses cellular ceramide levels.

Seipin Negatively Regulates Sphingolipid Production at the Er-ld Contact Site.

C. Wang, W. Su, Y. Lin; IPMB, Academia Sinica, Taipei, TAIWAN.

Seipin is an evolutionarily conserved protein regulating both adipocyte development and lipid droplet (LD) biogenesis. With its evidently crucial roles in controlling LD assembly at the contact site between endoplasmic reticulum (ER) and LDs, the molecular function of seipin has long been a focus in the field, yet remains largely controversial. Here, we identified a new function of seipin as a negative regulator for sphingolipid production. We provide evidence that seipin negatively regulates sphingolipid production by binding with two key enzymes, namely serine palmitoyltransferase and fatty acid elongase, thereby regulating the production of two major building blocks for sphingolipids, termed long chain base and very long chain fatty acid, respectively. We then uncovered that the regulations are organized at discrete regions of the ER in close vicinity to LDs, which led to the hypothesis that the ER and LD contact site is one place in the ER where cells synthesize sphingolipids. To decipher the potential interconnection of sphingolipid synthesis and LD formation at the same subdomain, we provide further evidence that LDs can form efficiently when sphingolipid synthesis is blocked, whereas excess sphingoid intermediates may affect LD morphology. Expression of human seipin rescued the altered sphingolipids in yeast seipin mutants, suggesting that the negative regulation of sphingolipid synthesis by seipin is likely an evolutionarily conserved process.

P1443/B575

Defining the Subcellular Distribution and Metabolic Channeling of Phosphatidylinositol.

J. G. Pemberton[1], Y. Kim[1], N. Sengupta[1], A. Eisenreichova[2], D. J. Toth[1], E. Boura[2], T. Balla[1]; [1]National Institute of Child Health and Human Development, NIH, Bethesda, MD, [2]Czech Academy of Sciences, Prague, CZECH REPUBLIC.

Among the structural phospholipids that form the bulk of eukaryotic cell membranes, phosphatidylinositol (PtdIns) is unique in that it also serves as the common precursor for low-abundance phosphorylated derivatives, called polyphosphoinositides (PPIn), which are central regulators of cellular physiology. In particular, the complex metabolic turnover of PPIn species has essential functions related to both intracellular signal transduction and membrane trafficking, however, there is still a limited understanding of how PtdIns synthesis and transport contributes to the turnover of the unique subcellular pools of PPIn lipids. To address these shortcomings, we established a molecular toolbox for investigations of PtdIns distribution and availability within intact cells that capitalizes on the substrate selectivity and high specific activity of the bacterial PtdIns-specific phospholipase C (bacPI-PLC) enzyme. Results using catalytically inactive mutants of the bacPI-PLC, which were designed to trap the bound PtdIns substrate, suggest that PtdIns is localized to the endoplasmic reticulum (ER), the biochemically-defined site of PtdIns synthesis, but is also enriched in the cytosolic leaflets of the Golgi complex, peroxisomes, and mitochondria. Strikingly, we did not observe significant localization of the bacPI-PLC variants within the plasma membrane (PM) or to endosomal compartments in any of the mammalian cell types examined. The membrane distribution of PtdIns was further investigated using recruitable versions of a modified bacPI-PLC scaffold to map PtdIns contents by monitoring the local production of diacyglycerol (DAG), the direct cleavage product of bacPI-PLC-mediated PtdIns hydrolysis. A chemically-inducible protein heterodimerization system was used to target the bacPI-PLC to specific organelle membranes and revealed the rapid production of DAG within the cytosolic leaflets of the ER,

mitochondria, peroxisomes, and Golgi complex. However, only minor increases in DAG production were observed following the targeted recruitment of the bacPI-PLC to the PM or to Rab5- and Rab7-positive endosomes. The recruitable bacPI-PLC construct was then used for kinetic studies on PPIn turnover that demonstrate the requirement for sustained PtdIns supply from the ER, rather than the absolute steady-state content of PtdIns, for the maintenance of monophosphorylated PPIn species within the PM, Golgi complex, and endosomal compartments. Overall, our findings provide a comprehensive map of the subcellular distribution of PtdIns within the membrane compartments of intact cells as well as support an important role for PtdIns transfer and substrate channeling in the spatial control of PPIn metabolism.

P1444/B576

A High-avidity Biosensor Reveals Plasma Membrane PI(3,4)P_2 is Predominantly a Class I PI3K Signaling Product.

B. D. Goulden[1,2], J. Pacheco[2], A. Dull[2], J. P. Zewe[2], A. Deiters[2], G. R. V. Hammond[2]; [1]Johns Hopkins University School of Medicine, Baltimore, MD, [2]University of Pittsburgh, Pittsburgh, PA.

Class I phosphoinositide 3-OH kinase (PI3K) signaling is central to animal growth and metabolism, and pathological disruption of this pathway affects cancer and diabetes. However, the specific spatial/temporal dynamics and signaling roles of its minor lipid messenger, phosphatidylinositol (3,4)-bisphosphate (PI(3,4)P2), are not well understood. This owes principally to a lack of tools to study this scarce lipid. Here we developed a high-sensitivity genetically encoded biosensor for PI(3,4)P2, demonstrating high selectivity and specificity of the sensor for the lipid. We show that despite clear evidence for class II PI3K in PI(3,4)P2-driven function, the overwhelming majority of the lipid accumulates through degradation of class I PI3K-produced PIP3. However, we show that PI(3,4)P2 is also subject to hydrolysis by the tumor suppressor lipid phosphatase PTEN. Collectively, our results show that PI(3,4)P2 is potentially an important driver of class I PI3K-driven signaling and provides powerful new tools to begin to resolve the biological functions of this lipid downstream of class I and II PI3K.

P1445/B577

Control of Circadian Rhythm Via Surface Density of Muscarinic Acetylcholine Receptors and Cytoplasmic Lipid Kinase Activities in Sympathetic Neurons.

M. Kruse, R. J. Whitten; Bates College, Lewiston, ME.

Superior cervical ganglion (SCG) neurons play an important role for controlling the circadian rhythm through innervation of the pineal gland. To further our understanding of this pathway, we analyzed action potential firing and its dependence on the phospholipid phosphatidylinositol 4,5-bisphosphate ($PI(4,5)P_2$) in SCG neurons from adult male rats through electrophysiological, biochemical, and mathematical approaches. Previously, we found action potential firing to be controlled by KCNQ2/3 and Maxi-K potassium channels, and a decrease in their activities by 80% was necessary to evoke action potential firing. Physiologically, action potential firing in SCG neurons is induced by hydrolysis of $PI(4,5)P_2$. While KCNQ2/3 channel activity has been shown to be strongly dependent on $PI(4,5)P_2$, a regulation of Maxi-K channel activity by phosphoinositides is under debate and has been speculated to be dependent on the subunit composition of Maxi-K channels. To analyze Maxi-K subunit expression in SCGs, we isolated total RNA from SCGs and performed RT-PCR with oligonucleotides for α- and β-subunits of Maxi-K channels. Our results showed expression of only the Maxi-K α-subunit. Expression of Maxi-K α-subunits in HEK293 cells showed no decrease in Maxi-K channel activity upon depletion of

$PI(4,5)P_2$ by either activation of muscarinic acetylcholine receptors or a voltage-sensitive lipid phosphatase, thereby identifying KCNQ2/3 channels as the sole $PI(4,5)P_2$-dependent potassium channels in SCG neurons. We incorporated our electrophysiological and biochemical results into a model of phosphoinositide metabolism of SCG neurons to develop a mathematical description of phosphoinositide metabolism and $PI(4,5)P_2$-dependent ion channel activity in SCG neurons. The model allowed for reproduction of experimentally determined characteristics of action potential firing with respect to phosphoinositide-dependent ion channel activities in SCG neurons, and highlighted critical roles for the control of cellular excitability by the density of muscarinic acetylcholine receptors and levels of $PI(4,5)P_2$ through cytoplasmic concentrations of lipid kinases. In conclusion, the newly developed model allows for the first time a simulation of phosphoinositide metabolism and its regulation of action potential firing of SCG neurons through modulation of muscarinic acetylcholine receptor activity, thereby providing an opportunity to analyze modulation of circadian activity in *silico*.

Comparison of Various Energy Transfer-based Biosensors to Monitor Phosphatidylinositol-4,5-bisphosphate Levels in the Plasma Membrane of Mammalian Cells.

P. Varnai[1,2], C. M. Moller[1], T. Balla[3], L. Hunyady[1,2], D. J. Toth[1]; [1]Department of Physiology, Faculty of Medicine, Semmelweis University, Budapest, HUNGARY, [2]MTA-SE Laboratory of Molecular Physiology, Hungarian Academy of Sciences and Semmelweis University, Budapest, HUNGARY, [3]Section on Molecular Signal Transduction, Program for Developmental Neuroscience, National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD.

Phosphatidylinositol-4,5-bisphosphate (PIP2) is found in the plasma membrane (PM) and plays an important role in the molecular signal transduction pathway initiated by Gq protein-coupled receptors, such as the type-1 angiotensin receptor (AT1R). Our research uses a rapamycin-induced translocation of an FKBP-fused 5-phosphatase (FKBP-5ptase) or stimulation of AT1R to modify and measure PM PIP2 levels using various phosphatidylinositol biosensors. Bioluminescence resonance energy transfer (BRET)-based biosensors were created and applied to determine which of them is most sensitive to PM PIP2 level changes. A modified type-1 angiotensin receptor (AT1R-Δ319), FKBP-5ptase and various phosphoinositide biosensors were transiently expressed in HEK 293 cells. BRET measurements were carried out 27-28 hours later. PIP2 depletion was achieved upon stimulation with angiotensin II or rapamycin-evoked translocation of the FKBP-5ptase to the PM. The biosensors were created from known lipid binding domains, such as the PH domains of PLCδ1 and PLCδ4 and the C-terminal part of Tubby (Tubby-C). In addition to the original PIP2 sensor (PLCδ1-PH), our study used the following sensors: PLCδ4-PH, Tubby-C, Tubby-C with a K330A mutation, and their tandem versions (PLCδ4-2xPH, Tubby-2xC, Tubby-2xC KA). Our results show that PM recruitment of FKBP-5ptase induced an acute depletion of PM PIP2. Sensors with PLCδ1-PH, PLCδ4-PH and Tubby-C domain were all able to follow the decrease of PM PIP2 level, but the tandem of PLCδ4-PH produced a significantly greater signal drop. Surprisingly, the tandem of Tubby domain revealed less response than Tubby-C. Mutated versions of the Tubby domain showed almost no change. Similar results were achieved after stimulation by angiotensin II with the exception of PLCδ4-PH which reflected an increase of the recruitment of the sensor upon hormonal stimulation. Overexpression of FKBP-5ptase showed a significant depletion of PM PIP2 levels

and PLCδ4-2xPH was found to be the most sensitive of the biosensors. Improvement of phosphoinositide biosensors is of great importance for future studies so that they can give information that is more accurate on phosphoinositide levels and lead to a better understanding of their dynamics.

Stim1 Associates with Vap B and Regulates Calcium Dynamics.

D. Holowka[1], B. Baird[1], C. Stefan[2]; [1]Cornell University, Ithaca, NY, [2]University Corllege London, London, UNITED KINGDOM.

The store-operated Ca^{2+}-entry (SOCE) pathway is integral to the physiology and function of numerous cell types including neurons and immune cells. In many immune cells, the Ca^{2+}sensor protein STIM1 is localized throughout the endoplasmic reticulum (ER) upon basal resting conditions. Depletion of Ca^{2+}ER stores by FcεRI signaling or the SERCA inhibitor thapsigargin induces STIM1 translocation to the cortical ER where it couples to and activates the Ca^{2+}channel protein Orai1 at the plasma membrane (PM). We find that the ER-localized VAP-B protein associates with the STIM1 protein during SOCE in RBL mast cells, as monitored by fluorescence resonance energy transfer (FRET). A dominant negative form of VAP-B (P56S) implicated in amyotrophic lateral sclerosis (ALS) is impaired in this interaction. Moreover, association of STIM1 with Orai1 is reduced by expression of the P56S mutant protein, in parallel with the partial inhibition of SOCE. Likewise, antigen-induced Ca^{2+}uptake into mitochondria is impaired in cells expressing the mutant VAP-B (P56S) protein. Consistent with these results, siRNA knockdown of the VAP-A and VAP-B isoforms results in impaired SOCE as well as mitochondrial Ca^{2+}uptake stimulated by antigen or thapsigargin. Altogether, our results indicate that the ER-localized VAP-B protein is involved in SOCE and inter-organelle Ca^{2+}handling.

Endoplasmic Reticulum Stress Sensor Ire1 Deploys a Divergent Transcriptional Programme in Response to Lipid Bilayer Stress.

G. Thibault, 637551[1], N. Ho[1], H. Wu[1], J. Xu[2], J. Koh[1], C. Chen[1], W. Yap[1], S. Taubert[2]; [1]Nanyang Technological University, Singapore, SINGAPORE, [2]The University of British Columbia, Vancouver, BC, CANADA.

The unfolded protein response (UPR), a complex adaptive stress response of the endoplasmic reticulum (ER), is compromised in disease and aging. Typically activated by the accumulation of misfolded proteins within the ER lumen, the UPR is similarly activated by alterations of fatty acids and lipid composition at the ER. Chronic UPR activation by ER lipid aberrations, which we termed lipid bilayer stress-induced UPR (UPR^{LBS}) is associated to the development of the metabolic syndromes. However, most studies to dissect the UPR^{LBS} mechanisms employ exogenous lipids or omit precursors of lipid biosynthesis. To systematically understand pathways that contribute to UPR activation, we performed a genome-wide genetic screen in *S. cerevisiae* and an RNAi screen in *C. elegans* to identify mutations that activate the UPR though LBS. Several unexpected cellular perturbations were identified to induce the UPR through LBS. As one of the strongest hits inducing the UPR, we further characterise the activation mechanism of Ire1 in Δ*opi3* where lack of phosphatidylcholine (PC) synthesis induces LBS. We found that the luminal domain (LD) of Ire1, which senses misfolded peptides, is dispensable to activate the UPR by LBS while LD overexpression was sufficient to uncoupled LBS-induced to proteotoxic-induced UPR. Conversely, we mutated Ire1 residue R537 located at the interface of the amphipathic and transmembrane helices

rendering it insensitive to LBS while retaining the capacity to activate the UPR by proteotoxic stress. Furthermore, transcriptomic and ChIP-qPCR data revealed that the UPR programme diverges if activated by LBS or proteotoxic stress. Together, our data point to the UPR as a broad-spectrum compensatory pathway in which LBS and proteotoxic stress-induced UPR deploy divergent transcriptional programmes.

Differences in Membrane Mobility between Salivary Gland Cells in Live Mice and Ex Vivo Cultured Tissue.

D. Chen[1], A. Masedunskas[2], N. Porat-Shliom[1], A. Shitara[3], R. Weigert[1]; [1]Laboratory of Cellular and Molecular Biology, National Cancer Institute, Bethesda, MD, [2]School of Medical Sciences, University of New South Wales, Sydney, AUSTRALIA, [3]Department of Pharmacology, Asahi University, Gifu-shi, JAPAN.

Membrane mobility depends on the lateral diffusion of molecules within the lipid bilayer, which reflects their non-covalent interactions between lipids, cholesterols, membrane proteins and macromolecular complexes interacting with the membranes intra- and extra-cellularly (i.e., extracellular matrix, cytoskeleton). Membrane mobility has been primarily assayed in cells cultured in *vitro*. However, these model systems do not always recapitulate the complex organization of membranes in *vivo*. Here we investigate how differences in membrane mobility between membranes in live animals and *ex vivo* model systems affect membrane remodeling dynamics, in particular during endocytosis and exocytosis. To measure membrane mobility in secretory epithelial cells in the salivary glands of live mice, we used fluorescence recovery after photobleaching (FRAP) in genetically engineered mice ubiquitously expressing a membrane-targeted peptide fused wit the fluorescent protein td-Tomato (mTomato). In parallel, FRAP was also performed in mouse salivary glands were explanted, dissected into lobules, and then cultured. We found that membrane mobility of cells in *vivo* was significantly lower than ex vivo cells. Notably, the uptake of selected molecules by salivary secretory epithelial cells in *vivo* was significantly slower than in *in vitro*. In addition, the number of endocytic vesicles in cells in *vivo* was significantly diminished in comparison to the in *vitro* model. We concluded that differences in the membrane mobilities in secretory epithelial cells in mice salivary glands in *vivo* and in *vitro* could potentially regulate the rate of endocytosis.

***In-vitro* FRET an alysis of Growth Arrest-Specific Protein 7 (GAS7).**

W. N. I. Wan Mohamad Noor, T. Nishimura, S. Suetsugu; Nara Sentan Kagakugijutsu-200572014S, Nara, JAPAN.

Many cellular processes that are correlated with membrane remodeling involve the actions of the Bin-Amphiphysin-Rvs167 (BAR) domain proteins. Growth Arrest-Specific protein 7 (GAS7) is one of the FCH (F)-BAR subfamilies. We have recently revealed that GAS7 binds to the lipid membrane and also takes a sheet-like assembly in the crystals, on the reconstituted membrane, and in mammalian cells. GAS7b also is thought to play a role in the formation of phagocytic cup. However, the kinetics of GAS7b oligomerization that assembles into the tightly packed sheet on the lipid membrane had not been revealed. To study the GAS7b assembly into the sheet on membranes, we examined the Fluorescence Resonance Energy Transfer (FRET) that occurred by the interaction between the fluorescent proteins at their vicinities. We tagged cyan fluorescent protein (CFP) or yellow fluorescent protein (YFP) to GAS7b or to GAS7b mutant, which has a mutation that affects the stabilization of GAS7 F-BAR domain, and

observed their interaction on liposome membrane by FRET. Interestingly, we observed the FRET between CFP-GAS7b and YFP-GAS7b only in the presence of liposomes. We also succeeded to observe the time-dependent increase in the FRET of GAS7b, which indicated the rapid oligomerization of GAS7. In contrast, the mutant had significantly lower FRET compared with that of GAS7b. Remarkably, the mutant had different or defective oligomer formation in crosslinking assay, indicating that the position of the mutation was essential for the oligomer assembly through the stabilization of F-BAR and interaction with another dimer of GAS7. Taken together, these results support that GAS7b can form oligomers on the membrane, which will help phagocytic cup assembly. Thus, what GAS7 can do in helping the phagocytosis system to act against the pathogen, as it has role in the phagocytotic cup formation, could be important for the future investigation.

Structural organization of caveolin-1 8S oligomers determined by cryo-electron microscopy.

B. Han[1], J. Porta[2], E. Binshtein[3], E. Karakas[3], M. Ohi[2], **A. Kenworthy**[1]; [1]University of Virginia School of Medicine, Charlottesville, VA, [2]University of Michigan Life Sciences Institute, an n Arbor, MI, [3]Vanderbilt University School of Medicine, Nashville, TN.

Cholesterol-rich membrane invaginations known as caveolae play a critical role in membrane buffering, mechanotransduction, and cellular signaling. The integral membrane protein caveolin-1 (Cav1) is essential for caveolae formation in eukaryotic cells and can even drive the formation of caveolae-like structures in bacteria. Cav1 contains an unusual hairpin shaped intramembrane domain predicted to bend caveolar membranes by a wedging mechanism and oligomerizes to form 8S complexes that function as the fundamental building blocks of caveolae. However, the molecular architecture of these complexes is currently unknown. To fill this gap in knowledge, we used negative staining and single particle cryo-electron microscopy to determine the structure of Cav1 8S oligomers. By negative staining we show that 8S complexes forms discs that are flat on one side, contain a central protrusion on the other, and vary in diameter. The diameters differ by a fixed amount, suggesting that they contain different numbers of Cav1 monomers. Using Venus as a fiduciary marker, we show the flat side of the disc corresponds to the membrane-facing side of the protein and the C-terminus of Cav1 is localized to the central protrusion. We also generated a ~10 Å resolution structure of the 8S Cav1 complexes using cryo-electron microscopy. At this resolution the discs are reminiscent of a wheel, consisting of an outer ring connected by spokes to an inner protruding ring. Interestingly, the intramembrane domains of Cav1 monomers are localized to the outermost portion of the wheel. Current work is focused on improving the resolution of 8S complex structure in order to build a more detailed molecular model of the complex and integrating a variety of biochemical, biophysical, and structural techniques to dissect how the 8S complexes form. Ultimately, these studies should provide a structural framework for understanding how caveolae assemble and control cellular functions.

P1452/B584

Importance of Lipid Phase State in a Selective Binding of *Bacillus Thuringiensis* Cyt2aa2 Toxin on Lipid Membranes.

S. Tharad[1], B. Promdonkoy[2], J. Toca-Herrera[1]; [1]Institute for Biophysics, University of Natural Resources and Life Sciences (BOKU), Vienna, AUSTRIA, [2]National Center for Genetic Engineering and Biotechnology, Pathumthani, THAILAND.

Bacillus thuringiensis (*Bt*) is a well-known bacterium because of its pesticidal property. Cytolytic toxin (Cyt) is one of *Bt* pesticidal proteins produced during its sporulation phase. Cyt2Aa2 toxin exerts its activity against insects and mammalian cells. The toxin directly binds to the lipid membrane and disturbs the membrane integrity. A biological lipid membrane comprises of many type of lipids which are able to form different lipid phase states. Recently, the combination of Atomic Force Microscope (AFM) and Quartz Crystal Microbalance with Dissipation (QCM-D) has been used to investigate the protein-lipid bilayer interaction. In this work, we have investigated the interaction of Cyt2Aa2 toxin with lipid bilayers that presented different lipid phases. Membrane lipids found in the cell membrane were selected to build the supported lipid membranes. The lipid bilayers were formed on silica surfaces by means of lipid vesicle fusion. QCM-D results revealed that Cyt2Aa2 toxin bound faster on L_o bilayers than L_d bilayers by increasing of cholesterol content in the POPC bilayer. However, the 1:1 DPPC/cholesterol ratio produced an exceptional L_o bilayer for Cyt2Aa2 toxin binding. In addition, Cyt2Aa2 toxin did not show any binding to gel phase (S_o) domains of either DPPC or sphingomyelin. Surprisingly, different molar ratios of DPPC/POPC mixture influenced the location for Cyt2Aa2 toxin binding. The L_d domains and L_d-S_o domain interface were the binding area of Cyt2Aa2 toxin on 1:1 and 4:1 DPPC/POPC bilayers, respectively. Furthermore, the specific binding of lipid phase and hemolytic activity relevance was demonstrated for the less active T144A mutant. Both QCM-D and AFM results confirmed the inability of POPC bilayer-T144A mutant binding. Addition of cholesterol and/or sphingomyelin to POPC bilayer (forming L_o bilayers) led to Cyt2Aa2 T144A-lipid binding, but the binding rate remained slower than the wild type. Finally, the Cyt2Aa2-lipid interaction was determined with an erythrocyte cell membrane. With sequential toxin exposure, the T144A mutant initially revealed the L_o domains and the L_d domains were detected later by Cyt2Aa2 wild type indicating to the L_d-L_o phase coexistence in the cell membrane. These findings suggest that L_d and L_o membranes are suitable for Cyt2Aa2 binding whereas S_o and DPPC membranes are unfavorable for the binding.

Super-resolution Microscopy of the an giotensin Receptor Clustering in the Plasma Membrane.

J. L. Kure[1], C. B. Andersen[1], C. Lagerholm[2], P. W. Wiseman[3], **E. C. Arnspang**[1]; [1]University of Southern Denmark, Odense, DENMARK, [2]University of Oxford, Oxford, UNITED KINGDOM, [3]McGill University, Montreal, QC, CANADA.

The cardiovascular physiology is highly affected by the an giotensin II Receptor type 1 (AT1R) membrane protein. The receptor directs the cardiac cells onto two pathways affecting either muscle contraction or proliferation of cells depending on the physiological context. The pathways can be distinguished by modified an giotensin II analogue which only activate a single pathway. We here show for the first time imaging data directly indicating that nanodomains affects the AT1R signal transduction. Therefore, knowledge of receptor dynamics in the plasma membrane and nanodomain formation in the different pathway could sheet light on the regulation mechanism. Photoactivated localization microscopy (PALM)

and pathway specific agonist allow us to identify the role of nanodomains in the regulation of the pathways. Preliminary data based on single particle tracking and k-space image correlation spectroscopy reveals differences in diffusion behavior depending on the stimulation, indicating pathway selection depends on AT1R nano-localization. Our results provide the first look at the broad, nanoscale organization and dynamics of AT1R, opening the door for a deeper understanding of AT1R regulation.

P1454/B586

Synthetic Membranes for the Reconstruction of Cellular Functions from the Bottom Up.

P. Torre, 94158[1], M. Good[2], V. Percec[3], Q. Xiao[3]; [1]University of California San Francisco, San Francisco, CA, [2]University of Pennsylvania, Cell and Deelopmental Biology Department and Bioengineering Department, Philadelphia, PA, [3]University of Pennsylvania, Department of Chemistry, Philadelphia, PA.

The reconstruction of the functions of living cells using non-natural components is one of the great challenges of natural sciences. Compartmentalization, encapsulation and surface decoration of globular assemblies, known as vesicles, represent key early steps in the reconstitution of synthetic cells. During my time at University of Pennsylvania I demonstrated that vesicles self-assembled from amphiphilic Janus dendrimers, called dendrimersomes, encapsulate high concentrations of hydrophobic components and do so more efficiently than commercially available stealth liposomes assembled from phospholipid components. These multi-layer onion-like dendrimersomes demonstrate a particularly high capacity for loading low molecular weight compounds and even folded proteins. Co-assembly of amphiphilic Janus dendrimers with metal-chelating ligands conjugated to amphiphilic Janus dendrimers generates dendrimersomes that selectively display folded proteins on their periphery in an oriented manner. A modular strategy for tethering nucleic acids to the surface of dendrimersomes is also demonstrated. These findings augment the functional capabilities of dendrimersomes to serve as versatile biological membrane mimics for the devise of synthetic cells and represent an useful strategy for the delivery of hydrophobic drugs.

P1455/B587

Effect of Hydrophobic Small Molecules on the Lipid Bilayer in the Presence of Cholesterol: What Can Differential Scanning Calorimetry Tell Us?

Z. Waizenegger, J. Lansberry, N. Thomas, J. M. Belanger; King's College, Wilkes-Barre, PA.

In cell biology, the thermal phase transitions of lipids within cell membranes can be characterized using differential scanning calorimetry (DSC). Understanding the thermotropic phase behavior when small hydrophobic molecules are incorporated into the hydrophobic region of membranes may have implications for in *vitro* studies where hydrophobic compounds are introduced into cells, and studies involving the incorporation of hydrophobic drugs in drug delivery systems. Phosphatidylcholine lipids when dispersed in an aqueous milieu form bilayer membrane structures known as liposomes that are used as simplified cell membrane mimics. When small molecules are added to these vesicles there is an effect on the thermal transitions of the lipids as has been classically noted for the addition of cholesterol. Previous research suggests that the hydrophobicity of small molecules added to a membrane have a profound effect on the thermal transitions implying that these molecules sit at different depths in the membrane bilayer. The resulting shifts in melting transition have been characterized as lower onset temperatures and lower enthalpies of melting. To our knowledge, studies have not been done to combine the effects of hydrophobic small molecules with cholesterol in the

membrane. In our research, DSC was used to characterize the phase transitions in dipalmitoylphosphatidylcholine (DPPC) liposomes in the presence of a hydrophobic small molecule, N-phenyl-1-naphthylamine (NPN). Three different preparations were added to DPPC liposomes: NPN only (added using dimethyl sulfoxide (DMSO)), cholesterol only, and both NPN and cholesterol. The presence of NPN alone lowers the temperature and enthalpy of melting resulting in a decrease of the onset and peak temperatures by 0.896°C and 0.417°C, respectively in comparison to the mock treated DPPC control. The enthalpy, however, changed less than 0.200 J/g between the NPN sample and the mock treated DPPC control. In the presence of cholesterol alone, the onset and peak temperatures decreased 1.08°C and 1.04°C in comparison to mock treated DPPC control. The enthalpy for cholesterol only also changed less than 0.200 J/g from the control. In the presence of both NPN and cholesterol, the onset and peak temperatures decreased 1.93°C and 1.54°C in comparison to mock treated DPPC control. The most significant of these findings is for the liposomes with both cholesterol and NPN incorporated, with a more than 0.800 J/g difference in enthalpy from the control. Interestingly, this phenomenon does not follow the trend from the small molecules incorporated individually. Research is ongoing to vary the amounts of the incorporated molecules to elucidate a trend in these values.

INPP5E Is Required for Recruitment of the TCR/CD3 Complex to the Immune Synapse Via the Ciliary Machinery.

T. Chiu, F. Yang, J. Liao; Institute of Atomic and Molecular Sciences, Academia Sinica, Taipei, TAIWAN.

The primary cilia function as a sensory organelle in many eukaryotic cells. Recently several proteins have been seen to co-exist in primary cilia and in immune synapses of T cells, although how a rod-shaped cilium is related to a plate-shaped immune synapse remains elusive. Here we show that T-lymphocytes, which lack primary cilia, express inositol polyphosphate-5-phosphatase E (INPP5E), a ciliary-specific protein responsible for regulating phosphoinositide localization. We find that INPP5E colocalizes with the microtubule organizing center (MTOC) and the distal appendages in Jurkat T-cells. In addition, INPP5E accumulates at the immune synapse during antigen-specific conjugation. Knockdown of INPP5E results in abolished T-cell receptor (TCR) /CD3 recruitment at the immune synapse. Moreover, proximal TCR signaling, including CD3ζ and ZAP70 phosphorylation, is disrupted in INPP5E-deficient cells. The defects in INPP5E-deficient cells are contributed by phospholipid distributions at the supramolecular activation cluster (SMAC), which is modulated by the catalytic domain of INPP5E. Together, these results suggest a repurposed ciliary machinery at the immune synapse for the recruitment of the TCR/CD3 complex and regulated by controlling phospholipid distributions through INPP5E.

Rafting with Rush: Membrane Rafts Mediate Protein Trafficking through the Biosynthetic Pathway.

I. Castello Serrano, B. Diaz-Rohrer, F. A. Heberle, R. Ippolito, K. R. Levental, I. Levental; UTHealth | the University of Texas Health Science Center at Houston, Houston, TX.

The organelles of eukaryotic cells maintain distinct protein and lipid compositions required for their distinct functions. However, the mechanisms by which components are sorted to their specific locations remain largely mysterious. In particular, how lipids and membrane proteins are coordinately delivered to various membrane-bound organelles is poorly understood. One proposed explanation is that the sorting of membrane components is mediated by membrane microdomains known as lipid rafts. Such

domains are small, dynamic clusters of preferentially interacting lipids and protein components. Recently, our lab has defined the structural determinants for protein partitioning to raft domains, identifying three independent aspects of protein transmembrane domains (TMDs) as key for raft affinity: TMD length, TMD surface area, and post-translational palmitoylation. Remarkably, all three were also correlated with protein subcellular localization, strongly suggesting a mechanistic link between raft affinity and protein sorting. To dissect the mechanisms of raft-mediated protein sorting, we have adapted the RUSH (Retention Using Selective Hooks) system to quantify the temporal dynamics of trafficking of transmembrane proteins through the secretory pathway and to the PM. We find that lipid raft affinity is necessary and sufficient for steady-state PM localization of a subset of transmembrane proteins. The TMDs of these proteins, encoding their raft affinity, were fully sufficient for PM sorting.However, raft affinity was not sufficient for rapid exit from the endoplasmic reticulum (ER), which required specific cytosolic sorting motifs. Importantly, we find that Golgi exit rates are highly raft-dependent, with raft preferring proteins exiting ~3-fold faster than mutants with perturbed raft affinity. We rationalize these observations with a mechanistic, predictive model of trafficking through the secretory pathway, which includes the partitioning of the Golgi into coexisting membrane domains. We identify an isoform of the small GTPase Rab6 as a central regulator for the Golgi-PM trafficking of raft proteins. These observations highlight a central role for lipid rafts in sorting in the secretory pathway and establish the core machinery for raft-mediated cellular trafficking.

Ca^{2+}-independent phospholipase A_2 inhibitors (PLAIs) induce the accumulation of cholesterol in the Endocytic Recycling Compartment (ERC) but only when sufficient amounts of LDL are available to cells. Certain proteins that associate with cholesterol also accumulate in the ERC under these conditions, notably Amyloid Precursor Protein (APP). Immunoblotting revealed that the processing of APP and association of APP-derived fragments with detergent-insoluble complexes was altered by PLAI treatment. Whether the pathogenic form of A-beta was produced could not be determined, but cholesterol has been associated with altered processing of APP that produces the pathogenic form of the protein. The production of this version of A-beta requires the interaction of APP with BACE protease. Since PLAIs lead to the colocalization of cholesterol and APP, we investigated the colocalization of APP and BACE when cells were grown in different levels of LDL and treated with the PLAI, ONO-RS-082, or simvastatin. SH-SY5Y, HeLa, and NPC1 cells were grown in low, moderate, or high levels of LDL, then treated with ONO and simvastatin alone or in combination. Immunofluorescence confocal microscopy revealed colocalization of APP and BACE in a small fraction of juxtanuclear puncta only in untreated cells grown in low-LDL media. No colocalization was observed in cells grown in higher levels of LDL or treated

with ONO or simvastatin. This suggests that newly-synthesized cholesterol may affect the processing of APP, and how cells obtain cholesterol may influence cellular processes. Since PLA2 enzymes are associated with different compartments involved in membrane trafficking, these proteins may also play a role in the trafficking of newly-synthesized cholesterol and affect the trafficking or processing of APP.

Exploring Cholesterol-dependent Membrane Interaction of a Beta-barrel Pore-forming Toxin *Vibrio Cholerae*Cytolysin and Its Association with Membrane Lipid Rafts.

R. Kathuria, K. Chattopadhyay; Indian Institute of Science Education and Research, Mohali, INDIA.

Vibrio cholerae cytolysin (VCC), an archetypical β-barrel pore-forming toxin, acts as a major virulence factor for the pathogenic strains of *Vibrio cholerae* that lack Cholera Toxin. VCC generates heptameric transmembrane pores in the eukaryotic cellular membranes. VCC has been shown to exhibit functional pore formation only in cholesterol-containing membrane bilayer. However, mechanistic details of how cholesterol governs functional activity of VCC have not been deciphered. The collective result from our study defines the critical requirement of membrane cholesterol in regulating the pore-forming activity of VCC. Our study provides detailed insights of how cholesterol in target membrane regulates the distinct steps of pore formation in both liposomes and eukaryotic biomembranes. Our findings for the first time demonstrated the marked tendency of VCC to partition into cholesterol-rich, membrane micro-domains or lipid rafts in human erythrocytes. Surprisingly, the variants of VCC having mutations that arrest the toxin at different stages of pore-formation mechanism, and even the mutant that could not interact with cholesterol tend to associate with lipid rafts of human erythrocytes with similar efficacy, suggesting that the sequestering of VCC to lipid rafts is possibly defined by the physicochemical environment of the membrane lipid rafts, or there could also be a possibility for presence of a yet unidentified specific receptor(s) or receptor-like entity in these lipid rafts regions that might drive the translocation of VCC to these regions for execution of pore formation.

Multiple Sterol Routes to Lysosome/vacuole for Lipid Domain Formation.

A. Toulmay[1], U. Bandyopadhyay[2], A. Murley[3], J. Yamada[3], J. Nunnari[3], M. Overholtzer[2], W. Prinz[1]; [1]National Institute of Diabetes and Digestive and Kidney Diseases, NIH, Bethesda, MD, [2]Sloan Kettering Institute, New York City, NY, [3]Department of Molecular and Cellular Biology, University of California, Davis, Davis, CA.

The composition of cellular membranes dramatically changes in response to stress. However, the mechanisms by which cells sense and regulate the composition and distribution of lipids in membranes remain poorly understood. During various stresses, such as glucose starvation, heat stress and weak acid stress, we have previously found that large, stable, sterol-enriched domains form in the membrane of the vacuole (lysosome-like organelle) in yeast. This is the first demonstration that sterol-enriched raft-like liquid ordered domains similar to those observed in artificial membranes form in living cells and have been linked to autophagy and Tor pathway. We found that these sterol-enriched domains are also enriched in phosphatidyl-inositol-3-phosphate (PI3P) and Diacylglycerol (DAG). The formation of these domains is tightly regulated and all three lipids are necessary for the formation of these lipid domains. In our current work, we reveal multiple additive routes for sterol to reach the vacuole membrane during glucose starvation: vesicular fusion (endocytosis), membrane degradation (autophagy, multivesicular

body, NPC proteins) and non-vesicular trafficking (ER/ mobilization from lipid droplets, lipid transfer proteins Ltc1/2p). In addition, we observed that similar lipid domains form in entotic structure found in human cancer cell lines and in lysosomes of Pompe disease mice model myotubes. Like the yeast vacuole, formation of these lipid domains depends on the presence of cholesterol and phosphatidylinositol phosphate. All together, these data show that the sterol-enriched domains are conserved from yeast to human and probably play an important role in stress response.

Induced Hyperleptinemia in Caveolin-1 Null Mice Dramatically Decreased the Outer Plasma Membrane Amount of White Adipocytes.

W. Li[1], B. Qu[2], R. G. W. An derson[1]; [1]Department of Cell Biology, University of Texas Southwestern Medical Center, Dallas, TX, [2]Department of Molecular Biology, Cell Biology & Biochemistry (MCB), Warren Alpert Medical School of Brown University, Providence, RI.

Caveolae are omega-shaped invaginations of plasma membrane rich in cholesterol and sphingolipids. Caveolin-1 is an important structural component of caveolae that are most abundant in adipocytes and other mammalian cell types. Adenovirus-induced hyperleptinemia rapidly depletes body fat in normal rats without increasing free fatty acids and ketogenesis, implying the fat is being oxidized in adipocytes. We induced hyperleptinemia in wild type (Wt) or Caveolin-1 (CAV-$1^{-/-}$) null mice with recombinant adenovirus containing the leptin cDNA followed by light and electron microscopic analysis. We found that leptinized adipocytes in both groups are shrunken, fat-depleted, crowded with mitochondria, and encased in a thick connective tissue matrix. Leptinized adipocytes of wild type revealed irregularly shaped shrunken cells with extreme folding of cell plasma membrane and also accumulated a large amount of caveolae just under the cell surface. Leptinized adipocytes of CAV-$1^{-/-}$ have no detectable caveolae which was observed previously. But CAV-$1^{-/-}$ adipocytes exhibited dramatically decreased cell surface plasma membranes, a lack of membrane folding and very few microvilli. The proliferation of filamentous mitochondria containing numerous cristae embedded in a highly electron-dense matrix were only seen in CAV-$1^{-/-}$ adipocytes. Our ultrastructural findings support the hypothesis that caveolae with Caveolin are integral to organizing and protecting the cell surface plasma membrane to response the mechanical changes.

Diurnal Phosphatidylserine Exposure during Retinal Photoreceptor Outer Segment Renewal.

S. C. Finnemann, N. J. Esposito, J. A. Vargas; Fordham University, Bronx, NY.

Mammalian photoreceptor outer segment renewal is a synchronized circadian and light driven process that involves collaboration of photoreceptor neurons and neighboring retinal pigment epithelial (RPE) cells and that is essential for life-long visual function. Diurnal exposure of the anionic membrane lipid phosphatidylserine (PS) specifically at distal tips of rod photoreceptor outer segments triggers their shedding and clearance phagocytosis by RPE cells. RPE-photoreceptor communication is critical for synchronized outer segment renewal with outer segment PS recruiting bridge proteins such as MFG-E8 and Protein-S to efficiently ligate RPE receptors (αvβ5 integrin and Mer tyrosine kinase) triggering POS engulfment. This study aims to elucidate the molecular mechanisms promoting PS exposure by photoreceptors. Experiments involve characterization of wild-type and knockout mouse models by PS live imaging and immunofluorescence microscopy and immunoblotting of retinal and RPE marker

proteins. We show that the peak of PS exposure by photoreceptor outer segments in *vivo* at daily light onset requires the soluble carbohydrate-binding protein galectin-1. We also find that RPE cells express galectin-1 and that galectin-1 levels in the interphotoreceptor matrix are elevated at light onset, coinciding with maximal PS exposure by outer segments. Moreover, purified galectin-1 added exogenously is sufficient to promote outer segment PS exposure. However, the capacity of photoreceptor neurons to externalize PS at their tip is variable depending on time of day and is abnormal in retina with defective RPE phagocytic machinery. Altogether, our results identify an essential role for galectin-1 in synchronized photoreceptor outer segment renewal.

P1463/B595

Plasma Membrane Compartmentalization during Leader Bleb-based Migration in Melanoma Cells Under Confinement.

A. Jha[1], P. Sengupta[2], J. Lippincott-Schwartz[2], C. M. Waterman[1]; [1]National Institutes of Health, Bethesda, MD, [2]Janelia HHMI, Ashburn, VA.

Metastatic cancer cells migrating in a confined tissue microenvironment can switch between different modes of migration dependent on the degree of confinement and availability of adhesive ligands. Cells with high contractility are prone to blebbing and when confined in the absence of adhesive ligands, exhibit “leader bleb-based” migration. This mode of migration is characterized by a highly polarized morphology with a long, stable leader bleb (LB) leading the direction of migration, that is separated from the trailing cell body (CB) by a narrow contractile neck. Metastatic cells carrying the BRAFV600E mutation exhibit polarized Erk signaling within the LB that promotes actin retrograde flow to drive fast, directional cell LB-based motility. However, the mechanisms mediating the establishment and maintenance of such extreme cell polarization during LB-based migration are not known. We seek to test the hypothesis that polarization of signaling during LB-based migration is mediated by compartmentalization of lipid and protein organization on the plasma membrane (PM) between LB and CB. To test this, we expressed fluorescent membrane proteins and lipid probes in human metastatic A375 melanoma cells under 3µm confinement with a polydimethylsiloxane (PDMS) or an agarose pad. We performed FRAP and time-lapse confocal microscopy to analyze mobility and spatial distribution within LB and CB, as well as cell motility parameters. To address the role of protein topology relative to the membrane in the LB and CB, we analyzed fluorescent fusions of single-pass transmembrane proteins (GFP-GT46 for non-raft, LAT-GFP for raft), those associated with the outer leaflet (GFP-GPI). Localization and FRAP photobleaching experiments revealed that transmembrane proteins showed restricted diffusion between LB and CB while proteins on the outer leaflet were free to diffuse. An alysis of an inner leaflet protein (HRas-GFP) as well as a transmembrane proteins associated with cytoskeleton (CD44-GFP) is underway. To address the role of lipid organization in the LB and CB, we analyzed the distribution of phosphoinositides using biosensors (PLCδ PH-GFP or tubby domain-GFP for $PI[4,5]P_2$, Akt PH-GFP for $PI[3,4,5]P_3$). This showed that PLCδ PH-GFP labeled the PM evenly, while tubby domain-GFP and Akt-GFP was excluded from the blebs. An alysis of lipid order using laurdan and Di-4-AnePPDHG dyes will be performed in the future. However, our results together reveal a striking degree of PM compartmentalization between LB and CB in melanoma cells migrating under confinement, though the mechanisms behind this still remains elusive. We are currently deciphering the mechanism by which such a compartmentalization is attained and how membrane organization regulates bleb dynamics and migration.

Development of Ph-sensitive Fluorescent Probes for Imaging of Cell Membranes in Live Cells.

D. Thomas[1], V. Rubio[1], V. Iragavarapu[2], E. Guzman[3], Q. Zhang[4], **M. J. Stawikowski**[1]; [1]Department of Chemistry and Biochemistry, Florida Atlantic University, Boca Raton, FL, [2]Charles E. Schmidt College of Medicine, Florida Atlantic University, Boca Raton, FL, [3]Harbor Branch Oceanographic Institute, Florida Atlantic University, Fort Pierce, FL, [4]Brain Institute, Florida Atlantic University, Jupiter, FL.

Biomembranes are essential to life and the understanding of lipid membranes is of fundamental interest for cell biology, biochemistry and drug design. The composition of lipid membranes depends on the membrane type, localization and cell type. Certain neurodegenerative diseases and cancers relate to disfunction of biomembranes and their components. Lipid membranes of cancer cells present substantial alterations in their composition, structural organization, and functional properties. Disturbance of processes related to lipid trafficking is considered a basis for some neurodegenerative diseases such as Alzheimer's. Reported here is the synthesis, characterization and application of novel pH sensitive probes for lipid membrane imaging. As a fluorescent probe the 1,8-naphthalimide scaffold was chosen. The 4-amino(substituted)-1,8-naphthalimide derivatives have very interesting electronic properties and ability to respond to internal charge transfer (ICT) excited state. Moreover, the ICT is also solvent-dependent process, giving rise to interesting solvatochromic properties of naphthalimide derivatives. Reported in this study are the probes containing substituted naphthalimides with aliphatic chains, probes containing cholesterol and amino-acid residues to be used in peptide synthesis for transmembrane peptides. The designed probes (λex ~400 nm, λem ~520 nm) are not only membrane specific but also increase fluorescence (several times) in slightly acidic environment (pH~6.5). Performed molecular dynamics simulations of probes in membrane models show how probes incorporate into lipid bilayers and interact with it. Two of the tested probes found their application for the imaging of lipid membranes of live (breast) cancer cells with an excellent signal-to-background ratio of ~1200-1500. Additional probe containing cholesterol moiety was designed to study cholesterol rich membranes as those present in neurons and synaptic vesicles. This probe is capable of interacting with lipids and transmembrane proteins through its cholesterol fragment and "head" piperazine moiety. An other naphthalimide moiety was also coupled to a lysine residue, resulting in fluorescent amino acid derivative that serves as a building block for synthesis and labeling of transmembrane peptides. The model transmembrane peptide when tested in micellar solution showed an ideal alpha-helix formation and green fluorescence emission. The physicochemical and spectral properties of all fluorescent probes is discussed and illustrated with a potential application towards imaging of lipid membranes of live cancer cells and neurons.

Interaction of Msc1 with Yy1 Is New Target of Sarcopenia.

G. Kong[1,2], H. Lee[1,2], q. Tran[1,2], C. Kim[1,2], J. Park[1,2]; [1]1Department of Pharmacology, Metabolic Syndrome and Cell Signaling Laboratory, Institute for Cancer Research, College of Medicine, Chungnam National University,, Daejeon 35015, KOREA, REPUBLIC OF, [2]2Department of Medical Science, College of Medicine, Chungnam National University,, Daejeon, KOREA, REPUBLIC OF.

In modern society, obesity is the leading cause of many complications such as diabetes and hyperlipemia. A typical phenomenon is that as the amount of fat increases, muscle mass gradually decreases, damaging many cells. YY1(YinYang1) is a transcription factor belonging to the GLI-Kruppel of zinc finger proteins. YY1 has been extensively studied for muscle regeneration. YY1 is an important factor in muscle differentiation. The muscle-specific deletions of YY1 lead to severe deformities of muscle formation, resulting in neonatal death. It was also reported that the deficiency of YY1 induced by satellite cells (SC) almost completely inhibited muscle repair induced by acute injury and worsened the phenotype of malnutrition caused by chronic injury. MSC1 is Methyllysine-binding protein, a component of the MOF histone acetyltransferase protein complex. MSC1 phosphorylation after DNA damage contributes to the down-regulation of p53 / TP53 We found that insulin resistance and muscle regeneration were reduced when the MSC1 TG mice feed with high fat diet (HFD). Moreover cardiotoxin-induced muscle regeneration in MSC1 Tg mice was also decreased. In addition, IP assay indicated that MSC1 interacts with YY1. The relationship between MSC1 and YY1 were confirmed through H & E and behavior test. This results implicated that MSC1 might be a targeting mediator for the treatment of sarcopenia.

Post-Translational Modifications in Signaling

Casein Kinase I Protein Hrr25 Mediates Cell Wall Integrity by Phosphorylating Pin4 in Budding Yeast.

A. Bhattarai, M. Bhondeley, **Z. Liu**; University of New Orleans, New Orleans, LA.

Casein kinase I protein Hrr25 plays important roles in a number of cellular processes including autophagy, vesicular trafficking, ribosome biogenesis, transcriptional regulation, and DNA damage response in the budding yeast. In a bioinformatics analysis of genes that genetically or physically interact with Hrr25, we found that Pin4 was a potential target of Hrr25. Pin4 is a multiply phosphorylated protein. We found that its phosphorylation is dependent on Hrr25. Pin4 has been reported to be involved in both DNA damage response and the cell wall integrity pathway. By performing a co-immunoprecipitation analysis and a yeast two-hybrid assay, we found that Pin4 physically interacts with Hrr25. *pin4* mutations form synthetic slow growth phenotypes with mutations in genes encoding Bck1 and Slt2, two of the protein kinases in the MAK kinase cascade that regulates cell wall integrity in the budding yeast. We found that *hrr25* mutations result in similar phenotypes to those of *pin4* mutations. Hrr25 possesses an N-terminal kinase domain, a middle region, and a C-terminal proline/glutamine rich domain. The function of the C-terminal P/Q rich domain of Hrr25 has been elusive. We found that the C-terminal region of Hrr25 is required for its interaction with Pin4 and that an *hrr25* mutant allele with the C-terminal region truncated forms synthetic growth defects with mutations in *BCK1* and *SLT2*. Our results suggest that Hrr25 positively regulates cell wall integrity by phosphorylating and activating Pin4.

P1468/B601

Phosphorylation of Nur77 by Tak1-p38 Mapk Pathway Regulates the Inflammatory Response.

P. Han Zhong[1], B. Huang[2], H. Chang[3], **S. Baek**[4]; [1]Yeungnam University, College of Medicicne, Daegu, KOREA, REPUBLIC OF, [2]Peking University, Shenzhen, CHINA, [3]Yeungnam University, College of Pharmacy, Gyeongsan-si, KOREA, REPUBLIC OF, [4]Yeungnam University, College of Medicine, Daegu, KOREA, REPUBLIC OF.

Nur77 is a member of the NR4A subfamily of nuclear receptors and has been shown to regulate various biological processes such as inflammation and apoptosis. The aim of current study is to determine whether Nur77 phosphorylation regulates their anti-inflammatory effects. Overexpression of Nur77 inhibited IL-6 production by TNFα, whereas knockdown of Nur77 amplified IL-6 production. Treatment of TNFα increased phosphorylation of two serine residues of Nur77 protein, S152 and S351 in HeLa cells. Next, we examined the signal transduction pathway regulating phosphorylation of Nur77. Inhibition of p38 MAPK decreased both S152 and S351 phosphorylation of Nur77 as well as IL-6 production. Suppression of TAK1 activity by siRNA or inhibitor decreased phosphorylation of Nur77 as well as p38 MAPK. In addition, TAK1 knockdown or inhibitor suppressed TNFα-induced IL-6 production. These results suggest that TAK1-p38 MAPK pathway regulates phosphorylation of Nur77. We investigated that S152 phosphorylation of Nur77 regulates IL-6 production. In the IL-6 production of TNFα stimulation, the S152A mutant suppressed more strongly than the WT Nur77, while the S351A mutant did not affect. These results suggest that although TNFα stimulates phosphorylation of S152 and S351 of Nur77 through TAK1-p38 MAPK pathway, only phosphorylation of S152 reduces the stabilization of this protein and eventually interferes the anti-inflammatory effect.

P1469/B602

Mating-induced Stabilization of Kar4p by Down-regulation of the E3-ubiquitin Ligase Ubr1p.

J. Kim[1], W. Yun[2], J. Alcantar[2], M. Rose[1]; [1]Georgetown University, Washington D.C., DC, [2]Princeton University, Princeton, NJ.

Signal transduction pathways respond to changes in a wide variety of external conditions to control cellular processes, such as proliferation, differentiation and development. Given that there are a limited number of signaling proteins, cells have evolved an elegant mechanism to maintain specificity between different developmental programs that share identical or similar regulators. In addition to phosphorylation to regulate the activities of signaling proteins, emerging evidence has shown a key role of ubiquitination and turnover in modulating the strength and duration of signaling pathways. In budding yeast, Kar4 is a multi-functional protein that has an essential role in various cellular processes with distinct functions. The protein is expressed in two forms. The long form is constitutive and responsible for meiosis and sporulation; the short form, initiated from an internal AUG, is highly induced by pheromone and Ste12 during mating to regulate karyogamy. Kar4p-short is stable during mating, when it complexes with Ste12 and transcriptionally induces the minus end-directed kinesin motor proteins Kar3/Cik1. Kar4-short is then rapidly degraded as cells return to mitosis. Here, we demonstrate that the pheromone signaling pathway regulates the Ubr1 E3-ubiquitin ligase. In mitosis, *ubr1Δ* mutation stabilized Kar4-short to the level of pheromone-treated cells. A *ubr1* RING-domain mutation also stabilized Kar4-short. Regulated turnover is not limited to Kar4; other Ubr1 substrates (C-terminal fragment of Scc1 and misfolded Ste6*) also showed an increase in turnover rate in mating cells, indicating that pheromone signaling down-regulates the Ubr1 pathway. An allele of Kar4 that does not bind to Ste12 failed to stabilize Kar4 during mating. A subsequent screen of Kar4-dependent genes identified Srl4 as being required for stabilization during mating; in pheromone-treated *srl4*Δ, the turnover rate of Ubr1 substrates was similar to the rate in mitotic cells, and mitotic cells overexpressing Srl4 showed reduced turnover. Consistent with this, sr*l4Δ* lowered the level of Kar4 and Kar3, which led to mating defects. Ubr1 is an N-end rule ligase that normally requires the canonical E2-conjugating enzymes Ubc2/Rad6. Interestingly mutation of Ubc2 and Rad6 did not affect Kar4 stability. Instead, deletion of a different E2, Ubc6, caused mitotic stabilization of Kar4 similar to *ubr1*Δ, suggesting that Kar4 is degraded by an alternate pathway. LC-MS showed that both Kar4 and Ubr1 are complexed with Srl4 in pheromone treated cells. However, no E2-ligases, including Ubc6, were detected. We are now testing that Kar4-induced Srl4 can block access of the E2-conjugating enzyme to Ubr1, thereby causing down-regulation of Ubr1 and stabilization of Kar4 during mating.

P1470/B603

The Functional Role of Calcineurin Regulating Factor 1 in β-amyloid Generation in Alzheimer's Disease.

S. Wang; Jining medical university, Jining, CHINA.

Alzheimer's disease (AD) is the most common neurodegenerative disease. The excessive generation of Aβ plays a major role in the pathogenesis of AD. The dysregulation of amyloid precursor protein cleaving enzymes, β-secretase and γ-secretase, is an important cause of AD. RCAN1.1L has been demonstrated to be up regulated in AD brains, which promotes neuronal apoptosis mediated by caspase 3 activation. In this work, we demonstrated the expression of BACE1, a dominated β-secretase leading to Aβ generation, was modulated by RCAN1.1L. Moreover, we also found that the expression of factor F was also regulated by RCAN1.1L in a calcineurin dependent pathway, which was involved in Aβ generation.

Conserved recognition motif of factor F was widespread in several amyloid precursor protein cleaving enzymes, including BACE1, indicating its potential role in Aβ accumulation via mediating degradation of BACE1. Our study suggests that RCAN1.1L might be implicated in Aβ generation by regulating factor F-mediated BACE1 degradation. This work is beneficial to further elucidate functional role of RCAN1.1L in pathogenesis of AD and may provide new potential targets for its treatment.

P1471/B604

Phosphorylation-dependent Regulation of the GLI Family of C2H2 Zinc Finger Transcription Factors.

E. Tarapore, Y. Tran, A. M. Valencia, S. X. Atwood; University of California, Irvine, Irvine, CA.

C2H2 zinc finger transcription factors (ZNTFs) are the largest family of transcription factors found within eukaryotes. How post-translational modification of ZNTFs regulates activity is still poorly understood. Our previous studies indicated that phosphorylation of the first and third zinc finger of the Hedgehog (Hh) pathway ZNTF GLI1 positively regulates DNA binding and transcriptional activity. To explore phospho-regulation of this ZNTF, we undertook a brute-force mutagenesis of every serine and threonine residue and found three conserved regions of regulation: 1) a permissive regulatory region, 2) a DNA binding region, and 3) a cell-cycle regulatory region. Specific phospho-mimetic mutations in the regulatory region increases DNA binding or transcriptional activity of GLI1, whereas phospho-mimetic mutations in the DNA binding or cell-cycle region abolishes DNA binding. We find these regions are conserved in other GLI family members and ZNTFs with similar zinc finger structure, suggesting a broadly conserved mechanism to post-translationally control ZNTF activity.

Prmt1-mediated Tsc2 Methylation Controls Tsc2 Stability and Mtorc1 Activity.

S. Gen, Y. Matsumoto, T. Suzuki, J. Inoue, Y. Yamamoto; Tokyo University of Agriculture, Tokyo, JAPAN.

[Objective] Insulin signals regulate cell growth by activating mammalian target of rapamycin complex 1 (mTORC1). Tuberous sclerosis complex 2 (TSC2), a tumor suppressor protein, is the intermediator of the insulin pathway and negatively regulates mTORC1 activity. The post-translational modifications of TSC2, such as TSC2 phosphorylation, inactivate TSC2 during the insulin stimulus. Protein methylation is a well-known protein modification wherein arginine methyltransferase 1 (PRMT1) methylates arginine residues on the Gly- and Arg-rich (GAR) motif. However, although TSC2 contains several GAR motifs, TSC2 methylation is poorly understood. This study aimed to characterize TSC2 methylation and its function. **[Methods]** Initially, the potential PRMT1-mediated TSC2 methylation was investigated by in vivo methylation assay. Next, we confirmed whether TSC2 stability is controlled by its PRMT1-mediated methylation. We further examined whether the TSC2 decrease through arginine methylation affects mTORC1 activity. Finally, we analyzed whether the decrease in TSC2 is controlled by methionine metabolism via the supplementation of S'-adenosyl methionine (SAM). Moreover, we investigated TSC2 localization by immunofluorescence. **[Results and Discussion]** to the best of our knowledge, this is the first study to report that TSC2 is directly methylated by PRMT1. In vivo methylation assay results indicated that PRMT1 inhibitor treatment decreases TSC2 methylation. Additionally, treatment with the PRMT1 inhibitor treatment and shPRMT1 KD cells decreased endogenous TSC2, which, in turn, promoted mTORC1 activity, as measured by S6K phosphorylation. These findings implied that PRMT1-mediated TSC2 methylation regulates cell growth through mTORC1 inactivation. The supplementation of SAM prevented a decrease in TSC2 upon methionine deprivation. In addition, TSC2 localization on

lysosomes significantly decreased upon methionine deprivation. **[Conclusion]** We identified a novel protein modification for TSC2 methylation. Inhibition of TSC2 methylation leads to TSC2 degradation. Moreover, methionine regulates TSC2 stability through TSC2 methylation.

Optogenetic Control of Subcellular O-GlcNAc Signaling.

Q. Ong[1,2], W. Han[2], X. Yang[1]; [1]Yale University, New Haven, CT, [2]Singapore Bioimaging Consortium, Singapore, SINGAPORE.

O-GlcNAcylation is a post-translational modification that regulates fundamental cellular processes in metazoans. A single pair of enzymes - O-GlcNAc transferase (OGT) and O-GlcNacase (OGA) - mediates dynamic cycling of O-GlcNAcylation on a wide variety of nucleocytoplasmic and mitochondrial proteins in a nutrient- and stress-responsive fashion. A significant hurdle towards understanding O-GlcNAcylation in cells arises from the lack of tools to perturb O-GlcNAcylation levels with spatiotemporal precision. To overcome these challenges and identify the role of O-GlcNAcylation in the subcellular context, we develop a set of optogenetic tools based on light-induced protein oligomerization to control the O-GlcNAcylation levels at the cellular and organelle levels. Here, we demonstrate that light-induced oligomerization of CRY2-OGT rapidly raised the overall O-GlcNAcylation levels in HEK 293 cells within 5 minutes. We then utilize the heterodimerization property of CRY2 and CIBN to recruit OGT to various organelles, including mitochondria. The optogenetic recruitment of OGT elevates mitochondrial O-GlcNAcylation levels and increases fusion events. This is associated with increased phosphorylation of dynamin-related protein 1 (DRP1) at Ser 637 and reduced phosphorylation at Ser 616. These results demonstrate the direct role of O-GlcNAc signaling in regulating mitochondrial dynamics and function. Our work describes a novel tool to study O-GlcNAcylation with high spatiotemporal specificity and provides insights into the role of O-GlcNAcylation at the subcellular level.

Acinus Supports Atg1-mediated Phosphorylation of Yorkie to Restrict Cell Growth.

N. Nandi, L. Tyra, H. Kramer; University of Texas Southwestern Med Ctr, DALLAS, TX.

Acinus has emerged as a signaling node that integrates multiple cellular stress signals and manages stress by regulating basal levels of autophagy in a TOR-independent pathway (1,2,3). Here, we identified Acinus-supported Atg1/ULK1-mediated phosphorylation of Yorkie as an additional inhibitory input restricting growth independently of the Hippo/Warts pathway. Two serine residues in Yorkie, S74 and S97, are Atg1/ULK1 consensus target sites phosphorylated by ULK1 in vitro. In vivo, Atg1 gain-of-function caused elevated Yorkie phosphorylation and reduced expression of Yorkie target genes. Conversely, knocking down Atg1, or its activator Acinus, reduced Yorkie phosphorylation and raised expression of Yorkie target genes to increase tissue size. Yorkie phosphorylated by ATG1 can still translocate to the nucleus, but was unable to bind the transcription factor Scalloped and failed to promote transcription of pro-proliferation genes, thereby restricting cell growth. Unlike Atg1's role in autophagy, Atg1-mediated phosphorylation of Yorkie does not require Atg13. Atg1 is activated by starvation or other cellular stressors and therefore can impose temporary stress-induced constraints on the growth-promoting gene network under control of Hippo/Yorkie signaling.

An In-cell Sensor Reveals the Spatiotemporal Dynamics of Phosphorylated Gbeta in Yeast Cells Decoding Pheromone Gradients.

R. Abdul-Ganiyu, L. A. Venegas, B. Kay, D. E. Stone; University of Illinois, Chicago, IL.

Directed cell growth in response to a chemical gradient (chemotropism) is necessary for cellular processes like axonal pathfinding, angiogenesis and fungal life cycles. Yeast mating is a well-studied chemotropic model system. Yeast cells interpret shallow pheromone gradients from cells of opposite mating type, polarize their growth toward the pheromone source, and fuse at the chemotropic growth site. When cells are unable to sense a pheromone gradient, they can fuse at the default polarity site. To accurately decode pheromone gradients, mating cells first assembly signaling, polarity, and trafficking proteins (the gradient tracking machine, GTM) at the default polarity site. The GTM then redistributes (tracks) toward the pheromone source until it reaches the chemotropic growth site. Phosphorylation of the G protein βετα subunit (Gβ) is important for this process. Phosphorylated Gβ ($G\beta^P$) inhibits receptor phosphorylation up-gradient promoting differential phosphorylation of the receptor, which is critical for gradient sensing. We postulate that gradient tracking depends on differential phosphorylation of the receptor,which in turn, depends on localized phosphorylation of Gβ. To test this prediction, we developed a biosensor that specifically recognizes phosphorylated forms of Gβ. Here, we describe the isolation and characterization of the $G\beta^P$ biosensor. We show that in mating cells expressing both RFP-Gβ and the $G\beta^P$ biosensor, the spatiotemporal behavior of gradient-tracking $G\beta^P$ relative to that of total gradient-tracking Gβ is consistent with our proposed role for Gβ phosphorylation in gradient tracking.Notably, we found that $G\beta^P$ anticipates the GTM transition from tracking to stabilization, suggesting that it positions the chemotropic growth site.

The Interplay between O-glcnac and Phosphorylation on Tyrosine Hydroxylase Activity and Cathecolamine Synthesis in Pc12 Cells.

B. d. Rodrigues, M. Lucena, A. Costa, I. Oliveira, D. Beckman, S. Ferreira, F. Mello, A. Todeschini, R. Reis, W. Dias; UFRJ, Rio de Janeiro, BRAZIL.

About 2% to 5% of all glucose that enters the cell are directed to the Hexosamine biosynthetic pathway, which has glutamine fructose-6-phosphate aminotransferase (GFAT) as the rate-limiting step enzyme. This pathway has UDP-GlcNAc as a final product, which is used as substrate for intracellular O-GlcNAc; a post-translational modification (PTM) resulting from the covalent attachment of a N-acetylglucosamine (GlcNAc) to the hydroxyl groups on serine and threonine residues in proteins. This reaction is catalyzed by O-GlcNAc transferase (OGT), and the removal reaction of this monosaccharide is made by O-GlcNAcase (OGA). The balance of the activity of such enzymes and UDP-GlcNAc availability will regulate the levels of O-GlcNAcylated proteins, with an O-GlcNAcylation, similarly to phosphorylation, highly inducible, dynamic and active in many cellular processes. Tyrosine hydroxylase (TH) is the rate-limiting step enzyme in catecholamine synthesis, responsible for hydroxylate L-tyrosine at meta-position to obtain L-DOPA, the precursor of dopamine, which has a physiological role as a neurotransmitter. There

are several supports on the literature that phosphorylation on serine 40 of TH increases its activity on a dynamical way, however, the mechanism of how O-GlcNAc plays a role on this modulation remains unknown. We showed in PC12 cells treated with the pharmacological inhibitor of OGA Thiamet G (TMG); and nerve growth factor (NGF), a compound that induces these cells in a process of neuritogenesis, that O-GlcNAcylation acts on the control of the phosphorylation levels of serine 40 in TH, where stimulation by 28% on the increase in phosphorylation at serine 40 decreases the levels of O-GlcNAc in 26% compared to control; while the increase of intracellular O-GlcNAc in 19% reduces the phosphorylation at serine 40 by 16%. In addition, HPLC analysis shows that the increase of intracellular O-GlcNAc reduces the levels of L-DOPA and dopamine by 80%. Finally, TH's immunoprecipitation analysis reveals that it is O-GlcNacylated, and this PTM regulates its activity. These data suggest a cellular mechanism that integrates carbohydrate metabolism (by HBP) with the catecholamine biosynthetic pathway in a neuritogenesis process; where competition between O-GlcNAc and phosphate at serine 40 tyrosine hydroxylase site modulates its activity, controlling the synthesis of dopamine levels in PC12 cells.

Proteomic an alysis Identifies the E3 Ubiquitin Ligase Pdzrn3 as a Regulatory Target of Wnt5a-Ror Signaling.

S. E. Konopelski[1], M. W. Susman[2], R. C. Kunz[2], M. D. Cohen[1], J. Tan[1], K. Okada[1], H. Lamb[1], S. S. Choi[1], E. P. Karuna[1], M. K. Scales[1], S. P. Gygi[1], M. E. Greenberg[2], H. H. Ho[1]; [1]University of California, Davis, Davis, CA, [2]Harvard Medical School, Boston, MA.

WNT5A-ROR signaling is a conserved pathway that regulates morphogenetic processes during vertebral embryonic development, but the downstream signaling events remain poorly understood. Using a large-scale proteomic screen, we identified the E3 ubiquitin ligase PDZRN3 as a new regulatory target of WNT5A-ROR signaling that is degraded upon pathway activation in a β-catenin independent, ubiquitin proteasome system dependent manner. To track this regulation, we developed a fluorescence-based reporter to monitor PDZRN3 abundance in live cells. By coupling this reporter with pharmacological perturbation and protein overexpression experiments, we delineated a signaling cascade involving Frizzled receptors, Dishevelled scaffolding proteins, Glycogen synthase kinase and Casein kinase 1 that leads to PDZRN3 degradation. Genetic epistasis analysis suggests that PDZRN3 resides in a branch of WNT5A-ROR signaling parallel to KIF26B, a previously identified regulatory target. Further, we discovered that PDZRN3 degradation requires WNT5A-dependent phosphorylation of its C-terminal LNX3H domain, and PDZRN3 homologs that contain a LNX3H domain are similarly regulated by WNT5A. Collectively, this work establishes a new WNT5A-ROR signaling cascade involving PDZRN3 phosphorylation and degradation.

Akt Activation by Ptdins(3,4)p_2-dependent Mtorc2 Recruitment into Early Endosomes.

S. Kim[1], S. Heo[2], D. Kang[2]; [1]Korea Basic Science Institute/Ewha Womans University, seoul, KOREA, REPUBLIC OF, [2]Ewha Womans University, seoul, KOREA, REPUBLIC OF.

The serine/threonine kinase AKT is a major effector during cell signal transduction in response to extracellular stimuli. AKT regulates cell physiological processes such as survival, growth and metabolism and is hyperactivated in metabolic diseases and cancer. AKT activation mechanisms have been extensively studied, but the mTORC2 mechanism that leads to AKT phosphorylation at Ser473 remains

elusive. Here, we investigated the upstream regulation of mTORC2 with confocal imaging and biochemical fractionation. We reveal that mTORC2 components are localized to the early endosome in cells activated with growth factor. The association of mTORC2 with early endosomes is responsible for local activation of AKT, which is critical for specific signal transduction through GSK-3β. Using inducible endosomal targeting lipid phosphatases, we found that endosomal PtdIns(3,4)P_2 provides a binding platform for mTORC2 to phosphorylate AKT at Ser473 on endosomes through mSIN, a PH domain-containing protein, and is dispensable for AKT phosphorylation at Thr308.

P1479/B612

Cell Cycle-dependent Regulation of Cyclic GMP-AMP Synthase (cGAS) Activity.

G. M. LoMastro, M. Levine, V. Gomez, A. Holland; Johns Hopkins University School of Medicine, Baltimore, MD.

In eukaryotic cells, DNA is sequestered in the nucleus and mitochondria. The presence of DNA in the cytoplasm triggers an immune response by activating the innate immune sensor cyclic GMP-AMP synthase (cGAS), which binds DNA from invading pathogens. cGAS localizes to self-DNA during mitosis and after mitotic errors that result in cytoplasmic DNA. The outcomes of cGAS localization in these different contexts are unique. Although nuclear envelope breakdown exposes chromosomes to cytosolic cGAS, mitotic cells do not produce cGAMP. Furthermore, cGAMP production in mitotic cell lysates cannot be stimulated by the addition of exogenous DNA in *vitro*. This indicates that regulatory mechanisms exist to downregulate cGAS-mediated cGAMP accumulation in mitosis. I will determine these regulatory mechanisms by identifying post-translational modifications and binding partners unique to cGAS in mitotic cells. In contrast, cGAS initiates an immune response following mitotic errors that result in aneuploid daughter cells. An euploidy contributes to tumorigenesis by providing a fitness advantage under specific circumstances that allows for the proliferation of cancerous cells. cGAS-driven recognition of aneuploid cells may allow for their removal. This hypothesis is being tested by monitoring aneuploidy levels and tumorigenesis in a cGAS knockout mouse model.

Low Birth Weight Correlates with Elevated Circulating Interferon-gamma and Vaccine Unresponsiveness Phenotype in Pigs.

S. Lipsit[1,2], J. Wilkinson[3,4], E. Scruten[2], A. Facciuolo[2], P. Griebel[2,5], T. Kusalik[6], T. Kusalik[6], G. Plastow[3], S. Napper[1,2]; [1]Department if Biochemistry, Microbiology, and Immunology, University of Saskatchewan, Saskatoon, SK, CANADA, [2]Vaccine and Infectious Disease Organization, University of Saskatchewan, Saskatoon, SK, CANADA, [3]Department of Agricultural, Food, & Nutritional Science, University of Alberta, Edmonton, AB, CANADA, [4]Illumina Centre, Great Abington, Cambridge, UNITED KINGDOM, [5]School of Public Health, University of Saskatchewan, Saskatoon, SK, CANADA, [6]Department of Computer Science, University of Saskatchewan, Saskatoon, SK, CANADA.

Vaccine-induced immunity to infectious disease can vary significantly between outbred animals and humans. An imals which fail to develop a protective response to vaccination remain at risk for infection while also endangering the population by compromising herd immunity. While a part of the solution is in the development of more effective vaccines, the ability to anticipate responsiveness prior to vaccination could also improve herd health by enabling alternate strategies for disease management. In the current investigation, piglets (n=117) were immunized with a commercial vaccine (Respisure-ONE), and the

vaccine-induced antibody titer was quantified through ELISA. Subpopulations of animals (n=6) representing the high and low extremes of responses were investigated to identify biomarkers and molecular mechanisms of vaccine responsiveness. Kinome analysis performed on peripheral blood mononuclear cells collected immediately prior to vaccination identified 53 differential phosphorylation events ($p<0.05$) between the high and low responders. Pathway over-representation analysis indicated elevated pro-inflammatory cytokine signalling in the low responders prior to vaccination. Consistent with this finding, low responders exhibited higher ($p<0.01$) levels of plasma interferon-gamma compared to the high responders. In addition, low responder pigs had lower ($p<0.01$) birth weights compared to high responders. Within the high and low responders, but not the entire population of animals, there were correlations between birth weight and antibody titer ($r=0.84$, $p<0.005$), and birth weight and plasma IFNγ ($r=-0.67$, $p<0.05$). The results presented suggest vaccine responsiveness may be impacted by birth weight and pre-vaccination cytokine concentrations, collectively strengthening the evidence for determining a biomarker of vaccine responsiveness.

N-terminal Cleavage of iκbα Ameliorates Er Stress in Cardiac Myocytes.

J. Park, E. Shin, K. Lee; CHA university, Pocheon, KOREA, REPUBLIC OF.

Canonical ER (endoplasmic reticulum) stress sensor, PERK (protein kinase-like kinase), involves cardiac hypertrophy and heart failure. The importance of IκBα/NF-κB signaling pathway in cardiac hypertrophy has been well known. Here, we describe the emerging role of IκBα on ER stress in cardiac hypertrophy. Proteasome inhibitor, MG132, targeted protein degradation by the ubiquitin-proteasome system (UPS) leads cleavage of IκBα at N-terminus as shown in our previous study with HSP90 inhibitor, geldanamycin, treatment. The N-term cleavage of IκBα by geldanamycin was inhibited when H9c2 cardiac myoblasts were treated with a caspase-8 inhibitor, z-IETD-fmk. Silencing of caspase-8 in geldanamycin-treated cells effectively blocks the cleavage of IκBα. To examine the role of cleavage of IκBα in ER stress, the putative caspase-8 cleavage site of Asp31 was mutated to Ala. Cleavage at N-term of IκBα (WT) under geldanamycin treatment did not occur in IκBα (D31A) and the cleavage-deficient mutant enhances the expression of PERK. These results suggest N-terminal cleavage of IκBα ameliorate ER stress in cardiac cells, providing an emerging role of IκBα cleavage for cardiac hypertrophy and heart failure.

Modeling Parietal Cell Physiology in Gastric Organoids Unraveled the Role of Alpk1-acapin Interaction.

D. Wang; University of Science and Technology, Hefei, CHINA.

Digestion in the stomach depends on acidification of the lumen. Histamine-elicited acid secretion is triggered by activation of the PKA cascade, which ultimately results in the insertion of gastric H,K-ATPases into the apical plasma membranes of parietal cells. Our recent study established gastric organoid model to delineate the molecular signaling underlying parietal cell secretion (Liu et al., 2019. *J. Mol Cell Biol.* doi: 10.1093/jmcb/mjz051; Yao & Smolka. 2019. *Gastroenterology*. 156, 2158-2173.). Here we show that acapin, an ARF6-ACAP4 interacting protein (Song et al., 2018. *J. Mol Cell Biol.*10, 559-572), interacts with ALPK1 kinase and elevates ARF6 GTPase gradient at the apical membrane for H,K-ATPase recruitment. Acapin physically interacts with ALPK1 and is a cognate substrate of ALPK during parietal cell activation. The phosphorylation site of acapin by ALPK1 was mapped by mass spectrometric

analyses. Importantly, phosphorylation of acapin is essential for acid secretion in parietal cells because either suppression of acapin or overexpression of non-phosphorylatable acapin prevents the apical membrane reorganization and proton pump translocation elicited by histamine stimulation. Mechanistically, phosphorylation of acapin enables its interaction with ACAP4-ezrin complex for apical establishment. Taken together, these results define a novel molecular mechanism linking the MST4-ALPK1-acapin signaling cascade to apical establishment and polarized acid secretion in gastric parietal cells.

Rho GTPase and DNA Repair: a New P53-dependent Road for IR-resistance of Glioblastomas?

Y. T. Magalhães, F. L. Forti; Institute of Chemistry, University of Sao Paulo, Sao Paulo, BRAZIL.

The Rho GTPases regulate several cellular processes related to tumor progression. The differential expression and activity of Rho GTPase family members dictates invasive strategies in glioblastoma (GBM), the most lethal cancer of the CNS, and are related to their malignancy. Despite aggressive therapies combining surgery and radio-chemotherapy, an effective treatment for these tumors remains obscure. We proposed that Rho GTPase pathway is modulating the genomic stability of GBM and their resistance to γ-radiation (IR) in a p53-dependent way. U87-MG (p53 wild-type) and T98G (p53 mutated) cells were subjected to Rho pathway inhibition by C3 toxin, knockdown of Rho pathway components mDia-1, Profilin-1 and MYPT1 or inhibition of ROCK by Y-27632 inhibitor. Comet assays showed that Rho inhibition by C3 and knockdown of mDia-1 and Profilin-1 led to increased DNA damage breaks and a delayed DNA repair after IR in U87-MG but not in T98G cells. The knockdown of MYPT1 reduced the amount of DNA breaks in both cells. The inhibition of ROCK sensitized the U87-MG while increased the resistance of T98G cells to IR. Immunofluorescence showed that foci formation of γH2AX and 53BP1 was compromised by Rho pathway inhibition and enhanced by its activation, with a pronounced effect in U87-MG cells. The impairment of Rho pathway increased the levels of phospho-Chk2 and decreased the phosphorylation of ATM, BRCA1 and NBS1 after IR in U87-MG cells only. Specific functional assays for the HR and NHEJ repair pathways showed that the impairment of Rho signaling decreased the DSBs repair by NHEJ only in U87-MG cells, while affected the HR repair in both cells. Conversely knockdown of MYPT1 increased the repair by HR in both cells while ROCK inhibition increased HR repair in T98G and had the opposite effect in U87-MG cells. These results indicate a striking regulatory relationship between Rho GTPase, DDR and HR/NHEJ repair pathways. Bioinformatics analysis in public databases indicated that high expression of RHOA and RHOC, as well as some of their downstream components, is closely related to aggressiveness of gliomas and a shortened patient survival. Comparative analysis of Rho activity in cells expressing wild-type or different p53-mutants showed that p53 mutated cells were more resistant to IR after Rho inhibition. An alysis of somatic mutations from databases showed that U87-MG cells has mutations in genes involved in DNA repair, actin remodeling dynamics and cell cycle regulation. Pearson correlation analysis showed that expression of this mutated genes and rho gene are positively correlated in GBM patient's samples. This work thereby shows the Rho pathway might be a fragile point in the resistance of gliomas against the usual therapies, being this effect very likely dependent on p53 transcriptional activities.

P1484/B617

Extraction of Active Rhogtpase by Rhogdi Regulates Rhogtpase Patterning.

A. Golding[1], I. Visco[2], P. Bieling[2], W. Bement[1]; [1]University of Wisconsin-Madison, Madison, WI, [2]Max Planck Institute of Molecular Physiology, Dortmund, GERMANY.

The subcellular localization and activity of the RhoGTPases are tightly regulated to ensure proper spatial control of processes such as cytokinesis, cell migration and cell wound repair. Classically, the RhoGTPases are characterized as membrane-associated molecular switches cycling between active, GTP-bound and inactive, GDP-bound states. The transitions between these two states are thought to be predominantly controlled by RhoGTPase regulators - GEFs and GAPs - that modulate interactions with the associated nucleotide. Yet at any given moment, 90-95% of RhoGTPases are not associated with membranes, but maintained in a soluble form by a third regulator named RhoGDI. RhoGDI is generally viewed as a passive shuttle for inactive RhoGTPases. Our current understanding of RhoGTPase:RhoGDI dynamics has been limited by two major experimental challenges: the direct visualization of the RhoGTPases in *vivo and* the reconstitution of the cycle in *vitro*. To study the regulation of RhoGTPases by RhoGDI, we developed methods to directly image vertebrate RhoGTPases both in *vivo* in the *Xenopus* oocyte wound repair model or on lipid bilayers *in vitro*. Using these tools in parallel, we identified pools of both active and inactive RhoGTPase associated with the membrane. We further showed that RhoGDI can actively extract not only inactive, but also active RhoGTPases, which contributes to the spatial regulation of RhoGTPase activity around wounds. In contrast to the textbook model of the RhoGTPase cycle, these results indicate that RhoGDI is more than a passive shuttle for inactive RhoGTPases; instead, it actively contributes to spatiotemporal patterning by removal of active RhoGTPases from the plasma membrane.

P1485/B618

Bnip-2, a Versatile Scaffold in Regulating Small Gtpases.

D. Wong, T. Chew, M. Pan, B. Low; Mechanobiology Institute Singapore, Singapore, SINGAPORE.

Despite being implicated in various physiological and pathological processes, how activity of Rho GTPase is regulated under different cellular contexts remains unclear. In some cells or systems, active Rho could activate or suppress cell morphogenesis and cell migration, raising the possibility that Rho alone is insufficient to exert such effects and that it may require other helper proteins to coordinate its function. For example, generation of force on extracellular matrix (ECM) through actin-myosin contractility and stress fibre is linked to active RhoA. Here, we further report that BNIP-2 that carries a highly conserved BCH domain, serves as a functional scaffold that carries a novel RhoA-interacting motif to exert a clear and effective spatial temporal activation of RhoA during cell morphogenesis. On the other hand, absence of BNIP-2 reduces RhoA activity, force generation on the ECM and focal adhesion dynamics. Functionally, changes in the BNIP-2 expression level could modulate cancer cell spreading and migration, thus providing further insights to the regulation of cell motility and metastasis.

P1486/B619

TC10 GTPase Regulates Matrix Degradation in Breast Tumor Invadopodia.

M. Huelsemann, S. Donelly, S. P. Mao, P. Verkhusha, J. E. Segall, L. Hodgson; Albert Einstein College of Medicine, New York, NY.

Cancer invasion utilizes specialized actin-rich protrusions known as invadopodia. Rho family p21 small GTPases regulate invadopodia functions, including degradation of extracellular matrix through recruitment of membrane-type 1 metalloproteinase (MT1MMP). We are investigating the role of TC10 GTPase as a regulator of MT1MMP function at tumor invadopodia. TC10 GTPase is a member of the Rho family p21 small GTPases. GTPases are molecular switches which cycle between an activated (GTP-bound) state or inactivated (GDP-bound) state and are critical for regulating cell motility and migration. While TC10 has been well-studied in other diseases, it remains understudied in relation to cancer. From our current studies, we demonstrate that TC10 regulates the ability of tumor cells to degrade the extracellular matrix at invadopodia. TC10 controls the vesicular trafficking and MT1MMP localization and its surface presentation at invadopodia, important for matrix degradation. We show directly the spatiotemporal coordination of TC10 activities at invadopodia in breast cancer cells through developing new generations of FRET biosensors for TC10. Our FRET biosensors revealed the dynamics of TC10 activity in tumor cell invadopodia structures. Moreover, our results suggest regulation of TC10 activity by putative upstream regulator GAP to control spatial and temporal locations of MT1MMP function at invadopodia. Importantly, mechanisms driven by TC10 directly impact breast adenocarcinoma invasion, dissemination and metastasis in mice. Our results point to TC10 as a new regulator of tumor metastatic cascade, important for controlling the ability of tumors to efficiently spread to distant sites.

Crosstalk of ROCK2 with the Dna Repair Machinery Regulates Radioresistance in Cervical Cancer.

A. PRANATHARTHI HARAN, 560034[1], P. Thomas[2], A. H. Udayashankar[2], S. Bangalore Suresh[2], S. Krishna[3], C. R. Ross[2], S. Srivastava[2]; [1]ST.JOHN'S MEDICAL COLLEGE HOSPITAL-NATIONAL CENTRE FOR BIOLOGICAL SCIENCES, Bangalore, INDIA, [2]ST.JOHN'S MEDICAL COLLEGE HOSPITAL, Bangalore, INDIA, [3]NATIONAL CENTRE FOR BIOLOGICAL SCIENCES, Bangalore, INDIA.

Crosstalk of ROCK2 with the DNA repair machinery regulates radioresistance in cervical cancer

Radiation is the most effective anticancer therapy in cervical cancer. Reportedly high relapse rates are associated with therapy in this cancer. In our study, we have identified ROCK2 a downstream effector of RhoC to contribute to the radioresistance in the tumor cells. ROCK2 increasingly localized to the nuclear compartment post-irradiation. The irradiated cells displayed an enhanced DNA damage repair response mainly of the NHEJ pathway. Overexpression of ROCK2 is shown to confer resistance, while its inhibition caused a reversal of the resistance phenotype in these cells. A transcriptomic analysis revealed that the ROCK2 high cells, live sorted using a novel technique, showed enrichment of genes of the DNA repair, survival and cell cycle pathways. Our data suggests an interaction between ROCK2 and pH2Ax involved in foci formation induced in response to irradiation. Additionally, ROCK2 inhibition resulted in a reduction in the number foci formed by pH2Ax and diminished levels of the MRE11 and RAD50 proteins of the MRN complex, following irradiation. ROCK2 and the DNA repair proteins expression analyzed in clinical sections showed an upregulation. Further, inhibition of ROCK2 in the clinical sample derived cells, in *vitro,* sensitized the tumor cells to radiation. Thus, our data suggests crosstalk of ROCK2 with the

DNA repair proteins modulates radioresistance in cervical cancer and could a potential target for biomarker development.

P1488/B621

GTPase Steering by an Enzymatic Corral.

T. Burke, N. Davenport, W. Bement; the University of Wisconsin at Madison, Madison, WI.

Dynamic arrays of actin filaments and myosin-2 ("actomyosin") drive a broad variety of dynamic biological processes ranging from cell division to wound repair. Such arrays are controlled by the Rho GTPases, proteins that exert their effects on actomyosin by stimulating "effector" proteins when in their active (GTP-bound) state. Traditionally, information flow from the Rho GTPases to the cytoskeleton has been viewed as linear, with GTPase activators (GEFs) stimulating a given GTPase, which then activates effectors which, in turn, modify actomyosin. Subsequently, the process is terminated by inactivation of GTPases by inhibitor proteins (GAPs). However, it is becoming apparent that control of actomyosin arrays entails rapid flux of GTPases from the active to inactive stages that is somehow subject to continual modulation via feedback from the actomyosin itself. Here we test a feedback model in which circular, ring-like waves of Rho activity that direct cell wound repair in the Xenopus oocyte model are driven forward by a self-organizing "enzymatic corral" that forms at their trailing edge. Results indicate that 1) trailing edge Rho inactivation depends on an F-actin binding protein Cortactin, 2) Cortactin exerts its effects on Rho activity by serving as a binding site for multiple GAPs (RG1, RG8, and P190RhoGAP), and 3) proper Cortactin and GAP localization/corral formation is F-actin dependent. Cortactin, P190RhoGAP, and RG1/8 localize behind the Rho zone, perfectly situated to facilitate the trailing-edge inactivation. As predicted, Cortactin and the GAPs functionally affect Rho levels. Over-expression of P190RhoGAP or RG1/8 dramatically and selectively diminishes the Rho zone. Expression of a Cortactin truncation missing its SH3 domain (implicated in GAP recruitment) causes decreased GAP localization and increased Rho levels. F-actin assembly, most likely mediated by the GTPase Cdc42, plays a crucial role in corral formation as well. Inhibition of F-actin polymerization via Latrunculin B treatment imparts gaps in the Cortactin, P190RhoGAP and RG1/8 rings, allowing active Rho to "escape" the corral and preventing wound closure. Additionally, recruitment of an actin depolymerization factor (DeActs) upon wounding displaces the F-actin ring outward, away from wound center. This too causes an outward spreading of active Rho and wound healing failure.

P1489/B622

Cdc42 GEF Gef1 Regulates Rho1 Activation During Cytokinesis**.**

U. Onwubiko, E. Koory, A. Mitoubsi, M. Das; University of Tennessee, Knoxville, TN.

Udo Onwubiko[1], Emma Koory[1], Ahmad Mitoubsi[1], and Maitreyi Das[1] [1]Department of Biochemistry & Cellular and Molecular Biology, University of Tennessee, Knoxville, TN, USA. Email: uonwubik@vols.utk.edu **Abstract** in cytokinesis, key steps ensure that the cytoplasm is properly partitioned, to yield two new, daughter cells after mitosis. We use *Schizosaccharomyces pombe* to understand the coordination of these cytokinetic steps. In *S. pombe*, septum formation is required for furrow formation. During anaphase the conserved GTPase Cdc42 is activated by the Guanine Nucleotide Exchange Factor (GEF) Gef1 to promote recruitment of the septum synthesizing enzyme Bgs1 at the division site and allow timely onset of ring constriction and septum formation.[1] Gef1 is also involved in the spatial organization of proteins along the actomyosin ring thus promoting centripetal furrowing and

septum formation.[2] We investigated the initiation of Bgs1 septum synthesizing activity during cytokinesis. Bgs1 activity requires Rho1 GTPase activity. Rho1 is activated by the essential GEF Rgf3, which localizes to the division site immediately after actomyosin ring assembly[3-5]. Using a mNeonGreen-tagged Rho-probe, we find that Rho1 is activated later, after completion of anaphase B. However, in *gef1Δ* mutants, the Rho-probe localizes prematurely, immediately after ring assembly. Interestingly Rgf3 localization is unchanged in both *gef1*$^{+}$ and *gef1*Δ cells. The p21-activated kinase has been implicated in premature initiation of ring constriction[7]. We find that premature Rho1 activation in *gef1* mutants is partially rescued by the *pak1* mutant *orb2-34*. Our results suggest that Gef1 inhibits Rho1 activation during anaphase at least in-part through Pak1. Thus, while Gef1 promotes Bgs1 recruitment during anaphase, it prevents early Bgs1 activity—and subsequent septum formation—likely by inhibiting Rho1 until chromosome segregation completes. Future studies will probe the mechanistic details of this regulation.

ARHGAP17, a Cdc42-Specific GAP, Localizes to Invadopodia and Regulates Their Turnover.

G. Kreider-Letterman, A. Castillo, F. Aftab, R. Garcia-Mata; University of Toledo, Toledo, OH.

Cancer cells can invade through tissues and metastasize by forming actin-rich membrane protrusions called invadopodia. The formation of invadopodia involves a dramatic rearrangement of the actin cytoskeleton, a process that is regulated by the Rho family of small GTPases. Rho GTPases cycle between an inactive GDP-bound and an active GTP-bound form. RhoGEFs (guanine nucleotide exchange factors) catalyze the activation of Rho proteins, whereas RhoGAPs (GTPase activating proteins) mediate their inactivation. Since RhoGAPs play a critical role in the termination of signal transduction, mutations in genes encoding RhoGAPs have drastic consequences and underlie several human diseases including cancer. However, compared with RhoGEFs, which have been studied more extensively, there is significantly less known about RhoGAPs, especially regarding their role in cancer progression and metastasis. Here, we have identified a RhoGAP, ARHGAP17, as a potential key regulator of invadopodia in both triple negative breast cancer (SUM159 and MDA-MB-231) and Head and Neck Squamous Cell Carcinoma (UMSCC1 and SCC61) cells. Our results show that ARHGAP17 localizes to invadopodia and negatively regulates their turnover. We also show that, in these cells, ARHGAP17 has GAP specificity for the Rho GTPase Cdc42. Based on our results, we propose that ARHGAP17 is targeted to invadopodia where it promotes invadopodia disassembly by locally inactivating Cdc42.

Connectivity an alysis of GEF/GTPase Networks in Living Cells.

D. J. Marston[1], M. Vilela[2], J. Ren[1], G. Glekas[1], M. L. Azoitei[1], G. Danuser[2], J. Sondek[1], K. M. Hahn[1]; [1]University of North Carolina-Chapel Hill, Chapel Hill, NC, [2]University of Texas Southwestern Medical Center, Dallas, TX.

Fluorescent biosensors are powerful tools to map the activation of signaling molecules in space and time. However, it has not been possible to quantify how different activation events, visualized at specific times and subcellular positions, affect one another or contribute to cell behavior. Here we demonstrate the use of partial correlation analysis to parse out such relationships from multiplexed biosensor imaging data. We show that these approaches can quantify the fraction of a Rho GTPase signal that results from a particular RhoGEF, the relative contribution a RhoGEF makes to each of the downstream

GTPases it interacts with, and importantly determine these relationships with respect to output, e.g. cell motility vs other downstream functions. First, we produced a new series of biosensors to visualize activation patterns of six diverse Dbl family RhoGEFs. We then focused on a pair of these, Vav2 and Asef, and correlated their activity with edge dynamics. To allow simultaneous imaging, we then red-shifted the emission wavelengths of GTPase biosensors and used these new sensors to image and correlate the activation of GEFs and GTPases concurrently in the same cell. Using partial correlation analysis, we identified when and where the GEF Asef regulates the GTPases Cdc42 and Rac1 to control cell edge dynamics. We found that Asef activity is strongly coupled to cell protrusion dynamics as compared to Vav2. Furthermore, Asef strongly activates Cdc42 signals related to cell edge movement. In contrast, the interaction between Asef and Rac1 is weaker and probably indirect, and not related to edge movement. This approach exemplifies a powerful means to elucidate the real-time connectivity of signal transduction networks.

P1492/B625

Induction of Cortical Excitability in Immature *Xenopus* Oocytes.

A. Michaud[1], G. von Dassow[2], A. B. Goryachev[3], M. Leda[3], W. M. Bement[1]; [1]Laboratory of Cell and Molecular Biology, University of Wisconsin-Madison, Madison, WI, [2]Oregon Institute of Marine Biology, University of Oregon, Charleston, OR, [3]Centre for Synthetic and Systems Biology, University of Edinburgh, Edinburgh, UNITED KINGDOM.

During cytokinesis in amphibian and echinoderm embryos, the cell cortex undergoes a dramatic, cell cycle-regulated change in its dynamics: it spontaneously generates propagating waves of Rho activation and inactivation and F-actin assembly and disassembly. The waves are proposed to result from Rho autoactivation, which is dependent on the Rho Guanine Nucleotide Exchange Factor (GEF) Ect2, coupled with delayed, F-actin-dependent, Rho autoinhibition. We have found that overexpression of a mutant form of Ect2 induces excitability in immature oocytes, which normally do not display cortical excitability. However, this excitability is low level and short-lived. In contrast, co-expression of the mutant Ect2 and a Rho GTPase Activating Protein (GAP) results in cortical excitability that is robust, long-lived, and characterized by remarkable spiral wave trains throughout much of the cortex. Using this model system, we have begun to uncover other potential regulators of cortical excitability and place them in the cycle. Diaphanous related formin 3 (diaph3/mDia2) displays excitable dynamics and appears to be the missing link between Rho activation and F-actin polymerization. An illin, a conserved cytokinetic regulator protein, also displays excitable dynamics in the immature oocyte model and appears to be involved in negative regulation of Rho dynamics. Together, these results indicate that both Rho GEFs and GAPs are needed to ensure a stable, excitable cycle, and also that the oocyte is a powerful model for understanding cortical excitability.

Extracellular Vesicle Signaling

Centrosome Amplification Promotes Extracellular Vesicles Secretion.

S. Godinho, S. Adams, J. Csere; Barts Cancer Institute, Queen Mary University London, London, UNITED KINGDOM.

Centrosome amplification is a recurrent feature of human tumours and enforced centrosome amplification plays a role in tumour initiation and progression. However, centrosome amplification occurs only in a subset of cancer cells and thus, partly due to this heterogeneity, the contribution of centrosome amplification to tumours in unknown. Our recent work uncovered an unexpected function for these abnormalities by altering secretion, suggesting a broader role in tumourigenesis. We found that centrosome amplification is sufficient to induce secretion of small extracellular vesicles secretion (sEVs) in pancreatic cancer cells. This is due to a stress response caused by increased reactive oxygen species (ROS). Blocking ROS in these cells prevents sEVs secretion. Our data indicates that increased ROS prevents efficient lysosome function and degradation of the multivesicular bodies, culminating with increase secretion of sEVs of endocytic origin. Interestingly, sEVs secreted by cells with extra centrosomes robustly activate pancreatic stellate cells, suggesting that they contain different cargoes. SILAC analyses identified several unique proteins that are present in sEVS secreted by cells with amplified centrosomes. We are now investigating the sEVs cargoes that could be responsible for PSC activation. Because activation of pancreatic stellate cells creates a strong fibrotic environment that is characteristic of pancreatic cancer, our data suggests that cancer cells with extra centrosomes could play important roles in the tumour microenvironment.

P1494/B627

Identification of Exosome Associated Factors That Protect Against Aminoglycoside Induced Hair Cell Death.

T. Q. Costain[1], L. Wang[1], A. M. Breglio[1], L. A. May[1], N. C. Welsh[1], D. E. An derson[2], M. Barzik[1], L. L. Cunningham[1]; [1]National Institute on Deafness and Other Communication Disorders, Bethesda, MD, [2]National Institute of Diabetes and Digestive and Kidney Diseases, Bethesda, MD.

Exosomes are cell-derived extracellular vesicles that facilitate cell-cell communication. They range from 50-150 nm in size, possess a lipid bilayer, and contain a distinct combination of proteins, lipids, and nucleic acids. Exosomes can induce functional changes in target cell behavior, either through interaction with cell surface receptors or fusion with the plasma membrane. We have recently shown that exosomes play a role in intercellular communication in the inner ear. Exosomes derived from heat-shocked utricles protect hair cells from aminoglycoside-induced ototoxicity and exosome-associated heat shock 70 kDa protein (HSP70) is required for this pro-survival effect. Given the small yield of exosomes from mouse utricles, we are expanding our studies to include cell line-derived exosomes. Here, we are further investigating the protective role of HSP70 as well as the functions of other exosome-associated proteins involved in exosome targeting and delivery, such as integrins. Whole-organ cultures of utricles from adult mice were used as a model system, and multiple cell lines were analyzed for exosome secretion. Exosomes were isolated via centrifugal ultrafiltration, quantified by nanoparticle tracking analysis, and applied to utricles to investigate their ability to inhibit neomycin-induced hair cell death. Tandem mass spectrometry and Western blot analysis were used to identify and

compare exosome content from inner ear tissue and cell lines. Native exosomes derived from an epithelial cancer cell line (CT26) protected hair cells from neomycin-induced hair cell death in a concentration-dependent manner. Both heat shock and exogenous expression of HSP70 increased the amount of HSP70 in CT26 exosomes. Comparative mass spectrometry analyses showed that CT26-derived exosomes contain multiple members of the HSP70 protein family. Exosomes derived from utricles and CT26 cells contain similar repertoires of integrin family members, which may play a role in targeting exosomes to inner ear cell types. The identification of otoprotective exosomes derived from cell lines enables the development of precision-engineered exosome therapeutics. Compared to inner ear tissue, cell lines can yield large quantities of exosomes and can be subjected to biological manipulation aimed at optimizing exosome content. In addition, analysis of exosome cargo established an inventory of factors that may be required for the pro-survival effect in the inner ear. Using this information, we intend to engineer cell line-derived exosomes to systematically investigate which exosome-associated factors are necessary and sufficient to protect hair cells.

P1495/B628

Exosomes Mediate Sensory Hair Cell Protection in the Inner Ear.

M. Barzik[1], A. M. Breglio[1], L. A. May[1], N. C. Welsh[1], S. P. Francis[1], T. Q. Costain[1], L. Wang[1], D. E. Anderson[2], R. S. Petralia[1], Y. Wang[1], T. B. Friedman[1], M. J. A. Wood[3], L. L. Cunningham[1]; [1]NIDCD/NIH, Bethesda, MD, [2]NIDDK/NIH, Bethesda, MD, [3]University of Oxford, Oxford, UNITED KINGDOM.

Hair cells are the mechanosensory receptors of the inner ear, responsible for hearing and balance. Hair cell death and consequent hearing loss are common results of treatment with ototoxic drugs, including the widely-used platinum chemotherapeutics or aminoglycoside antibiotics. Induction of heat shock proteins (HSPs) confers protection against aminoglycoside-induced hair cell death via paracrine signaling that requires extracellular Heat Shock 70 kDa Protein (HSP70). Here we investigated the mechanisms underlying this non-cell-autonomous protective signaling in the inner ear. We found that in response to heat stress, inner ear tissue releases exosomes, nanometer-sized endosomally-derived secretory vesicles that mediate intercellular communication by delivering protein, lipid, and nucleic acid cargo. Unique surface molecules allow exosomes to interact with target cells either by internalization or by signaling through cell surface receptors, and this can alter target cell function and fate. Tandem mass spectrometry analysis showed that exosomes secreted from heat-shocked inner ear tissue carry HSP70, as well as a variety of classical exosome markers and other proteins. Isolated inner ear exosomes were sufficient to improve the survival of hair cells exposed to the ototoxic aminoglycoside antibiotic neomycin, while depletion of exosomes from the extracellular environment or inhibition of exosome biogenesis abolished the protective response commonly induced by heat stress. A conditional knock out mouse model was used to demonstrate that expression of the known receptor for HSP70, Toll-like receptor 4 (TLR4), on sensory hair cells was necessary for the protective effect of exosomes, and a proximity ligation assay showed that exosomal HSP70 interacted with TLR4 on hair cells. Taken together, our results reveal a previously-undescribed mechanism of pro-survival intercellular communication in the inner ear and show that exosomes mediate non-autonomous hair cell survival under ototoxic conditions. These exosomes may hold potential as a new class of therapeutics for hearing loss.

P1496/B629

Fibronectin in Extracellular Vesicles from Hepatocytes Mediates Target Cell Binding.

X. Li[1], R. Chen[1], S. Kemper[1], **D. Brigstock**[1,2]; [1]Nationwide Children's Hosp, Columbus, OH, [2]The Ohio State University, Columbus, OH.

Background: Extracellular vesicles (EVs) are emerging as important mediators of intercellular signaling in the healthy and diseased liver. Recently we showed that cell surface integrins mediate the cellular binding of EVs from liver cells such as hepatocytes or hepatic stellate cells. In our quest to identify potential integrin ligands in EVs, we now report the presence of fibronectin (FN1) in hepatocyte EVs and its requirement for EV binding to target cells. Our findings point to a new role for FN1 in mediating binding interactions between hepatocyte EVs and hepatic target cells. We also show that serum FN is, in part, EV-associated. **Methods and Results:** EVs were collected by differential ultracentrifugation of serum-free conditioned medium from mouse AML12 hepatocytes. These EVs, termed EV-Hep, were 50-500nm in diameter as assessed by nanoparticle tracking analysis and were positive by Western blot analysis for EV-associated proteins such as CD63, CD9, and Flotillin-1. Proteomics showed that FN1 was the most abundant protein in EV-Hep. Sequence analysis of EV FN1 confirmed its identity as principally the plasma form of FN1 which is well characterized as a hepatocyte product (as compared to the cell-associated form of FN1 which is produced by numerous cell types). The abundant presence of FN1 in EV-Hep was verified by Western blot and co-immunoprecipitation with EV proteins. After iodixanol isopycnic ultracentrifugation, FN1 co-sedimented with EV-Hep at a buoyant density of approx. 1.15 g/ml. FN1 knockout AML-12 cells (FN1KO) were generated using CRISPR-cas9 and the EVs produced from these cells (EV-Hep^{FN1KO}) were used for functional analysis. Yield and size-range for EV-Hep^{FN1KO} were similar to those of EV-Hep, indicating that FN1 is dispensable for EV biogenesis. Fluorophore-labeled EV-Hep bound to FN1KO cells as efficiently as parental cells whereas the binding of EV-Hep^{FN1KO} to either target cell was highly reduced. These results suggest that vesicular but not cellular FN1 is required for binding of EV-Hep to target hepatocytes. As compared to EV-Hep which we have reported to be anti-fibrogenic for HSC, EV-Hep^{FN1KO} showed reduced binding to HSC and reduced ability to attenuate fibrogenic gene expression (CCN2, collagen 1α1). Finally, FN was also present in EVs from primary mouse hepatocytes, human hepatoma HepG2 cells, and human or mouse serum. **Conclusions:** FN1 is abundantly associated with hepatocyte-derived EVs and is required for EV binding to and downstream signaling in target hepatocytes or HSC. EVs are potentially important vehicles for FN transport intercellularly and in the circulation.

Analytical Ultracentrifugation and Super-Resolution Microscopy Identify Distinct Populations of Extracellular Vesicles: First Steps Toward Discovery of Signaling EV-omics.

I. Nikonorova, J. Wang, G. An drowski, M. Barr; Rutgers University, Piscataway, NJ.

Autosomal dominant polycystic kidney disease (ADPKD) is characterized by abnormal formation of cysts in the lining of renal tubules. 95% of ADPKD cases are caused by mutations affecting ciliary TRP polycystin channel complex formed by two proteins, PKD1 and PKD2 (Polycystic Kidney Disease 1 and 2). In healthy kidney, the polycystins localize to renal cilia. Mutations that abrogate ciliary localization of PKD2 (yet preserve its channel function) also cause cysts. Beside cilia, PKD2 is also found in other subcellular locations including extracellular vesicles (EVs) of human urine. Whether these PKD2-carrying EVs are of ciliary origin and what role they play in healthy and diseased kidney remains unknown. PKD2

is evolutionary conserved across all members of Eumetazoa. In the model organism *C. elegans*, PKD2 is exclusively expressed in the ciliated male-specific neurons and is trafficked to cilia and EVs. The C. elegans PKD-2 containing-EVs play signaling role in inter-organismal communication. Evolutionary conservation and similarity in cellular localization of PKD2 among *C. elegans* and mammals suggest that their network of molecular interactions is likely to be conserved. We propose that PKD2 plays distinct roles in cilia and ciliary EVs. This work aims to identify PKD2-associated EV proteome, transcriptome, and metabolome of *C. elegans to* understand the role of PKD2-carrying EVs in inter-organismal signaling. We established a pipeline for fluorescent labeling and tracking single cell specific EV cargoes in a living animal using super-resolution microscopy. This innovative approach also enables identification of the specific EVs during biochemical enrichment procedures and allows for streamlined optimization. Our results of buoyant density centrifugations in iodixanol gradients suggest that there are two populations of PKD2-carrying EVs that correspond to the densities of 1.12 and 1.14 g/mL. We are currently characterizing these two distinct populations using transmission electron microscopy and refining our enrichment protocol for protein identification by mass spectrometry, sequencing of their RNA cargoes and metabolome analysis. Identification of molecular mediators of the PKD2 signaling will inform on the interactome of human PKD2 and its function in cilia versus EVs.

Macrophage Primary Cilium Lengthening Inhibits Osteoclastogenesis.

M. M. Sutton, C. R. Jacobs; Columbia University, New York, NY.

Osteoporosis is a metabolic bone disease characterized by low bone density and deterioration of bone architecture that ultimately increases the risk of fragility fractures. The physical impairment is compounded by the insufficiency of prophylaxis and treatment options devoid of negative side effects. As a result, there is a need to discover better therapeutic solutions to address this disease. Our lab and others have established the osteocyte primary cilium - a mechanosensing, antenna-like organelle - as a promising pharmaceutical target to exploit the body's natural anabolic response to physical loading to maintain bone health. However, little is known about the potential impact of targeting the primary cilium in relation to osteoclasts, the bone resorbing cell. Thus, the *objective* of this study is to determine the presence or absence of osteoclast primary cilia and determine whether or not the macrophage primary cilium serves a functional role in osteoclastogenesis. We cultured RAW 264.7 cells in DMEM supplemented with 10% FBS and 1% P/S, and added 30 ng/mL of macrophage colony stimulating factor (m-CSF) and 100 ng/mL of receptor activator of nuclear factor-Kappa B ligand (RANKL). We performed double immunocytochemistry to observe the centrosomes, primary cilia, and cortical actin of both macrophages and osteoclasts. Next, we treated one group with 10µM fenoldopam mesylate (a known cilia-lengthening agent) for 16 hours. Cells grew for an additional 4 days prior to fixation or lysis. RNA isolation was performed using TriZol, followed by standard curve RT-qPCR to quantify relative measures of tartrate resistant acid phosphatase and cathepsin K. After five independent stains of undifferentiated RAW 264.7 cells, we counted a total of 484 cells and noted a 49% cilia incidence in macrophages, concluding that these osteoclast precursors do in fact possess primary cilia. However, almost none of the differentiated osteoclasts possessed a primary cilium. In addition, we found that cells treated with fenoldopam had statistically significantly lower expressions of ACP5 and CTSK than the vehicle control. We have concluded that while primary cilia are present on macrophages, they are absent from

osteoclasts themselves. Furthermore, inhibiting macrophage primary cilia resorption downregulates osteoclastogenesis, indicating that resorption may be a necessary step for differentiation to occur. Although it is currently unclear, elucidating the role of primary cilium disassembly will shed light on the process of osteoclast formation and function. Lastly, our findings indicate that the primary cilium as a therapeutic target for bone disease may in fact offer a dual beneficial approach to both promote bone formation and downregulate osteoclast activity.

P1499/B633

Proteomic Identification of Centrin-like Proteins from the Cytoskeleton of the Ciliated Protozoan *Spirostomum*.

J. E. Honts[1], S. Bhamla[2]; [1]Drake University, Des Moines, IA, [2]Georgia Institute of Technology, Atlanta, GA.

Some species of ciliated protozoa, such as *Vorticella* or *Spirostomum*, undergo very rapid contractions that do not require ATP and are triggered by cytosolic Ca^{2+}. These contractions are mediated by specialized cytoskeletal structures, called spasmonemes or myonemes, which are composed of bundles of thin filaments in close association with membrane-bound Ca^{2+} stores. To better understand the structure and regulation of these contractile assemblies, methods were developed to prepare cytoskeletal residues from *Spirostomum*. Detergent-based methods to isolate the cytoskeletal framework of this large ciliate were initially frustrated by the fragility of the extracted cells. It was found, however, that chemical cross-linking prior to detergent extraction stablized the cytoskeletal structures, while still removing most other cellular contents (confirmed using DIC microscopy). Proteins from pelleted cytoskeletal residues were analyzed by gel electrophoresis and two major protein bands were excised for analysis by mass spectrometry using the published *S. semivirescens* transcriptome data (Hines et al., 2018). An alysis of the mass spectrometric data revealed the presence of three different EF-hand calcium-binding proteins, which were homologous to centrins and *Paramecium* infraciliary lattice proteins. Genes encoding these putative components of *Spirostomum* myonemes are being synthesized for expression in bacteria with the goal of reconstituting this contractile apparatus in *vitro*.

Dynamic Basal Body-associated Striated Fibers Promote Ciliary Array Organization through Basal Body Coupling and Cortical Interactions.

A. Soh[1], T. van Dam[2], A. Stemm-Wolf[1], A. Pham[1], G. Morgan[3], E. O'Toole[3], C. Pearson[1]; [1]University of Colorado an schutz medical campus, Aurora, CO, [2]Utrecht University, Utrecht, NETHERLANDS, [3]University of Colorado at Boulder, Boulder, CO.

Multi-ciliary arrays promote cellular motility and fluid flow using the polarized and coordinated beating of hundreds of motile cilia. Basal bodies (BBs) nucleate and position cilia into longitudinal rows. Cilia beat in an asymmetric pattern and produce forces that are imposed upon BBs and the cell cortex. Even in the face of these forces, BBs maintain their position and polar orientation. To promote BB anchorage and orientation, each BB possesses appendages, including striated fibers (SFs) and bundles of microtubules that establish BB coupling. Mutants resulting in shorter SFs cause BBs to disorient. Here, we show that disoriented BBs in *Tetrahymena* multi-ciliary arrays are reoriented into organized ciliary rows when the length of the SF is restored. This reveals that multi-ciliary arrays possess error correction mechanisms to resolve BB disorientation. EM tomography and super resolution fluorescence microscopy were used to show that BBs within the same longitudinal rows are coupled by interactions between the

SFs and post-ciliary microtubule bundles. In addition, SFs adopt different length states by their shrinkage and growth in response to reduced and elevated ciliary forces, respectively. This promotes dynamic BB coupling and cortical interactions that are responsive to environmental forces. An alogous to vertebrate SFs, *Tetrahymena* SFs are multiprotein macromolecular complexes. They are composed of a network of at least eight protein components, belonging to the SF-assemblin protein family, that exhibit distinct and overlapping localization profiles within the SF structure. Components associated with the base of the SF control both steady state SF length and high ciliary force-induced SF elongation. Thus, the dynamic regulation of SFs promotes BB and cortical interactions to organize and couple cilia within ciliary arrays. This enables efficient generation of hydrodynamic flow to serve cellular and extracellular motility.

T-cell Priming Is Enhanced by Maturation-dependent Stiffening of the Dendritic Cell Cortex.

D. Blumenthal[1,2], J. K. Burkhardt[1,2]; [1]Children's Hospital of Philadelphia, Philadelphia, PA, [2]Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA.

Priming of T-cell responses by dendritic cells (DCs) is essential for protective immunity against pathogen invasion and cancer. T cell activation involves multiple receptor-ligand interactions occurring in concert at a specialized cell-cell contact site termed the immunological synapse (IS). Recently, it has become clear that T cell activation at the IS depends on the application of mechanical forces exerted by the T-cell actin cytoskeleton. Since the DC acts as the substrate for T cell activation, we reasoned that the biophysical properties of the DC cortex are likely to provide important mechanical cues. While conventional imaging approaches have greatly advanced our understanding of T-DC interactions, they do not provide information on the biophysical properties of the cells and their role in relaying mechanical cues at the IS. We therefore turned to atomic force microscopy to measure the cortical stiffness of DCs. We show that as part of the maturation process induced by inflammatory stimuli, DC cortical stiffness is increased 2-3 fold, in an actin cytoskeleton dependent manner. Using pharmacological inhibitors and DCs from KO mice, we identify several actin regulatory pathways downstream of Rho GTPases that govern the maturation-associated modulation of DC stiffness. By manipulating the stiffness of T-cell substrates using stimulatory hydrogels or DCs expressing mutant cytoskeletal proteins, we show that increasing stiffness over the range observed for DC maturation lowers the agonist dose needed to initiate T-cell activation. Thus, DC cortical stiffness is a novel, biophysical costimulatory mechanism that functions in concert with canonical receptor-ligand signaling cues. Taken together, our data reveals that maturation-associated changes in the DC cytoskeleton alter its biophysical properties to create a platform for enhanced mechanotransduction, facilitating T cell priming.

P1502/B636

Actomyosin Contractility Dependent Immunological Sensitivity of Immune Cell Activation.

D. Kim; KU-KIST Graduate School of Converging Science and Technology, Korea University, Seoul, KOREA, REPUBLIC OF.

Macrophages play an important role in inflammation and immune responses, and their malfunctioning is associated with the progression of chronic human diseases such as cardiovascular disease, obesity, and cancer. By recognizing surrounding physiological condition through various membrane receptors, macrophages can be activated and dramatically changes the functional phenotype to perform various

immunological tasks. There are multiple functional states of macrophage activation induced by various immune pathways, including the most well-known contrasting phenotype, pro-inflammatory (M1) and alternative (M2) activation. Although macrophages are located in various tissues exposed to different physical environments, however, how the extracellular mechanical signals determine their immunological activation remains unclear. Here, we demonstrate that immunological activation of bone marrow-derived macrophage (BMDM) is precisely controlled in response to cellular mechanosensation of substrate compliance. To quantitatively assess the cellular heterogeneity of macrophages, we have developed an automated high-throughput cell phenotyping (HtCP) technology, which enables us to obtain essential cellular information such as morphology and specific protein expression at the single cell level. As the substrate stiffness decreases, BMDMs are poorly spread with decreasing F-actin level and show reduced expression of iNOS and arg-1 in response to immunological activators of M1 and M2 activation pathways. Moreover, nuclear translocation of NF-κB and STAT6, key transcription factors of activation pathways, is controlled by substrate stiffness, and vertical compressive forces, which potentially increases nuclear stresses, also promotes nuclear localization of transcription factors. We also find that protein expression of iNOS and arg-1 induced by macrophage activation is tightly coupled with nuclear translocation of each transcription factors, respectively. In addition, the reduction of actomyosin contractility by using cytoskeletal drugs resulted in a decrease of the level of macrophage activation, especially the M2 activation was more sensitively regulated. These results reveal that actomyosin contractility mediated cell spreading can act as a common immuno-regulatory pathway to determine the immunological sensitivity of macrophage to the physical properties of extracellular microenvironment, providing a new perspective on the relationship between physical cues and immune responses.

Clot Contraction Drives Structural Redistribution of Platelets, Fibrin and Red Blood Cells through Energy Minimization.

V. Tutwiler[1], X. Chen[1], R. I. Litvinov[1], R. Khismatullin[2], C. Nagaswami[1], J. W. Weisel[1], V. Shenoy[1]; [1]University of Pennsylvania, Philadelphia, PA, [2]Kazan Federal Research University, Kazan, RUSSIAN FEDERATION.

Blood clot contraction, or the volume shrinkage of the clot, plays a critical role in the restoration of blood flow past otherwise obstructive thrombi. Contraction is driven by platelet actomyosin forces and results in the compression of erythrocytes into a tessellated network in the core of the clot, leading to the terminology of polyhedrocytes. The aim of this work was to determine the mechanism driving the redistribution of components of the clot, fibrin and platelets on the exterior and erythrocytes in the interior. Through the use of histology and scanning electron microscopy, we quantified the redistribution of platelets and fibrin to the exterior and erythrocytes into the core of the clot in a time dependent manner during clot contraction. Coupling experimental results with a poroelastic computational model of contracting clots allowed us to discover why this segregated distribution was more favorable than a homogenous distribution. If the clot had a homogenous distribution, it would reach a mechanical steady state immediately. However, as platelets begin to exert contractile forces, if segregation occurs this results in the compression of erythrocytes into the core. As erythrocytes are compressed, they stiffen which effectively results in the platelets generating more contractile forces, furthering the compression of erythrocytes and redistribution of the clot components. The result is a lower energy for the overall system when compared to a homogenous clot distribution, revealing that

energy minimization drives the structural redistribution of components of contracting clots. This conclusion has important clinical implications, since we have previously shown that patients with thrombotic conditions, such as ischemic stroke and venous thromboembolism, have impaired clot contraction compared to healthy subjects, pointing to a potential role of contraction in the obstructiveness and embologenicity of thrombi. Furthermore, the structural redistribution of contracting clots observed here provides a potential basis for the decrease in efficacy of thrombolytic treatment with increasing time following symptom onset and has implications for the development of novel thrombolytics.

P1504/B638

Mechanical Coupling of β_2 Integrins to the Actin Cytoskeleton by a Mechanosensitive Molecular Clutch Drives Complement-mediated Phagocytosis.

V. Jaumouille, A. X. Cartagena-Rivera, C. M. Waterman; National Institutes of Health, Bethesda, MD.

αMβ2 and αXβ2 integrins (complement receptors 3 and 4) are major receptors for phagocytosis of many pathogens and participate in clearance of dead cells and tumor cells. Other integrins mediate cell migration, where their activity and functions are mechanically linked to actin dynamics through focal adhesions (FAs). We tested the hypothesis that mechanical coupling of β2 integrins to a dynamic actin cytoskeleton via FA proteins is essential during phagocytosis for particle binding, outside-in signaling, and engulfment. We used live-cell imaging approaches to characterize actin dynamics, probe the role of key FA proteins, and examine the force generation and stiffness responses of macrophages during integrin-mediated phagocytosis of complement-opsonized target particles. Particle internalization was mediated by formation of Arp2/3-dependent actin protrusions that wrapped around the particle in a formin-dependent manner. Small focal complex-like adhesions formed in the phagocytic cup that contained β2 integrins, vinculin, α-actinin and zyxin, as well as tyrosine-phosphorylated paxillin, FAK and Syk. Perturbation of talin and Syk showed that a talin-mediated link between integrin and actin and tyrosine kinase-mediated recruitment of vinculin mediate force transmission to target particles to promote efficient phagocytosis. Altering target mechanical properties demonstrated more efficient integrin-mediated phagocytosis of stiffer targets. Thus, professional phagocytes co-opt the cell migration machinery, using tyrosine kinase signaling to build a mechanosensitive, talin- and vinculin-mediated molecular clutch, which couples integrins to cytoskeletal forces to drive particle engulfment.

The C-terminal Domain of Talin Forms a Force-responsive, Directional Bond to F-actin.

L. Owen, N. Bax, W. Weis, A. Dunn, A. Dunn; Stanford, Stanford, CA.

Integrin-based adhesion complexes are dynamic regulators of force transduction between the actomyosin cytoskeleton and the surrounding extracellular matrix. The linkage between integrins and filamentous actin is largely mediated by talin, a 270 KDa adapter protein that also recruits additional actin-binding proteins to assemble the focal adhesion. Force transmission through talin is thought to be initiated by F-actin binding to talin's C-terminal actin binding site (ABS3). Although ABS3 has been characterized in bulk biochemical and cell biological assays, very little is known about how it binds to F-actin under load. We used a single-molecule optical trap assay to study the force-dependent kinetics ABS3 from talin 1 binding to F-actin. We find that ABS3 forms a catch bond to actin when force is applied towards the pointed end of the actin filament, with binding lifetimes more than 100-fold longer than

when force is applied towards the barbed end. Long-lived bonds to F-actin require the ABS3 C-terminal dimerization motif, whose cleavage has been reported to regulate focal adhesion turnover. These results support a mechanism in which the C-terminal actin binding domain of talin preferentially binds and orients actin filaments with barbed ends facing the cell periphery, thus reinforcing F-actin alignment in the lamellipodium and localizing the formation of nascent adhesions.

Mechanosensitivity Mechanisms of the Lim Domain Protein Testin.

S. Sala, P. Oakes; Loyola University Chicago, Maywood, IL.

Mechanical signals generated by the cellular environment influence a wide variety of cellular processes including proliferation, differentiation and migration. The majority of mechanical interactions in cells are mediated by the actin cytoskeleton, which can not only generate and transmit forces, but also convert mechanical signals into biochemical signals in a process called mechanotransduction. Previously, proteins in the LIM family such as zyxin and paxillin, have been shown to be mechanosensitive by localizing to stochastic stress fiber tearing events in the cytoskeleton. The mechanisms underlying this behavior, however, remain unknown. To address this question, we investigated the potential mechanosensitive properties of another multimodular LIM domain protein, the tumor suppressor testin. Testin consists of a CR domain, a PET domain and 3 LIM domains. Using focused laser light, we can induce damage and strain along stress fibers in human fibroblasts leading to recruitment of LIM proteins such as zyxin. When full length testin is overexpressed, it is distributed throughout the cytoplasm and does not localize to sites of strain. When a truncated form consisting of the N-terminal domains is expressed, it localizes to actin stress fibers but does not recognize sites of strain either. When a truncated form of the protein consisting of just the C-terminal LIM domains is expressed, however, it localizes to focal adhesions and will recognize sites of strain. Interestingly, only stress fibers that are not fully severed show recruitment of testin's LIM domains suggesting that these domains recognize a strain-induced conformational change in the actin filaments and not free barbed ends. Additional truncations reveal that the first LIM domain is required for mechanosensitivity. Furthermore, we found that various phosphomutants of testin can drive the full-length protein to focal adhesions but that only a subset of them become mechanosensitive. Specifically, testin becomes mechanosensitive when tyrosines 72 and 111, located between the CR and PET domains, and in the PET domain respectively, are mutated to alanine. Surprisingly, tyrosines 237, 251 and 288 in the first LIM domain, do not affect testin's mechanosensitivity when mutated to alanine. Together, our results indicate a potential role of the N-terminal tyrosines 72 and 111 in regulating the conformation of testin, thereby controlling the mechanosensitivity of the C-terminal LIM domains and their ability to recognize local strain in actin filaments. We speculate that similar mechanisms could be at play in regulating the mechanosensitive behavior of other members of the LIM protein family.

Effects of Environmental Modifications on *Dictyostelium* Adhesion and Mechanosensation.

S. M. Fuller; SUNY Oswego, Oswego, NY.

Dictyostelium discoideum is a social amoeba used as a model organism to study directed cell migration, including in response to mechanical stimuli. When introduced to a brief shear flow stimulus *D. discoideum* cells have rapid and transient activation of a number of signal transduction pathways, as

well as actin polymerization at the cortex, although how the cells initially sense the mechanical stimulus is unclear. Currently, there is no known information as to how adhesion affects the response of *D. discoideum* to mechanical stimuli. The question we are addressing is whether a change in adhesion will make a difference in the ability of *D. discoideum* cells to sense mechanical stimuli. Due to a lack of genes coding for integrin, these cells can adhere non-specifically to a variety of surfaces. Sugars and amino acids have been previously shown to inhibit adhesion of *D. discoideum*. Thus, we tested whether glucose, glycine, or a combination of the two treatments affect mechanosensation. Only addition of glucose or a combination of glucose and glycine, but not glycine alone, appeared to lower cell adhesion. However, glucose treatment did not affect the response to a brief, 2 sec stimulation with shear flow, measured by actin polymerization or recruitment of Ras-binding domain as a marker of signal transduction network activation. Future work will focus on testing whether a combination of glucose and glycine, which has the largest effect on random migration of the cells compared to other treatments tested, affects mechanosensation. This study will help us understand whether integrin-independent adhesion plays a role in the cell's ability to detect a mechanical cue and convert it to a biochemical response.

P1508/B642

Effects of Surface Composition on *Dictyostelium* Adhesion and Mechanosensation.

M. A. Urman, Y. Artemenko; SUNY Oswego, Oswego, NY.

Highly motile cells of the Dictyostelium discoideum social amoeba are commonly used as a model system for the study of directed cell migration. Mechanical cues, such as shear flow, can induce directed migration of various cells, including Dictyostelium; however, molecular mechanisms that allow cells to sense mechanical cues are poorly understood. Although integrins have been implicated in mechanosensation, Dictyostelium lacks integrins and attaches to substrate in large part due to non-specific interactions mediated by Van der Waals forces. The purpose of this study was to test whether reducing integrin-independent adhesion of cells to the surface would affect Dictyostelium mechanoresponse. To reduce adhesion of cells we used bovine serum albumin (BSA), which has non-specific binding domains that can interfere with electrical charge interactions that bind the cell to the surface. We evaluated cell mechanosensation by measuring actin polymerization in response to very brief, 2 sec, exposure to shear flow on the surfaces coated with various concentrations of BSA. Mechanical stimulation response of Dictyostelium cells grown on a bacterial lawn, which are known to produce a robust response in this assay, was the same on BSA compared to control coating. Interestingly, when we tested adhesion of bacterially-grown cells, there was no significant difference on BSA compared to the control surface, in contrast to previously published literature. Indeed, standard axenically grown cells on BSA-coated surface showed a significant decrease in adhesion and a corresponding increase in velocity during random migration. These results suggest that cells in different stages of Dictyostelium growth and development respond differently on surfaces of differing chemical compositions. Efforts are currently underway to find surface modifications that reduce attachment of bacterially-grown cells to allow for examination of their mechanoresponse under reduced adhesion conditions.

Mapping the Biochemical Interactions of the Mechanoresponsive Contractility Controller.

P. Kothari, D. N. Robinson; Johns Hopkins School of Medicine, Baltimore, MD.

Every biological process, ranging from cell migration to embryogenesis, relies on the cell's ability to adapt to changing mechanical environments. By studying the model shape change process cytokinesis in *Dictyostelium*, we find that the cell is a finely tuned control system, with proteins that modulate their behavior in response to mechanical and biochemical signals (Kee *et al*, 2012; Srivastava *et al*, 2015). We are now unraveling the biochemical interactions that allow force propagation through the cortical network in the contractility controller. We used a proteomics approach to identify direct interactors of two key nodes of the control system, actin crosslinker cortexillin I and scaffolding protein IQGAP2. This analysis identified mechanoenzyme myosin II as a biochemical interactor of both cortexillin I and IQGAP2. We find that the cooperative mechanoaccumulation of myosin II and cortexillin I is potentially due to their direct interaction. IQGAP1, in turn, competes with IQGAP2 to bind myosin II and cortexillin I, thus negatively regulating contractility. Our data also suggest that multi-protein complexes (mechanoresponsive contractility kits, MCKs) are pre-formed in the cytoplasm, primed for activation by chemical or mechanical stimuli to engage with the cytoskeletal network (Kothari *et al*, 2019). In addition, we find a few unusual interactors by mass spectrometry analysis that we previously identified in genetic suppressor screens, providing greater evidence for their function in the network. In particular, we are now investigating the role of methylmalonyl-semialdehyde dehydrogenase (mmsdh), an enzyme that catalyzes a step of the valine degradation pathway. Mmsdh overexpression was initially shown to rescue the growth defect and localization of an assembly-deficient myosin II mutant (Ren *et al*, 2014). Using Fluorescence Cross-Correlation Spectroscopy (FCCS) to measure apparent in *vivo* K_D values, we have found that both myosin II and cortexillin I interact with mmsdh in live cells. Using the contractility controller as a model, we are identifying a quantitative interaction map, complete with new interactions, that is uncovering new biochemistry associated with the mechanobiome.

Polarity Signaling Ensures Epidermal Homeostasis by Coupling Cellular Mechanics and Genomic Integrity.

M. Dias Gomes[1], S. Letzian[1], M. Saynisch[1], S. Iden[1,2]; [1]CECAD, Cologne, GERMANY, [2]CMMC, Cologne, GERMANY.

Epithelial homeostasis depends on an elegant equilibrium between progenitor self-renewal and differentiation. This process was thought to primarily be mediated by the orientation of mitotic spindles, but there is growing evidences that other mechanisms contribute. Here, by combining genetic ablation, live cell imaging, atomic force microscopy and mechanochemical reconstitution, we describe a novel function of mammalian Par3 in controling epidermal homeostasis. Inactivation of Par3 impairs actomyosin contractility and viscoelastic properties of keratinocytes, leading to diverse mitotic aberrancies. These mitotic failures trigger aneuploidy, mitosis-dependent DNA damage responses and p53 stabilization that eventually fuel premature differentiation. We unveiled a novel mechanical signaling network in which Par3 regulates RhoA activity and p190GAP expression in keratinocytes. Remarkably, reconstituting myosin activity was not only sufficient to rescue mitotic aberrancies and genome integrity in *vitro* but could also normalize the increased suprabrasal sorting behavior of $Par3^{KO}$ keratinocytes in a stratification model. Collectively, this study deciphers a novel role of Par3

independent of spindle orientation, that couples genome integrity and epidermal fate decisions via the regulation of keratinocyte mechanics.

P1511/B645

An Asymmetric Mechanoresponse at Cadherin Junctions Ensures Epithelial Integrity during Mitotic Rounding.

M. Gloerich[1], J. Monster[1], L. Donker[1], M. Vliem[1], Z. Win[2], J. De Rooij[1], B. Baum[2]; [1]UMC Utrecht, Center for Molecular Medicine, Utrecht, NETHERLANDS, [2]UCL, London, UNITED KINGDOM.

Epithelia are continuously self-renewed, but how epithelial integrity is maintained while cells undergo dramatic shape changes during mitosis is not fully understood. Here, we show that mitotic entry coincides with an increase in tensile forces on adhesions between mitotic cells and their neighbours. By physically confining epithelia in height, we demonstrate that the increase in junctional tension is a direct consequence of mitotic cell rounding. To withstand intercellular forces, cadherin-based cell-cell adhesions can trigger an adaptive response to reinforce junctions through recruitment of the actin binding protein Vinculin. Surprisingly, we find that Vinculin is not recruited to cadherin in the mitotic cells but only in their neighbours, resulting in asymmetry in the composition of cadherin junctions. When junctional Vinculin recruitment is inhibited in mitotic neighbours, this results in junctional breakage and a weakened epithelial barrier upon mitotic entry. Conversely, preventing junctional release of Vinculin in mitotic cells attenuate the ability of cells to round up in mitosis. Our data thus identify an asymmetric mechanoresponse at cadherin adhesions during mitosis, which is essential to maintain epithelial integrity while at the same time enable the shape changes of mitotic cells.

P1512/B646

ERK Activation Waves Mediated by Intercellular Mechanical Forces Underlie Long-range Guidance for Collective Cell Migration.

N. Hino[1], M. Matsuda[1,2], T. Hirashima[2]; [1]Graduate School of Biostudies, Kyoto University, Kyoto, JAPAN, [2]Graduate School of Medicine, Kyoto University, Kyoto, JAPAN.

Collective cell migration is a fundamental process involved in many biological phenomena including epithelial wound healing and embryonic development. During collective cell migration of Madin-Darby canine kidney (MDCK) cells, activation of extracellular signal-regulated kinase (ERK) is propagated as multiple waves from leader cells to follower cells, which directs migration of the follower cells. However, the mechanism underlying the intercellular propagation of ERK activation remains elusive. By combining Förster resonance energy transfer (FRET) biosensor imaging and the use of optogenetic and drug-inducible dimerizers, here we report that intercellular force transmission mediates ERK activation waves. Correlation-based image analysis showed that the follower cells collectively move forward by repetitive cycle of extension and shrinkage, and that the cell deformation waves are propagated as the ERK activation waves. Cross-correlation analysis revealed that the cell deformation waves slightly precede the ERK activation waves; i.e., a cell is first extended, followed by ERK activation, and then the cell starts shrinking. Consistent with this temporal sequence, passive stretching of cells on an elastic chamber results in ERK activation, and optogenetic activation of ERK triggers cell contraction. Given the tight physical connection between the epithelial monolayer cells, we speculated that the ERK-induced cell contraction should lead to mechanical stretch of adjacent cells, by which ERK activation is propagated to the adjacent cells. As anticipated, induction of cell contraction by drug-induced Rho GEF

activation system results in the ERK activation in the neighboring cells. Furthermore, disruption of adherence junctions by the knockout of α-catenin severely impairs the ERK activation waves, confirming that intercellular transmission of mechanical force mediates ERK activation waves. Collectively, we have shown that ERK activation waves are mediated by intercellular force transmission, which underlies long-range transmission of directional cues for collective cell migration.

P1513/B647

Vinculin-mediated Mechanocoupling during Epithelial Sheet Expansion.

E. M. Gates, B. D. Hoffman; Duke University, Durham, NC.

Tissue expansion and remodeling, which underlie many fundamental morphogenetic processes, are thought to be driven by the generation and transmission of actomyosin forces. However, the interplay of adhesion structures and cell-generated forces remains poorly understood. As actomyosin forces are transmitted through both focal adhesions (FAs) and adherens junctions (AJs), we probed the mechanical loading of vinculin, which is known to localize to both adhesions and serve as an actin cross-linking protein, to determine if vinculin is differentially loaded in these compartments. Using a 2D expansion assay and a previously developed Förster resonance energy transfer-based vinculin tension sensor (VinTS), we characterized vinculin load in all three compartments of two epithelial cell lines, one that forms prominent lamellipodia and expands quickly and another that forms pluricellular actin belts and expands slowly. While vinculin load at FAs was similar between the cell lines, we found vinculin was loaded at AJs and throughout a cytosolic (non-stress fiber) actin network only in the fast-expanding cell line. Because a well-defined actin structure was not visible using traditional light microsopy, we confirmed that vinculin was acting as a cross-linker by using fluorescence recovery after photobleaching (FRAP). To determine if vinculin loading was specific to actomyosin contractility, we implemented an actin-binding mutation (I997A) and found VinTS loads were reduced. Additionally, the I997A mutation increased vinculin's turnover in the cytosol based on FRAP measurements. As large mechanical forces in the cytosolic (non-stress fiber) actin network were unexpected, we developed and employed a novel FRET-based tension sensor that acts as a synthetic actin cross-linker. This sensor reported large forces in lamellipodia-based migration, corroborating our findings in VinTS. When cells were plated individually, we discovered that VinTS became unloaded in the cytosol. In total, this work suggests that AJ formation enables the formation of a loaded cytosolic actin network, and we hypothesize this network is important for lamellipodia formation to mediate fast expansion.

Elevated Extracellular Fluid Viscosity Stimulates Migration of Metastatic Cancer Cells.

M. Pittman, K. Li, Y. Chen; Johns Hopkins University, Baltimore, MD.

While the significance of the stiffness of the extracellular microenvironment has been well-studied, the role of others physical factors, such as fluid viscosity, are less understood. The viscosities of biological fluids span orders of magnitude, and due to lymph circulation, disease development, and fluctuations in protein secretion, cells directly in contact with mucus, extracellular fluid (ECF), and saliva are often subjected to variations in viscosity. In the context of cancer, leaky vasculature and matrix degradation within the tumor microenvironment lead to high local concentrations of plasma proteins and soluble collagen that could increase ECF viscosity. Moreover, mucins, the large, heavily-glycosylated extracellular proteins responsible for the high viscosity of mucus and saliva, are overexpressed in many

malignancies. In this study, the cellular response to increased viscosity is characterized, especially in terms of tumor progression and metastasis, and a mechanism for this response is proposed. To simulate elevated ECF viscosity, an inert thickening agent, is added to culture medium to increase viscosity up to a maximum of 11,000 times that of water at low shear. Strikingly, human breast cancer cells MDA-MB-231 moved ~2-fold faster in viscous medium for at least 24 hours. In addition to single cell tracking, this result was confirmed using Transwell migration and invasion assays, which demonstrated a similar ~2 fold increase in the fraction of cells passing through a membrane of micron-sized pores. Notably, other types of cancer cells tested also exhibited similar behaviors. This finding is the opposite of what has been reported in neutrophils, which typically exhibit amoeboid rather than mesenchymal migration, suggesting that high viscosity might stall immune mobilization but accelerate metastasis. High-speed timelapse microscopy revealed that an expansion in cell spread area begins instantaneously upon addition of viscous medium. This expansion, which plateaus at approximately 150% and is reversible upon replacement of regular medium, is associated with explosive growth and remodeling of focal adhesions. Drug treatment has shed light on parts of the mechanism of this response, showing that the elevated cell motility and cell spread area are integrin- and actin-dependent.

P1515/B649

Uniaxial Contraction Sustains Cell-generated an terior 3D Matrix Prestress to Initiate and Maintain a 3D Mesenchymal Cell Migration Cycle.

A. D. Doyle[1], D. Sykora[1], G. Pacheco[1], M. L. Kutys[2,3], K. M. Yamada[1]; [1]National Institute of Dental and Craniofacial Research, NIH, Bethesda, MD, [2]Department of Bioengineering, Boston University, Boston, MA, [3]Wyss Institute, Harvard University, Boston, MA.

During cell migration, cytoskeletal contractile forces are transmitted to the microenvironment through integrin-based focal adhesions in a process known as mechanotransduction, which provides a bidirectional pathway for mechanical information to pass to and from the extracellular matrix (ECM). This process has been classically characterized on two-dimensional, flat surfaces, yet it remains unclear how these processes occur within a three-dimensional (3D) microenvironment and how they are incorporated into 3D migration. Here we have uncovered a unique contractile mechanism used by fibroblasts and mesenchymal cancer cells (HT-1080s) to migrate efficiently through 3D collagen gels. An alysis of ECM deformations during 3D cell spreading suggests that 3D cell polarization is highly force-dependent, with cells establishing an unbalanced matrix prestress: Fibroblasts protrude, polarize and initiate migration in the direction of highest ECM deformation. This matrix prestress is maintained through a unique contraction where cells locally pinch the matrix in a uniaxial fashion immediately behind the leading edge, which is concealed by the large absolute ECM deformations but is revealed by instantaneous kinetic analysis. We find this uniaxial contraction (UAC) occurs prior to leading edge protrusion and coordinates a distinct 3D migration cycle that varies between cell types. Local matrix severing using two-photon ablation to disrupt matrix prestress, as well as local contractile inhibition to ablate a uniaxial contraction, both halt forward migration, suggesting both mechanisms are required for mesenchymal migration and may represent a mechanosensing mechanism. An alysis of ECM deformations suggest that fibroblasts transmit large forces to the microenvironment ~3.8-fold higher than MDA-MD-231 cells. We find that epithelial cancer cells (MDA-MB-231) rarely demonstrate a sustained matrix prestress or a uniaxial contraction; however, MDA cell lines established from secondary brain tumors that demonstrate higher myosin IIB expression, but not from secondary bone tumors, demonstrate both mesenchymal phenotypes. Moreover, analysis of integrin ligation and myosin II (A

and B) expression suggests higher expression of both increases a cell's mesenchymal characteristics. Fibroblasts lacking myosin IIA, or if integrin ligation has been reduced, lack a mesenchymal phenotype, while overexpression of either myosin IIA or IIB increases the UAC phenotype We propose that mesenchymal cells can sense ECM stiffness in 3D, generating their own matrix prestress in a myosin IIA- and integrin-dependent manner to migrate. They do so through continued uniaxial contractions that maintain a 3D migration cycle.

P1516/B650

Extracellular Fluid Viscosity Enhances Cell Motility and Invasion.

K. Li, M. Pittman, Y. Chen; Johns Hopkins University, Baltimore, MD.

Cell migration is critical for many biological processes, including embryonic development, immune cell mobilization and wound healing, among others. In response to both chemical and mechanical cues, cells can move in a directional manner. While migration of normal cells is an important part of homeostasis, motility of diseased cells, especially cancer cells, can lead to undesired consequences, such as metastasis. Cell migration is a complex and highly regulated process. In vivo, motile cells move through the extracellular matrix while immersed in the extracellular fluid (ECF). It is known that the presence of macromolecules such as mucins can increase ECF viscosity, but the effect of viscosity on cell migration is poorly understood. In this study, we investigate how cell migration changes when immersed in the fluid of various viscosity values. Timelapse microscopy was used to record cellular migration in culture medium supplemented with different polymers to adjust viscosity and osmolarity, and cell tracking software was used to analyze the average cell speeds. Here we report evidence that viscous ECF enhances cell motility in both metastatic breast cancer cells MDA-MB-231 and NIH-3T3 fibroblast cells in a graded and sustained manner. For example, in 2D, MDA-MB-231 cells move nearly twice as fast when immersed in medium with a viscosity of ~1000cP. Transwell migration assay showed that viscosity also enhances the cell invasion through confined spaces. Moreover, the increase in migration is viscosity-dependent but osmolarity-independent. Autocorrelation analysis of the trajectories of migrating cells revealed viscosity does not change the migration persistence. Having established that viscosity enhances cell motility and cell invasion, we identified that cells can sense and respond to ECF viscosity by cell spreading. Because viscosity is observed to be significantly higher in tumors due to the leaky vasculature and overexpression of mucins, viscosity-sensing and enhanced motility could play a critical role in tumor progression.

P1517/B651

Plectin Linkages Aid in Moving the Nucleus through Cross-linked 3d Matrices.

P. Chengappa[1], S. Jambhekar[1], G. Wiche[2], R. Petrie[1]; [1]Drexel University, Philadelphia, PA, [2]University of Vienna, Vienna, AUSTRIA.

Plectin linkages aid in moving the nucleus through cross-linked 3D matrices Pragati Chengappa[1], Samir Jambhekar[1], Gerhard Wiche[2], and Ryan J. Petrie[1] [1]Department of Biology, Drexel University, Philadelphia, PA [2]University of Vienna, Vienna, Austria Fibroblast migration through three-dimensional (3D) matrices is essential for wound healing and tissue homeostasis. However, the movement of the nucleus is a barrier to cell migration through 3D matrix environments due to its size and rigidity. To overcome this, fibroblasts migrating through cross-linked matrices, such as 3D cell-derived matrix (CDM) and mammalian dermis, use the power of actomyosin contractility to pull the nucleus forward and

maintain rapid 3D migration. The forward movement of the nucleus raises the hydraulic pressure in the front of the nucleus and generates high-pressure protrusions called lobopodia. The nucleus is wrapped by a basket of vimentin intermediate filament which aids in pulling the nucleus through the matrix and generating compartmentalized pressure. Currently, it is not clear how the force generated by actomyosin contractility is connected to the vimentin basket to pull the nucleus through the matrix. Plectin is a cytolinker protein that can cross-link vimentin with other cytoskeleton filaments to arrange and maintain the cytoarchitecture during processes such as cell adhesion and migration. Our work tests the hypothesis that plectin links vimentin and actomyosin filaments to connect the myosin II-generated forces to the nucleus to help pull it through the tight spaces in cross-linked 3D matrices. We found that actin and vimentin filaments are closely associated (often within 10 nm or less) in the cytoplasm of primary human dermal fibroblasts migrating on 2D glass. Both plectin expression and myosin II activity were required to maintain these actin-vimentin interactions in the cytoplasm. These results suggest that plectin mediates actin-vimentin interactions in fibroblasts in a myosin II-dependent fashion. Interestingly, plectin knockdown cells exhibit increased velocity on 2D glass. However, plectin knockdown cells in 3D CDM had significantly reduced hydraulic pressure and vimentin filaments around the nucleus, indicating that the nuclear piston machinery was dismantled. Together, these data suggest that plectin-mediated linkages between actin and vimentin filaments are required for moving the nucleus through 3D CDM, but slow down 2D fibroblast migration. Further, myosin II contractility may be required to maintain these linkages while it is driving nuclear and whole cell movement through physiological 3D cross-linked matrices.

P1518/B652

Microtubule Acetylation Promotes Rigidity Sensing and Mechanosensitive Migration of Astrocytes.

S. Seetharaman[1], B. Vianay[2], V. Roca[1], S. Etienne-Manneville[1]; [1]Institut Pasteur, Paris, FRANCE, [2]Paris University, INSERM, CEA, Hôpital Saint Louis, Institut Universitaire d'Hematologie, Paris, FRANCE.

Cell adhesion to the extracellular matrix occurs through integrin-mediated focal adhesions, which sense the mechanical properties of the substrate and impact cellular functions such as cell migration. Mechanotransduction at focal adhesions affects actin dynamics resulting in migration of cells. Although microtubules are key players in cell adhesion and migration, their role in mechanotransduction still remains unstudied. Using a combination of microfabrication methods, biophysical approaches and imaging techniques such as hydrogel patterning, traction force microscopy and electron microscopy, we show that substrate rigidity affects microtubule acetylation through β_1 integrin signalling in astrocytes but not in glioblastoma cells. Moreover, αTAT1, the enzyme responsible for microtubule acetylation, is required for the mechanosensitive migration of astrocytes. αTAT1 also reorganizes the actomyosin network, increases traction force generation and promotes cell migration on stiff substrates. Our results suggest a novel feedback mechanism involving a crosstalk between microtubules and actin in mechanotransduction at focal adhesions whereby, cells sense the rigidity of the substrate through integrin-mediated adhesions, modulate their levels of microtubule acetylation, which then controls the actomyosin cytoskeleton, force transmission on the substrate and promotes cell migration.

P1519/B653

Cell Matrix Invasion Requires Non-Muscle Myosin 2A/B Polarity and Nuclear-force Coupling Generated from Adhesion Sites.

L. E. Young[1], T. Newman[1], T. Waring[1], E. Madondald[1], P. Caswell[2], L. Machesky[3], M. Morgan[1], T. Zech[1]; [1]University of Liverpool, Liverpool, UNITED KINGDOM, [2]University of Manchester, Manchester, UNITED KINGDOM, [3]Beatson Insitute, Glasgow, UNITED KINGDOM.

Dynamic cell polarisation is observed during cell invasion of 3D matrices. In this study we set out to identify the parameters required for invasive cell migration in 3D environments. Transmembrane-spanning integrin adhesion complexes (IACs) allow the cells to respond to changes in the extracellular environment. IACs are well characterised in cells plated on 2D surfaces, yet much less is known about them in cells embedded in 3D matrices. We establish a BioID-based technique to compare the composition of IACs of invasive breast cancer cells in 2D versus 3D matrices and measure 3D IAC dynamics of endogenous (knock-in) proteins. We identify a novel interaction complex consisting of N-WASP/WIP -> β-PIX -> Myosin-18A (M18A), which is enriched in 3D adhesive sites. Depletion of β-PIX or M18A abolishes cancer cell invasion, without negatively affecting matrix degradation or protrusion formation in collagen matrices. Instead, β-PIX/M18A drive the polarised recruitment of non-muscle Myosin 2A (NM2A) to the tips of protrusions. This recruitment of NM2A is required for the creation of a NM2A/B gradient, which assembles from protrusion to the nucleus. A NM2A/B gradient will provide the actomyosin network with differing catalytic properties of the NM2 isoforms. NM2A is known to have faster motor activity than NM2B, whereas NM2B has a higher affinity for ADP, reflecting longer high affinity attachment to actin filaments. The NM2A/B gradient couples protrusion assembly with nuclear movement, enabling effective invasive migration and polarisation. These findings suggest that actomyosin mediated nuclear-force coupling through a NM2 isoform gradient is a crucial mechanism required for invasive cell migration through 3D matrix.

P1520/B654

Nuclear Pressure and Movement Govern 3D Motility.

T. M. Jones, R. J. Petrie; Drexel University, Philadelphia, PA.

Fibroblast migration through three-dimensional (3D) matrix environments is essential for normal wound healing. During 3D migration, cell morphology and the mechanism of migration are largely dictated by the interactions of the cell with its local microenvironment, including the ability of a cell to squeeze its bulky rigid nucleus through narrow openings. To efficiently translocate their nuclei through the small pores within heavily cross-linked matrices, fibroblasts use actomyosin contractility to pull their nuclei forward like a piston to generate compartmentalized pressure and switch from a lamellipodia- to a lobopodia-based migration. However, it remains unclear how this nuclear piston mechanism is activated in response to specific cell-matrix interactions. Recently, it was shown that the nuclear envelope can transiently rupture in cells moving in 3D environments, suggesting mechanical stress on the nucleus can lead to a dramatic increase in pressure inside the nucleus. Here, we test the hypothesis that cells moving through cross-linked 3D matrices activate the nuclear piston mechanism in response to increased resistance and mechanical stress on the nucleus. Mechanical stress on the nucleus was indirectly measured by quantifying changes to nuclear morphology and intranuclear pressure. Our results show cells moving from the 2D surface to the interior of 3D matrices can dramatically elongate their nuclei without activating the piston mechanism. Since physically deforming the nucleus was not sufficient to

trigger the nuclear piston, we next measured changes in nuclear pressure in cells immediately before and after piston activation. Nuclear pressure was not only compartmentalized and distinct from cytoplasmic pressure, but also increased upon piston activation, suggesting the nucleus is under elevated mechanical stress when the piston is on. Next, we investigated how nuclear pressure was controlled in dermal fibroblasts. We determined myosin II activity and intact nucleoskeleton-cytoskeleton connections are required for the increase in nuclear pressure during piston activation. Overall, our current model of piston activation consists of three distinct steps: 1) the nucleus becomes stuck when migrating in 3D matrix, 2) tension on nesprin linkages increase nuclear pressure and 3) initiation of a signaling cascade within the cytoplasm triggers the actomyosin contractility required to pull the nucleus forward. Future work will determine the temporal coordination of pressure changes inside the nucleus and cytoplasm during piston activation.

Confinement-induced DNA Damage Causes Increased Matrix Degradation and Invasiveness in Breast Cancer Cells.

G. P. F. Nader[1], S. Aguera-Gonzales[1], C. Lodillinsky[1], M. Maurin[1], M. Gratia[1], C. Cadart[2], M. Gentili[3], A. Yamada[4], C. Villard[1], J. Viovy[1], C. Tripodo[5], G. Scita[6], P. Chavrier[1], N. Manel[1], M. Piel[1]; [1]Institut Curie, Paris, FRANCE, [2]UC Berkeley, Berkeley, CA, [3]Broad Intitute, Boston, MA, [4]École Normale Supérieure, Paris, FRANCE, [5]University of Palermo-School of Medicine, Palermo, ITALY, [6]University of Milan-IFOM, Milan, ITALY.

During migratory events such as tissue morphogenesis, immune surveillance and cancer invasion, intracellular forces are transmitted to the nucleus. Using as a model the development of tumor xenografts in the mammary duct of mice Lodillinsky et al. (2016) showed that to breach out of the mammary gland ducts, MCF10 ductal carcinoma in situ cells (MCF10.DCIS) degrade the basement membrane, what induced degradation remained unknown. We observed that the nuclei of these cells are less deformed in early tumor stages when compared to later stages, which also displayed increased DNA damage. We previously showed that strong nuclear deformation leads to nuclear envelope (NE) rupture and DNA damage in RPE1 cells. We thus tested whether the increased nuclear deformation and DNA damage observed in the DCIS xenografts contributes to trigger the invasive phenotype acquired by these cells to progress to invasive carcinoma. We observed that DCIS cells embedded in 3D collagen following strong (2µm) but not mild (10µm) confinement exhibited highly dynamic actin protrusions and increased MMP-dependent collagen degradation. DCIS cells confined at 2µm but not 10µm exhibited frequent NE rupture events and increased DNA damage. We then developed an *on-chip* duct assay to reproduce the confined growth observed in intraductal tumor xenografts. Strikingly, as cell density increased in this device, NE rupture and DNA damage increased, likely due to the high migratory activity of the crowded cells in the confining duct. In both DCIS and RPE1 cells DNA damage is associated to NE rupture, so we next sought to identify a potential cytoplasmic factor that would access the exposed nuclear DNA following NE ruptures. TREX1 is an exonuclease shown to attack chromatin bridges that persisted in cytokinesis following rupture of the NE that reformed around them. Strikingly, both transient TREX1 depletion and stable CRISPR KO in DCIS and RPE1 cells nearly abolished DNA damage associated to NE rupture. TREX1 depletion followed by strong confinement also abrogated collagen degradation and invasion in the *on-chip* duct assay. Strikingly, strong confinement of RPE1 and untransformed DCIS cells (MCF10A) triggered a TREX1-dependent DNA damage and cell senescence. Here we describe a causal relationship between cell confinement, NE rupture and TREX1-dependent

DNA damage with specific long term cellular phenotypes: collagen degradation and invasion in DCIS cells and senescence in RPE1 and MCF10A cells. The mechanism of TREX1-dependent DNA damage in confined cells with NE rupture could relate the observation of deformed nuclei and increased DNA damage (both in duct xenograft tumors in mice and in human breast tumors) to the development of an invasive phenotype and thus contribute to the initiation of certain types of breast cancers.

Mechanical Compression Reprograms Transcription by Increasing Macromolecular Crowding.

T. Szoradi[1], S. Pinglay[1], G. P. Brittingham[1], M. Delarue[2], **L. J. Holt**[1]; [1]New York University, New York, NY, [2]LAAS-CNRS, Toulouse, FRANCE.

Tens of thousands of biochemical reactions occur simultaneously in the cell, organized at a wide range of length-scales. Small molecules are channeled through metabolic pathways at blistering speeds. However, at higher length-scales, macromolecular complexes, such as those that orchestrate transcription, experience a high degree of mesoscale crowding that approaches the physical limits where jamming will occur. We combined a new genetically encoded nanoparticle technology with microfluidic pressure chambers to reveal that mechanical compression increases molecular crowding in both the nucleus and cytoplasm. Changes to nuclear crowding increased expression of some genes and decreased others. We propose that crowding increases that activity of some promoters by driving assembly of transcriptional machinery through attraction depletion, while other promoters are sensitive to jamming. This differential response of genes to changes in crowding provides a potential physical mechanism to respond to mechanical compressive stress without the need for a canonical signal transduction pathway.

A Viscoelastic Model Predicting Cell Mechanical Memory through Mechanical Energy Dissipation of the Cell Nucleus.

D. Perez-Calixto, G. Vazquez-Victorio, **M. Hautefeuille**; Universidad Nacional Autónoma de México, Mexico, MEXICO.

Cellular processes are directly impacted by the mechanicals signals from their microenvironment. Some of those signals are directly transmitted from the adhesion complex to the nucleus via the actomyosin apparatus, stressing the organelle and causing reversible and irreversible phenomena. To fully understand the dynamics of this nuclear strain responsible for important mechanoresponsive behaviors, it is crucial to build a model that considers all the nuclear mechanical properties that have been reported to impact nuclear strain. We developed a model integrating the viscoelastic property of the nucleus caused by histone deacetylation and lamins in order to consider the time-dependent contributions of such important nuclear elements. The model managed the contribution of lamin-A,C and lamin-B to the nuclear strain and stress for different ECM stiffnesses as previously shown experimentally by others. Furthermore, the dynamic role of lamins levels is suggested as an explanation of cell mechanical memory through mechanical energy dissipation that induce irreversibility of the nuclear shape. An d finally, the model seems to suggest to experimentally study the kinetics of nuclear deformation to better understand ECM-stiffness-related mechanisms on cell nuclei, as the timescale during which stress is applied is of great relevance in defining the future of a cell.

A Polarized Spectrin Cytoskeleton Stabilizes Multivalent Endothelial Adhesion Receptor Complexes to Facilitate Rolling Adhesion.

S. M. Mylvaganam[1,2], M. Riedl[2], S. Freeman[2], S. Grinstein[1,2]; [1]University of Toronto, Toronto, ON, CANADA, [2]Hospital for Sick Children, Toronto, ON, CANADA.

In the early stages of an immune response, multivalent complexes of endothelial adhesion receptors (e.g. clustered selectins) engage leukocytes to orchestrate their trafficking to inflamed tissues. Sufficient stability and density of these receptor complexes must be maintained for efficient trafficking to occur. We demonstrate that a polarized, spectrin cytoskeleton regulates apical actin-filament stability and mediates the frequent immobilization of the abundant transmembrane protein CD44. We used single-particle tracking and super-resolution microscopy to investigate the effects of a stable CD44-spectrin network on the diffusion and distribution of bystander selectin clusters that do not directly associate with the submembrane cytoskeleton. The network restricted selectin mobility and served to stabilize selectin clusters, bolstering transient, multivalent heterocellular interactions. In this way, the spectrin network is proposed to regulate the initial contacts between leukocytes and endothelial cells to ultimately mediate extravasation.

A Template for Actin Organization at the Leading Edge.

A. Pipathsouk, R. Brunetti, J. Town, O. Weiner; University of California, San Francisco, San Francisco, CA.

How local interactions of actin regulators yield large-scale organization of cell shape is not well understood. For example, why does the WAVE complex build lamellipodia, broad sheet-like protrusions that power cell migration, whereas the highly related actin regulator N-WASP forms finger-like actin networks? from in vitro reconstitutions, sheet-like actin structures require spatially organized actin nucleation along a linear structural template. What is the endogenous basis of a template for lamellipodia in living cells? to investigate whether WAVE complex self-organizes into a template that sculpts lamellipodia, we studied its nanoscale organization at the plasma membrane. Our previous work showed that WAVE complex self-associates into small foci following actin depolymerization. At conventional resolution, these appeared to be amorphous blobs, similar to droplet-like phase transitions exhibited by N-WASP. Using super-resolution microscopy, we found the WAVE complex “foci” are actually highly ordered rings, 280nm wide, which can elongate into micron-length spirals. These linear structures indicate that WAVE complex self-assembles into a linear structure that could represent the physical template for lamellipodial formation; actin assembly perpendicular to these linear arrays of WAVE complex could generate the actin sheets that are the basic unit of lamellipodia organization. An alysis of the membrane organization around these rings provided further insight into the role of geometry in cell morphogenesis. These rings localize to necks of membrane invaginations, which are saddle point geometries (positive curvature in one axis and negative curvature in the other axis). This suggests a specific geometric input into WAVE complex’s localization. This saddle preference for the WAVE complex could explain emergent cell behaviors such as the expanding self-straightening behavior

of lamellipodia as well as the ability of endothelial cells to seal transcellular holes. To investigate the molecular mechanism of saddle curvature recognition, we show that the WAVE complex and IRSp53, an inverse BAR domain protein, collaborate together to recognize saddle geometry that neither can recognize on its own. Our work highlights how partnering protein interactions enable complex shape sensing and how feedback between cell shape and actin regulators yields self-organized cell morphogenesis.

P1526/B660

A Computational Method to Quantify Cell Membrane Remodeling and Cortical Localization of Actomyosin Cytoskeletal Components during Cell Migration in Live an imals.

D. Chen[1], N. Melis[1], W. Losert[2], R. Weigert[1]; [1]Laboratory of Cellular and Molecular Biology, National Cancer Institute, Bethesda, MD, [2]Physics Department, University of Maryland, Bethesda, MD.

Active cell migration requires local membrane remodeling, which involves dynamic protrusions and retractions driven by cytoskeletal rearrangements. State of the art two-photon intravital subcellular microscopy (ISMic) enables the acquisition of 4-D (3D in time) movies of interstitial neutrophil migration during immune response in *vivo* with a resolution of a few hundred nanometers and a frame rate of fewer than 10 seconds. Here, we describe a tool to analyze the dynamics of cell migration at the subcellular level and to understand how local actomyosin dynamics and cell membrane remodeling coordinate to drive the cell migration through the complex interstitial extracellular environment in *vivo*. The proposed computational method was implemented by customized MATLAB codes. The cell shape was quantified in a semi 3-D fashion through a level-set “snake” algorithm, which took into consideration both image brightness gradient and cell boundary smoothness. The codes were applied to the 2-D max z-projections of the segmented 3-D cell voxels to identify reasonable cell boundary contours. At each frame, the cell boundary was defined by consecutive boundary points at subpixel resolution, which enabled the calculation of local boundary curvatures. The local boundary motion from one frame to the next was identified by tracking the boundary points according to the minimum displacement criterion. For each boundary point, a box of a selected depth was defined, and the average intensity of cell voxels projected in that box for the non-muscle myosin IIA (NMIIA)-GFP or LifeAct-GFP acquired signals. This allowed the correlation between the actomyosin complex along the cell cortex and local cell membrane remodeling. Using this tool and the associated statistical analyses, we found that NMIIA was recruited not only to the retracting rear of migrating neutrophils but also at the leading edge. NMIIA localization positively correlated with the local cell boundary curvature and membrane retraction, but not protruding activity. Notably, this quantitatively defined phenotype was not recapitulated in standard in *vitro* assays for neutrophil migration where NMIIA is mostly concentrated at the retracting rear of the cell.

P1527/B661

Regulation of Septin Architecture and Function by the Lkb1-Like Kinase Elm1.

J. R. Marquardt, E. Bi; University of Pennsylvania, Philadelphia, PA.

The septins are a highly conserved family of GTP-binding proteins that assemble into heterooligimeric filaments in eukaryotic cells. These filaments can further organize into higher-order structures such as rings, hourglasses, and gauzes. Septins are essential for (or play essential roles in) many cellular processes including cytokinesis, cellular morphogenesis, ciliogenesis and spermatogenesis, and fungal

pathogenicity. In the budding yeast *Saccharomyces cerevisiae*, the septins localize to the bud neck and function as a scaffold for proteins involved in cytokinesis and other processes and as a membrane diffusion barrier preventing the intermixing of membrane-associated proteins between mother and daughter compartments. Based on their importance and ability to adopt a variety of architectures, it is of no surprise that the septins are tightly regulated throughout the cell cycle. One such regulation is through phosphorylation by kinases such as Elm1 (an LKB1/PAR4-related kinase). Elm1 localizes with septins at the bud neck, regulates the morphogenesis checkpoint controlling the apical-to-isotropic switch in bud growth, and plays an ill-defined role in maintaining septin structure at the bud neck. To elucidate the mechanism underlying the last function, we imaged *elm1Δ* cells by 3D time-lapse microscopy, and found that the daughter-half of the septin hourglass was selectively lost shortly after bud emergence in this mutant. As a consequence, the morphogenetic checkpoint regulators at the daughter side of the bud neck were also lost, which could explain the elongated morphology associated with a loss of Elm1 function. Using platinum-replica electron microscopy to see the septin architecture at the filament level, we believe the mechanism for this instability of the septin hourglass may be through the inability of paired septin filaments to form efficiently in *elm1Δ* cells. Thus, the major function of Elm1 is to control the stability of the septin hourglass, specifically the daughter half. Cells lacking Elm1 also exhibit mild defects in cytokinesis. Strikingly, cells lacking both Elm1 and the septin Shs1 display major defects in cytokinesis, including actomyosin ring destabilization and defects in primary septum formation. These data suggest that Elm1 and Shs1 function in parallel pathways to regulate the septin architecture required for proper cell morphogenesis and cytokinesis in budding yeast.

Dchs1 and the Septin Cytoskeleton: a Molecular and Developmental Etiology Underlying Mitral Valve Prolapse.

K. S. Moore, R. Moore, D. B. Fulmer, L. Guo, C. Gensemer, R. Stairley, M. Rumph, R. Norris; Medical University of South Carolina, Charleston, SC.

Mitral valve prolapse (MVP) is a potentially life threatening cardiac disease that affects 1 in 40 individuals and is the most common reason for mitral valve surgery. MVP is defined by a disease of the valve leaflets which exhibit progressive disruption of the extracellular matrix (ECM) and is characterized by collagen fragmentation and increased proteoglycan and elastin production. As a result, the mitral valves enlarge and become biomechanically incompetent, resulting in leaflet billowing and failure to close during ventricular systole. There are no effective nonsurgical treatments for MVP and therapeutic efforts have been hindered by an incomplete understanding of its fundamental causes. Our group was the first to identify a genetic cause for MVP through identification of mutations in the atypical cadherin gene, *DCHS1, in* multiple families of non-syndromic MVP. In an effort to further define the intracellular mechanisms regulated by DCHS1, we recently performed a series of two-hybrid studies and co-immunoprecipitations (Co-IP's) and identified a novel protein complex consisting of DCHS1, Lix-1 like (LIX1L), and septin-9 (SEPT9). We performed a series of in *vivo* epistasis experiments that support the genetic interactions between *Lix1L and Dchs1* as we saw a synergistic effect of compound heterozygosity on mitral valve morphogenesis. We were able to refine the interaction between LIX1L and SEPT9 to a 36 a.a. binding domain, which allowed us to generate a cell permeant 36-mer peptide to target the distinct LIX1L-SEPT9 interaction in the following approaches. Since SEPT9 is able to crosslink and bundle actin monomers, we measured actin filament content with G-actin/F-actin polymerization

assays and immunocytochemistry analyses. We observed a significant decrease in septin-actin organization and defects in cell and nuclei shape in cardiac fibroblasts (CFs) deficient of *Dchs1, Lix1L,* or both. We also found that the DCHS1-LIX1L-SEPT9 (DLS) complex promotes cell, ECM, and actin filament alignment through application of a novel 3D *ex vivo* culture system that. These data support a mechanism in which DCHS1 based cell-cell adhesions regulate actin stability through LIX1L-SEPT9 interactions during critical stages of valve development.

Reconstituting Cytoskeletal Assembly from Budding Yeast Extracts Reveals Basic Biophysical Properties of Septin Filament Polymerization.

B. Woods, K. Cannon, A. Gladfelter; University of North Carolina, Chapel Hill, NC.

Cells build large, micron-scaled structures from relatively small, nanometer-scaled proteins. The septin cytoskeleton is particularly adaptable in its ability to form micron-scale structures in a variety of shapes and sizes for various functions. Septins are GTPase proteins that self-assemble into oligomeric “rod-shaped” subunits 17-32 nm long, and are conserved from fungi to mammals. These oligomers can then polymerize into much larger filaments at the plasma membrane or in association with other cytoskeletal proteins. Filaments can be arranged into higher-order assemblies such as laterally associated bundles, crosslinked lattices, wrapped gauzes, and curved rings. Higher-order assemblies serve as platforms for protein localization including the polymerization of other cytoskeleton proteins, scaffolds for cytokinesis and cell signaling events during morphogenesis, and act as protein diffusion barriers. Septin assemblies go through substantial rearrangements throughout the cell cycle suggesting that septin filament polymerization is finely tuned and regulated. Much about what is known about actin and microtubule assembly came from seminal studies that uncovered biophysical properties underlying polymerization. A network of regulatory proteins modulate actin and microtubule biophysical properties to build and arrange higher-order assemblies. Very little is known about how cells control where and when septin filaments polymerize, and how filaments are arranged into higher-order assemblies. Genetic studies in yeast have identified a suite of potential septin regulators, including septin-associated kinases, cell polarity proteins, and cell cycle regulators. However, how these regulators mechanistically modulate septin filament polymerization or filament arrangements remains mysterious. To uncover the biophysical properties of septins and to investigate how regulators tune polymerization, we married a filament polymerization reconstitution system with cell extracts from budding yeast. Extracts are incubated on supported phospholipid bilayers and individual filaments are imaged by TIRF microscopy and SEM. We found that septin filament polymerization is most consistent with it being an isodesmic rather than cooperative process. We also found septins from extracts polymerize into distinct spatial patterns different from filaments polymerized from recombinant protein. Moreover, SEM has revealed a new, undescribed filament arrangement found from extracts. This combined extract-reconstitution approach enables us to dissect the underlying biophysical mechanisms of septin polymerization while simultaneously affording control of its regulators by utilizing the power of yeast genetics.

The Role of Atx-2 and Vpr-1 on Sperm Positioning in the *C. Elegans* Meiotic Embryo.

C. Bailey[1], M. T. Panzica[2], F. J. McNally[1]; [1]University of California Davis, Davis, CA, [2]University of California Los an geles, Los an geles, CA.

The role of ATX-2 and VPR-1 on sperm positioning in the *C. elegans* meiotic embryo Fertilization occurs during female meiosis in most animals, which raises the question of what prevents the sperm body (DNA, centrioles, and organelles) from interacting with the meiotic spindle. In a previous study, we found that *Caenorhabditis elegans* sperm DNA stays in a fixed position at the opposite end of the embryo from the meiotic spindle while yolk granules are transported throughout the embryo by kinesin-1. In the absence of F-actin, the sperm body was transported with the yolk granules, resulting in sperm DNA within 2 µm of the meiotic spindle. We are currently exploring the possibility that contacts between the maternal ER, paternal mitochondria, and cortical F-actin may play a role in tethering the sperm body to the posterior end of the embryo. In preliminary studies we found that depletion of Ataxin-2 (ATX-2) caused disruption of the sperm body, the incorrect positioning of sperm DNA, and the scattering of paternal mitochondria. In contrast, the sperm body remained intact upon depletion of VAP-B (VPR-1), but was incorrectly positioned within the embryo. Further studies are needed to deduce how these proteins are specifically involved in correct sperm positioning inside the embryo.

P1531/B665

Climp-63 Regulates Nuclear Movement during Polarization of Migrating Cells.

C. S. Janota, J. Costa, A. Pezzarossa, E. R. Gomes; Instituto de Medicina Molecular, Lisbon, PORTUGAL.

In our lab we are interested in understanding how cells position their nuclei in different biological contexts and the role for nuclear positioning. The connection between the cytoskeleton and the nucleuskeleton are crucial for most of these events, however how the endoplasmic reticulum (ER) is organized during cellular polarization remains to be elucidated. The ER is a dynamic organelle with three functional and morphological domains, the nuclear envelope, flat sheets and reticular tubules. Being the largest cell organelle, its morphology is also the most complex. Using migrating NIH 3T3 fibroblasts in a wounding assay where nuclei are repositioned away from the leading edge, we found that ER sheets accumulate at the perinuclear region, while ER tubules distribute along the leading edge upon nuclear movement. Moreover, by performing FIB-SEM we observed that nuclear positioning was correlated with bigger and more continuous ER sheets at the perinuclear region. Therefore we tested if ER morphology could regulate nuclear positioning in the wound assay. To this end, we depleted different ER proteins previously reported to be involved in ER morphology and found that depletion of Climp-63, a sheet-enriched ER transmembrane protein thought to be responsible for ER luminal spacing, prevents nuclear movement away from the leading edge. In addition, cells without Climp-63 failed to increase perinuclear ER accumulation during nuclear movement. Nuclear movement away from the leading edge is mediated by actin retrograde flow and actin dorsal cables attached to the dorsal side of the nucleus via TAN lines. We tested if depletion of Climp-63 had any effect on actin cytoskeleton, either on dorsal or ventral actin, and on TAN lines. We found that the speed of actin retrograde flow and the number of TAN lines upon Climp-63 depletion were not different from the control. Surprisingly, we found that the number of ventral actin stress fibers under the nucleus increased. In the ventral side of the nucleus we observed that ER was wrapped around ventral actin cables. In the absence of Climp-63, the ER area and thickness in the ventral side of the nucleus was decreased and we observed less wrapping of the ER around the

actin cables. Given these results, we propose that ER membrane might be necessary to wrap around actin cables under the nucleus to prevent the connection of ventral static actin cables to the nuclear envelope proteins and allow the nucleus to slide on top of immobile ventral actin cables.

Netosis Proceeds by Cytoskeleton and Endomembrane Disassembly and Pad4-mediated Chromatin De-condensation and Nuclear Envelope Rupture.

H. R. Thiam[1], S. L. Wong[2,3,4], R. Qiu[5], M. Kittisopikul[5], A. Vahabikashi[5], A. E. Goldman[5], R. Goldman[5], D. D. Wagner[2,3,6], C. M. Waterman[1]; [1]Cell and Developmental Biology Center, National Heart, Lung, and Blood Institute, NIH, Bethesda, MD, [2]Program in Cellular and Molecular Medicine, Boston Children's Hospital Boston, Boston, MA, [3]Department of Pediatrics, Harvard Medical School, Boston, MA, [4]Lee Kong Chian School of Medicine, Nanyang Technological University, Singapore, SINGAPORE, [5]Department of Cell and Molecular Biology, Northwestern University Feinberg School of Medicine, Chicago, IL, [6]Division of Hematology/Oncology, Boston Children's Hospital Boston, Boston, MA.

Neutrophil extracellular traps (NETs) are web-like DNA structures decorated with histones, antimicrobial and cytotoxic proteins released by activated neutrophils. Initially described as a way for neutrophils to trap and neutralize pathogens during innate immunity, NETs are now widely implicated in the detrimental effects of several autoimmune diseases. Peptidylarginine deiminase 4 (PAD4) citrullinates histones and is required for NETs formation (NETosis) in mouse neutrophils. While various molecular mechanisms mediating NETosis are being revealed, the cellular events driving NETs release are still unclear. Here, we determined the sequence of cellular events in NETosis, and examined the role of PAD4 in these events. We performed high resolution time-lapse microscopy of mouse and human neutrophils (PMN) and differentiated HL60 neutrophil-like cells (dHL-60) labelled with fluorescent markers of the cytoskeleton and organelles and stimulated with ionomycin or lipopolysaccharides to induce NETosis. We found that stimulated neutrophils eject NETs after decondensation of the nuclear DNA in the nucleus, rupture of the lamin meshwork and nuclear membrane allowing the release of decondensed DNA to the cytosol, disassembly of the actin, microtubule and vimentin intermediate filaments networks, vesiculation of the endoplasmic reticulum and plasma membrane and finally rupture of the plasma membrane. More importantly, we found that these cellular pathways occur in a specific and well conserved temporal order suggesting a requirement for a precise sequence for progression through NETosis. Indeed, inhibition of actin disassembly, one of the first cellular events, blocked NETs release. To examine the role of PAD4 in NETosis we isolated neutrophils from PAD4-deficient mice and generated a PAD4-knock down (KD) HL60 CRISPR line. We found that chromatin de-condensation, lamin meshwork and NE rupture and extracellular DNA release required the enzymatic and nuclear localization activities of PAD4. Thus, NETosis proceeds by a well conserved, step-wise sequence of cellular events culminating in the PAD4-mediated expulsion of DNA. Our data further suggest that targeting these cellular pathways might be a better approach for controlling NETosis progression than targeting the various divergent signaling pathways. Indeed, plasma membrane microvesicle shedding, actin and lamin meshwork disassembly, DNA de-condensation, nuclear envelope and plasma membrane rupture are now potential therapeutic targets for NETosis inhibition.

P1533/B667

Curvature Sensitive Septin-membrane Interaction Drives Membrane Deformation.

A. Beber[1], c. Taveneau[1], m. nania[2], d. levy[1], p. bassereau[1], j. Cabral[2], H. Isambert[1], s. Mangenot[1], **A. Bertin**[1]; [1]Institut Curie, Paris, FRANCE, [2]Imperial college, london, UNITED KINGDOM.

Septins are cytoskeletal proteins that assemble into a variety of supramolecular organizations from paired filaments to bundles, ring like structures or gauzes of orthogonal filaments [1]. Septins are bound to the inner plasma membrane through specific interactions with phosphoinositides [3]. Septins are essential for cytokinesis, participate in the formation of diffusion barrier and might be involved in membrane deformation and rigidity. Septins are localized in situ at sites displaying a micrometric Gaussian curvature. We have used a combination of in vitro bottom approaches and theory to analyze how the curvature sensitivity of septins could induce membrane deformations. Besides we analyzed in details the septin-membrane interaction. We have shown that septins arrange differently on positive or negative curvatures [4] using scanning Electron Microscopy imaging on undulated PDMS substrates. Besides, this curvature preference is closely related to the ability of septins to reshape and deform membranes. Indeed, bound to Giant unilamellar Vesicles (GUVs), septins induce striking deformations with regular spikes and hollow micrometric deformations at the surface of liposomes, as visualized by fluorescence microscopy. Smaller vesicles (LUVs of 100-300 nm in diameter), highly positively curved, are flattened by Septin filaments into “pancake” like objects as shown in 3D by cryo-electron tomography. With the resolution of cryo-EM we visualize both the septin filaments and the deformed vesicles. To get more details into the Septin-membrane interaction at the molecular scale we have started carrying out sub-tomogram averaging. Preliminary analyses highlight the orientation of the Septin domains interacting with the membrane. **References**: [1] A. Bertin, et al. (2010), Phosphatydinositol 4,5 biphosphate promotes budding yeast septin filament assembly and organization, J. Mol. Biol., 404(4), 711-31. [3] A.Bertin, et al. The 3D Dynamics of Macropinosome Formation and PI3K Activity in Macrophages Revealed by Lattice Light-sheet Microscopy.

B. L. Scott[1], S. E. Quinn[1], L. Huang[2], J. G. Kerkvliet[2], J. A. Swanson[3], S. Smith[1], A. D. Hoppe[2], N. W. Thiex[2], R. B. An derson[1]; [1]South Dakota School of Mines and Technology, Rapid City, SD, [2]South Dakota State University, Brookings, SD, [3]University of Michigan, an n Arbor, MI.

Macrophages are sentinels of the innate immune system that are constantly sampling solutes within their environment. This immune surveillance is accomplished by creating actin-rich membrane ruffles that are shaped into macropinosomes filled with extracellular fluid in a process generally requiring phosphatidylinositol 3 kinase (PI3K) mediated activity. To correlate membrane reshaping with the timing and localization of PI3K activity, we used volumetric imaging of macrophages dually expressing fluorescent protein probes for the plasma membrane (Lck membrane targeting sequence) and for PI3K products (Akt PH domain). Macrophages exposed to different polarizing stimuli formed macropinosomes with diverse morphological mechanisms. In resting macrophages, the predominant form of macropinocytosis we observed fits the canonical model of linear ruffle extension, followed by

ruffle circularization, and cup closure mediated by fusion of the ruffle with the cell surface. By combining multiple volumetric representations, we observed that many macropinosomes also formed at the base of large sheets during the extension phase. Following a growth factor starvation and stimulation sequence, a large circular dorsal ruffle formed that restricted diffusion of PI3K products to the inside of the ruffle, and many macropinosomes were formed in a flurry of membrane activity as the ruffle constricted. Stimulation with lipopolysaccharides produced clusters of dorsal ruffles rich in PI3K products that moved around the surface and produced multiple macropinosomes. Using chemical inhibition of PI3K, we demonstrated the role of $PI(3,4)P_2/PIP_3$ in coordinating membrane circularization. Inhibition did not impact ruffling activity throughout the cell, but dysregulated cup closure and resulted in failed macropinosome formation. The improved spatiotemporal resolution by lattice light-sheet microscopy combined with advanced image analysis enabled a more quantitative view of the membrane dynamics and PI3K signaling controlling macropinosome formation.

Coupling between Eukaryotic Cell Shape and Polarity: a Route to Micron-scale Curvature Sensing?

A. Singh, **B. Camley**; Johns Hopkins University, Baltimore, MD.

A cell's crawling direction is in part controlled by the polarization of Rho GTPase activity on the cell. Spontaneously-developing polarization in Rho GTPase activity can be sensitive to the shape of the cell. Reaction-diffusion simulations of Rho GTPase dynamics show that regions of high activity localize to the narrow end of elongated cells. We earlier showed [Camley et al. Phys. Rev. E **95**, 012401 2017] that when Rho GTPase activity drives cell protrusion, and cell shape reorganizes Rho GTPase signaling, this positive feedback loop can create persistent turning trajectories of cells. Persistent turning very similar to our predictions has recently been observed experimentally in keratocytes [Allen et al. BioRxiv doi:10.1101/443408]. Can the coupling of Rho GTPase activity to cell shape provide a route for cells to use nanometer-sized proteins to sense their shape even when the membrane is curved on the micron scale? We extend these ideas to understand which membrane shape features control the localization of Rho GTPase activity. We show that we can develop an "energy landscape" for Rho GTPase activity as a simplified model that describes where Rho GTPase activity occurs as a function of the membrane shape; this landscape predicts the results of more complex reaction-diffusion simulations. We find that the accuracy of shape sensing depends on an interplay between the size of the area of high Rho GTPase activity, the shape of the membrane, and the roughness of the membrane around its average shape, with larger domains of activity being more robust to roughness.

P1536/B670

Leader Cells in Collective Chemotaxis: Optimality and Tradeoffs.

A. Hopkins, **B. Camley**; Johns Hopkins University, Baltimore, MD.

Clusters of cells can work together in order to follow a signal gradient, chemotaxing even when single cells do not. Cells in different regions of collectively migrating neural crest streams show different gene expression profiles, suggesting that cells may specialize to leader and follower roles. We use a minimal mathematical model to understand when this specialization is advantageous. In our model, leader cells sense the gradient with an accuracy that depends on the kinetics of ligand-receptor binding while

follower cells follow the cluster's direction with a finite error. Intuitively, specialization into leaders and followers should be optimal when a few cells have more information than the rest of the cluster, such as in the presence of a sharp transition in chemoattractant concentration. We do find this - but also find that high levels of specialization can be optimal in the opposite limit of very shallow gradients. We also predict that the best location for leaders may not be at the front of the cluster. In following leaders, clusters may have to choose between speed and flexibility. Clusters with only a few leaders can take orders of magnitude more time to reorient than all-leader clusters.

P1537/B671

The Lamellipodium as a Migration Direction Decision Module.

J. A. Galbraith, N. Smith, E. Tschebotarjew,, **C. G. Galbraith**; OHSU, Portland, OR.

The lamellipodium is the 1-2 micron region at the front of the cell that evaluates the suitability of the surrounding extracellular matrix (ECM) for migration. Without the Arp2/3 network at the core of the lamellipodium, cells cannot detect ECM gradients. However, no physical link is known to connect the Arp2/3 network and integrin ECM receptors while the cell is probing and evaluating -- linkages form after integrins are bound to ECM and cells have accepted the ECM as suitable for migration. Here we show that despite not being physically bound to each other, the Arp2/3 actin network creates a high-density band of conformationally inactive, unligated integrins throughout the width of the lamellipodium. This high-density pool of integrin is dispersed when either the integrin tail is truncated or Arp2/3 is inhibited with CK666. Without the high density of unligated integrin in the lamellipodium, cells migrate slower and less persistently, changing direction more frequently than cells with intact lamellipodia. In contrast, alteration of the actin lamellipodium organization by inhibition of formins with SMIF2 does not displace the concentration of integrin, and SMIF2 treated cells migrate faster and more persistently than untreated cells. Neither treatment removes the very thin band of high-affinity integrins that outline the outermost edge of the lamellipodium. Together, these data suggest that the Arp2/3 actin network in the lamellipodium traps unligated integrin at the front of the cell to spatially evaluate the suitability of ECM - creating a migration direction decision module at the front of the cell.

Collective Stabilization of Migratory Polarity Drives Cluster Dispersal in Vivo.

B. Lin, J. Luo, R. Lehmann; New York University School of Medicine, NYC, NY.

Single cell migration programs shape tissue architecture during development. Often, such migrations initiate when subsets of cells separate from a cohesive group. Although much is known about how cells separate from an epithelium, the mechanisms underlying dispersal from dynamic, clustered cell ensembles remains poorly understood in *vivo*. Here, using the developmental migration program of Drosophila primordial germ cells (PGCs), we show that migratory polarity is stabilized to mechanically disrupt a motile cell cluster. PGCs utilize a G protein coupled receptor (GPCR), Tre1, to orient and maintain front-back migratory polarity radially from the cluster. Stabilization of the migratory axis positions myosin II dependent contractile forces at the rear to generate constant tension on cell-cell adhesions until rupture. Randomly migrating cells produce transient tension of equal magnitude on cell-cell adhesions but fail to separate, demonstrating a temporal tension threshold for detachment. We further show that migration based cluster dispersal is robust to increases in cell-cell adhesion and is more efficient when coordinated. Our results demonstrate that stabilization of the forces driving cell

movement are sufficient to disperse cell clusters under physiological settings and present a paradigm for how such events could occur in development and disease.

Non-canonical Hh Signaling Directs Germ Cell Migration through Regulating Pi(4,5)p_2 and Actin Dynamics.

J. KIM, C. D. Hanlon, S. Vohra, D. J. An drew; Johns Hopkins School of Medicine, Baltimore, MD.

Directional cell migration is a complex integrated process that requires coordinated changes in signal transduction, cytoskeletal structures and membrane organization. In tissue development and homeostasis, many cells acquire motility and migrate in response to guidance signals that direct cells to their destinations. Certain pathological conditions such as inflammation and cancer metastasis are directly related to abnormally migrating cells, emphasizing the importance of understanding the molecular and cellular mechanisms directing cell migration. Drosophila embryonic germ cell (GC) migration has served as an ideal model for studying directional cell migration due to the ease of tracking this cell population, the stereotypical migration patterns, and the wide range of cell biological and genetic tools available in Drosophila. Two distinct mechanisms have been proposed to guide GC migration. In the attractant model, Hedgehog (Hh) secreted by the somatic gonadal precursors (destination cells) attracts migrating GCs. In the repulsion model, a repellent signal generated by localized lipid phosphatases prevents GCs from straying from their correct migratory routes. Here, we report a set of findings that support a role for Hh signaling in GC migration through the GPCR Tre1 and its downstream effectors. First, we showed that GCs null for *Tre1* are fully capable of migrating but cannot navigate. Second, we showed that Tre1 induces local PI(4,5)P_2 synthesis by recruiting dPIP5K, a Drosophila PI4P 5-kinase, and that localized dPIP5K and PI(4,5)P_2 overlap F-actin-enriched protrusions in GCs. Third, we showed that WASP, an actin nucleation promoting factor activated by PI(4,5)P_2, is required for GC migration and localizes at the F-actin protrusions. Fourth, F-actin protrusions were diminished in *Tre1* mutant GCs, together with loss of local concentrations of dPIP5K and PI(4,5)P_2. Fifth, Smo activation by Hh induced increased localization of Tre1 on the plasma membrane and increased Tre1 binding to dPIP5K. Taken together, these results indicate that Hh signaling steers GC migration by regulating Tre1 localization. Tre1 interaction with dPIP5K activates local PI(4,5)P_2 synthesis and local actin polymerization, through WASP, to generate the F-actin protrusions that “pull” migrating GCs toward the somatic gonadal precursors, the source of the Hh ligand. Our findings suggest that non-canonical Hh signaling through the Tre1 GPCR regulates the cytoskeleton to facilitate developmental cell migration. These findings have potential clinical implications for Hh-related diseases, including cancer metastasis.

P1541/B675

Mitofusin 2 Regulates Neutrophil Adhesive Migration and the Actin Cytoskeleton.

Q. Deng, 47906; Purdue University, West Lafayette, IN.

Mitochondrial membrane potential is required for neutrophil migration, although the mechanism remains unclear. Here, we report that mitochondrial outer membrane protein Mitofusin 2 (Mfn2) regulates neutrophil homeostasis in vivo. *Mfn2*-deficient neutrophils are released from the hematopoietic tissue and trapped in the vasculature in zebrafish embryos. Human neutrophil-like cells deficient with MFN2 fail to be arrested by activated endothelium under sheer stress or perform

chemotaxis on substrates. Deletion of Mfn2 results in a significant reduction of neutrophil infiltration to the inflamed peritoneal cavity in mice. *Mfn2*-deficient neutrophil-like cells and mouse embryonic fibroblasts display heightened Rac activation. Mechanistically, MFN2 maintains mitochondria-ER interaction and prevents excessive elevation of cytosolic calcium and subsequent phosphorylation of CaMKII upon stimulation. Inhibiting CaMKII or the Rac GEF Tiam rescues the chemotaxis defect that results from Mfn2 depletion. Altogether, we identified an Mfn2-CaMKII-Tiam-Rac axis in regulating neutrophil migration and discovered a role of *MFN2* in regulating the actin cytoskeleton.

A Balance between Turning and Persistent Motion Is Critical for Fast and Efficient 3 Dimensional Neutrophil Migration.

J. François[1], Y. Yeh[2], C. Ayala[3], R. Firtel[2], J. del Alamo[4], S. Chien[2], J. Lasheras[2]; [1]Harvard Medical School, Boston, MA, [2]University of California, San Diego, La Jolla, CA, [3]University of California, Berkeley, Berkeley, CA, [4]University of Washington, Seattle, WA.

While much research has been dedicated to identifying the cascade of specific biochemical processes involved in the recruitment of neutrophils, much less is known about the mechanical events driving their directed migration. In particular, it is still unclear how neutrophils generate the necessary traction forces to migrate across three-dimensional (3-D) extravascular spaces and the effects of matrix porosity on turning events and persistence during this process. In this study, we examine the effects of extracellular matrix properties on the mechanics of 3-D neutrophil motility in collagen gels. We embedded neutrophil-like differentiated human promyelocytic leukemia (dHL-60) cells in collagen matrices of different concentrations containing fluorescent micro-beads. To induce directed migration, we introduced the chemokine formyl-Methionyl-Leucyl-Phenylalanine (fMLP) to dHL-60 cells in a custom build device. We then used brightfield microscopy to track chemotaxing cells and both confocal and fluorescent microscopy techniques to image the movement of the embedded micro-beads and fluorescently labeled cells. We find that turning events, mediated by the Arp 2/3 complex, are crucial for fast 3-D neutrophil migration. Additionally, the Arp 2/3 complex and myosin II play an increasingly important role in 3-D migration as matrices become denser. Finally, we find that cellular force patterns vary in response to matrices with various degrees of pore size heterogeneities and cell's intrinsic abilities to engage in path-finding and contractility. The results from our study show that neutrophils migrating in 3-D environments employ distinct mechanical mechanisms that depend on the local structure of their mechanical environments. Our work has implications for understanding how neutrophils interact physically with their surrounding environment what conditions may be necessary for fast 3-D neutrophil migration.

P1543/B677

Coordination of Actomyosin Contractility and Mitochondrial Positioning during Interstitial Neutrophil Migration in Live an esthetized an imal.

N. Melis[1], B. Subramanian[1], D. Chen[1], W. Losert[2], C. Parent[3], R. Weigert[1]; [1]Laboratory of Cellular and Molecular Biology, Center for Cancer Research, National Cancer Institute – National Institutes of Health, Bethesda, MD, [2]Department of Physics, Physical Sciences Complex, University of Maryland, College Park, MD, [3]Department of Pharmacology, University of Michigan, an n Arbor, MI.

Cell migration is a fundamental biological process in which membrane remodeling is a critical step occurring as a result of a constant re-arrangement of the actin cytoskeleton. Neutrophil migration has been particularly studied due to their role in the immune response, and because their immune function is directly associated to their ability to migrate. Neutrophil migration induces extensive plasma membrane remodeling through a combination of protrusion generated by actin polymerization at the leading edge of the cell and retraction generated by non-muscle myosin II a (NMIIA) contraction at the cell uropod. In addition, membrane remodeling is energetically unfavorable and has to be supported by an adjustment of the cellular metabolic activity.Most of our knowledge on membrane remodeling comes from *in-vitro* 2-D model systems and only very limited work has been performed in more complex models or *in-vivo*. To this end, here we use intravital subcellular microscopy coupled to a computational analysis in 3D to understand the underlying mechanisms of the coordination among plasma membrane remodeling, actomyosin cytoskeleton and cell metabolism during interstitial neutrophil migration in the mouse ear. In our model, migrating neutrophils exhibit a very active and dynamic membrane remodeling with a continuous formation of micron-scale membrane protrusions, which interact with the tissue microenvironment (i.e. extracellular matrix (ECM)). Differently from what has been previously described, we observe that NMIIA is not only present at the uropod of the cell but also at the leading edge and in large lateral protrusions. In these new locations, NMIIA is not actively retracting membrane, and its localization is correlated with the architecture of the ECM. Furthermore, NMIIA recruitment at the leading edge is RhoA/ROCK independent, possibly indicating a new role for NMIIA in a machinery involved in sensing the ECM and a new mode of recruitment of NMIIA in neutrophil.Finally, we observe that mitochondria constantly reposition throughout the cells at the sites of NMIIA assembly, most likely in order to supply the ATP required to sustain the contractile activity, and change their polarization status during the various phases of migration. In summary, we have highlighted a novel correlation between mitochondria function and the dynamic rearrangement of the actomyosin complex *in-vivo*.

The Role of Cytosolic Phospholipase A_2 during Neutrophil Chemotaxis.

F. Javed, C. A. Parent; University of Michigan, an n Arbor, MI.

Neutrophils are the most abundant immune cells in human blood and are the first line of defense against any pathogenic insult. They play a key role in mediating and resolving inflammation, which is often the root cause of various diseases including asthma, arthritis, and heart disease. Inflamed and damaged tissues release Damage and Pathogen Associated Molecular Patterns (DAMPs/PAMPs) that serve as primary chemoattractants to recruit nearby neutrophils. These activated neutrophils secrete the secondary chemoattractant Leukotriene B_4 (LTB_4), which has been shown to dramatically amplify the range of the primary inflammatory signals and the robust recruitment of neutrophils. Defects in the ability to produce, secrete, or detect LTB_4 results in greatly attenuated responses to injury or

inflammation. LTB_4 production is a highly regulated process that is initiated by the interaction of primary chemoattractants with their cognate G-Protein Coupled Receptor. Following stimulation, cytosolic phospholipase A_2 ($cPLA_2$) translocates to the nuclear envelope (NE) and releases arachidonic acid (AA), which is converted to LTB_4 by the sequential action of 5-Lipoxygenase, 5-Lipoxygenase Activating Protein and Leukotriene A_4 Hydrolase. $cPLA_2$ plays a critical role in LTB_4 production as disruptions in its activity lead to a decrease LTB_4 production and neutrophil migration. $cPLA_2$ belongs to group IV calcium dependent PLA_2 family that hydrolyze the fatty acid chains on the *sn-2* position of triglycerides. $cPLA_2$ has six isoforms: α, β, γ, δ, ε and ζ. These isoforms share only 30% sequence homology with no redundancy in activity known. Interestingly, the status of different $cPLA_2$ isoforms in neutrophils and whether these isoforms are involved in LTB_4 production is currently unknown. We found that neutrophils express $cPLA_2$ α, β, γ, ε and ζ. Our results also demonstrate the over expression of GFP-$cPLA_2$α does not affect migration of *neutrophil-like* cells. Visualization of GFP-$cPLA_2$α dynamics reveal that it redistributes to the NE following stimulation with primary chemoattractants. These results indicate that GFP-$cPLA_2$ isoform overexpression system represents a useful system to elucidate the intracellular dynamics of $cPLA_2$ isoforms and to determine their role during neutrophil migration.

Polo-like Kinase 4 Inhibition Modulates the Migration of Neutrophil-like Cells.

L. C. Klemm, L. E. Hind, R. A. Denu, M. E. Burkard, A. Huttenlocher; University of Wisconsin, Madison, WI.

Polo-like kinase 4 inhibition modulates the migration of neutrophil-like cells Lucas C. Klemm[1,2], Laurel E. Hind[2], Ryan A. Denu[3, 4], Mark E. Burkard[4], an na Huttenlocher[2] [1]Molecular and Cellular Pharmacology Graduate Training Program, University of Wisconsin-Madison, Madison, WI [2]Department of Medical Microbiology and Immunology, University of Wisconsin-Madison, Madison, WI [3]Medical Scientist Training Program, University of Wisconsin-Madison, Madison, WI [4]Division of Hematology/Oncology, Department of Medicine, University of Wisconsin-Madison, Madison, WI Neutrophils are fast-moving cells of the innate immune system and are often the first responders to sites of injury or infection. They are adept at both sensing and integrating complex gradients of multiple signals to migrate in a directional manner. Chemoattractants signal through G protein-coupled receptors, which activate downstream small Rho GTPases that induce neutrophils to polarize. The polarization of neutrophils is dependent on the maintenance of a “front” and “back”. “Frontness” and “backness” are mediated by specific signaling pathways and are maintained via a combination of feedback loops and cytoskeletal components such as microtubules. Here, we addressed the role of centrosome in neutrophil migration using both inhibitors and genetic tools. Inhibition of PLK4 with Centrinone B promotes neutrophil directed migration and induces robust frontness signaling with the formation of dynamic F-actin waves at the leading edge of neutrophil-like PLB-985 cells. We also find that PLK4 inhibition with Centrinone B leads to centrosome depletion. Genetic depletion of SAS-6, a protein necessary for centrosome duplication, also results in improved chemotaxis and the formation of actin waves at the leading edge. We find that Centrinone B does not significantly increase the velocity of SAS-6 depleted cells. Taken together, these findings suggest that the centrosome is not necessary for neutrophil directed migration and may negatively regulate the actin cytoskeleton and cell motility.

P1546/B680

Aurora Kinase a Coordinates Collective Migration by Determining Font Polarized Leader Cells.

T. Chu; University of British Columbia, Vancouver, BC, CANADA.

PROBLEM- Metastasis mediated by epithelial cancer cells often invade the neighboring tissue in a collective manner. BACKGROUND-Collective migration is reliant on leader cells which provide directionality cues to the migrating sheet. Numerous studies identified that leader cells possess heterogeneous phenotypes compared the other cells. Previously, we found that the abundance of phosphorylated HMMR-T703, a substrate for Aurora kinase A, predicts breast cancer specific survival and relapse-free survival in patients with estrogen receptor (ER)-negative, triple negative phenotype, or basal-like subtype breast cancers. Aurora kinase a (AurA) is a mitotic kinase which is important for centrosome maturation, duplication, spindle pole assembly and chromosome segregation. AurA is also found to play a role in cell migration as well as metastasis. METHODS: Live cell imaging was used to track the formation of leader cells during collective migration of mammary cells as well as the integrity of migrating sheet in wound closure assay. We used MCF10A cell line which is engineered with fluorescent labelled-tubulin a1b. These cells enable us to monitor the spatial-temporal pattern of centrosomes during migration. The localization and abundance of AurA, K14, and Cyclin B1 were assessed by fluorescence microscopy. Overexpression and impairment of AurA activity were achieved by lenti-viral transduction and small molecular inhibition, respectively. RESULTS- Here, through multi-parameter imaging of wound closure assays, we find that leader cells were found to have front-rear polarity whereas non-leader cells possessed random polarization. Small molecule inhibition of Aurora kinase activity, which is specifically expressed in leader cells, impaired centrosome polarity in leader cells. The loss of leader cells led to the loss of integrity of migrating sheet retarding collective migration. Overexpression of AurA elevated the migratory potential in wound closure assay by augmenting front polarization and microtubule nucleation of centrosomes. CONCLUSION- AurA specifically expressed in leader cells is important to drive collective migration by coordinating the migrating sheet as a whole. AurA plays a role in establishing front-rear polarity in leader cells which is one heterogeneous phenotype compared to the other cells. Together, these data indicate that AurA is one potential therapeutic target to influence the collective migration of human breast carcinoma cells.

Migrating Neutrophils Execute Front Protrusion and Rear Retraction Programs with Certainty Until Doubt Or Completion.

A. Hadjitheodorou[1], G. R. R. Bell[2], F. Ellett[3], D. Irimia[3], R. Tibshirani[4], S. R. Collins[2], J. A. Theriot[5]; [1]Department of Bioengineering, Stanford University, Stanford, CA, [2]Department of Microbiology and Molecular Genetics, University of California Davis, Davis, CA, [3]Department of Surgery, BioMEMS Resource Center Massachusetts General Hospital, Harvard Medical School, Boston, MA, [4]Department of Statistics, Stanford University, Stanford, CA, [5]Department of Biology, University of Washington, Seattle, WA.

Chemotaxing neutrophils continuously engage in directional decisions as they navigate complex environments. During interactions with obstacles, neutrophils often develop multiple competing fronts, raising the question of how the cell is able to select which front to maintain and which front(s) to abandon. To tackle this question, we challenged HL60 neutrophil-like cells with an oval-shaped obstacle positioned symmetrically in 6 x 3 um microfluidic channels. Cells respond to the mechanical challenge by

creating two equivalent competing fronts that encounter identical chemotactic gradients. The symmetry breaks when one front starts retracting allowing the dominant front to drive the cell around the obstacle. From time-lapse microscopy data, we extracted hundreds of image features that report on cell shape and distributions of cytoskeletal components. Through a supervised statistical learning approach, we identified a small subset of features that carry predictive power; using these we asked how far back in time could we accurately forecast the direction outcome. Among the examined features, cell shape and actin features appear to have the largest predictive power. Surprisingly, we could predict the cell's turning direction with accuracy greater than 70% only during the last third of the decision-making process (about 18 sec before the initiation of retraction). In this context, cell decision-making does not apparently require amplification of pre-existing asymmetries. Previous work (Yang*, Collins* & Meyer, 2016, *Nat. Cell Biol.* **18**: 121) showed that Cdc42, a Rho-family GTPase, is predictive of cell turning in chemotaxing neutrophil-like cells. To determine if Cdc42 activity gives improved prediction of cell decision-making, we combined our microfluidic assay with cells expressing an optogenetic G-protein coupled receptor and a spectrally compatible FRET biosensor for Cdc42 activity. This system enables light-stimulated neutrophil "chemotaxis" while measuring downstream GTPase activity in the same cells. Repetitive stimulation to one of the competing fronts is sufficient to bias the cell's direction with a 90% success rate. Interestingly, administering stimulation only during the early phase of competition did not bias the cell's stochastic choice. This suggests that inducing a transient asymmetry at an early stage is not sufficient to drive the system out of its steady state. We hypothesize that the two fronts are independently executing their protrusion programs and only late in the competition they start "raising doubt" and are amenable to re-programming. In addition, we found that once a cell has made a decision, the losing front enters a refractory period that requires complete retraction to the cell body before stimulation can encourage a new protrusion.

P1548/B682

Modulation of Transplantable Photoreceptor Replacement Cell Chemotactic Mechanisms in Retinal Biomimetic Ligand Gradients.

O. Onwumere[1,2], C. Shi[3,2], T. Hoque[2], M. Wong[2], R. Gharbaran[4], J. Mighty[1,2], A. Ma'ayan[5], S. Redenti[2,1,3]; [1]Biology Doctoral Program, the Graduate School and University Center, City University of New York, New York, NY, [2]Department of Biological Sciences, Lehman College, City University of New York, Bronx, NY, [3]Biochemistry Doctoral Program, the Graduate School and University Center, City University of New York, New York, NY, [4]Department of Biological Sciences, Bronx Community College, City University of New York, Bronx, NY, [5]Department of Pharmacological Studies, Icahn School of Medicine at Mount Sinai, New York, NY.

Disease or trauma induced loss of rod and cone photoreceptors is a major cause of vision loss worldwide. To replace photoreceptors and restore vision, laboratories around the world are investigating photoreceptor replacement strategies using subretinal injection of photoreceptor precursor cells (PPCs) and retinal progenitor cells (RPCs) [1-2]. A major obstacle in the field is that transplanted photoreceptor replacement cells exhibit extremely limited migration into host retina following injection into the subretinal space [1-3]. In this study, we show that PPC receptor expression and retinal ligand interaction modeling can target cell signaling pathways facilitating migration. In addition, we demonstrate that using systems pharmacology, drugs can be targeted to upregulate PPC receptors enhancing photoreceptor replacement cell migration. Previously, we developed a database of retinal ligand and PPC receptor pairs involved in migration [1]. Ligand-receptor pairs significantly

expressed and predicted to facilitate chemotactic migration included SDF-1/CXCR4, VEGF/KDR and Osteopontin/ITGAV. In this work we modeled the ligand-receptor activated cytoplasmic and nuclear signaling for SDF-1/CXCR4, VEGF/KDR, and Osteopontin/ITGAV to identify downstream mechanisms facilitating PPC and RPC migration (Fig. 2). We then visualized these three target receptors on the surface of both PPCs and RPCs (Fig.2). Next, we entered our PPC receptor data into a systems pharmacologic database to identify FDA approved drugs to modulate expression of receptors correlated to migration (Fig.3). Viability was evaluated in RPCs treated with drugs for 3hr, 6hr and 12hr at a concentration of 10μM (Fig. 4). Ligand-receptor driven PPC and RPC chemotactic migration was quantified using microfluidic channels and steady-state ligand gradients of VEGF, SDF and Osteopontin (Fig. 5). The data reveal combined bioinformatics modeling and systems pharmacology can be used to modulate of transplantable photoreceptor replacement cell chemotactic machinery to enhance migration toward improved transplantation outcomes.

Stimulation of A_{2B} Adenosine Receptors Enhances Activity of Connexin26 Hemichannels in Epithelial Cells of the Human Respiratory Airway.

A. Dierks, A. Bader, T. Lehrich, **A. Ngezahayo**; Leibniz Universität Hannover, Department of Cell Physiology and Biophysics, Hannover, GERMANY.

Inflammatory conditions of the respiratory airway upregulate the release of adenosine and change the expression of connexins (Cx). As a component of the lung's innate immune defense, adenosine participates in the mucus clearance and has anti-inflammatory and tissue protective effects in acute inflammation. In chronic conditions however, adenosine and Cx channels may contribute to inflammation firing and tissue detrimental events. We used Calu-3 cells to analyze the interplay between adenosine signalling and Cx channels in epithelial cells of the respiratory airway. The gold nanoparticle mediated laser perforation (GNOME-LP) intercellular dye transfer technique and dye uptake experiments were used for a quantitative estimation of the gap junction intercellular communication (GJIC) and the activity of Cx hemichannels, respectively. After we found that the adenosine receptor agonist NECA reduced the GJIC and enhanced the Cx hemichannel activity, we analysed the expressed Cx isoforms and adenosine receptor subtypes using quantitative RT-PCR and western blotting. Pharmacological agents and specific siRNAs allowed to determine the specific contribution of the different adenosine receptor subtypes, the induced signalling pathways as well as the respective connexin isoforms. We found that the NECA-related increase of the dye uptake rate depended on increased cAMP synthesis and subsequent activation of the protein kinase a (PKA). This reaction was predominantly related to stimulation of the A_{2B} adenosine receptor subtype. Moreover, the NECA-related enhancement of the dye uptake was accompanied by an upregulation of Cx26 expression and protein synthesis. The findings suggest that in epithelial cells of the human respiratory airway, stimulation of A_{2B} adenosine receptors activates the cAMP/PKA pathway, resulting in upregulation of Cx26 expression and synthesis. Cx26 forms gap junction hemichannels in the cell membrane. The identified mechanism integrates adenosine signalling and gap junction hemichannel activity and gives evidence that adenosine signalling and Cx channels may act together to promote persistent inflammation, the hallmark of various pathological conditions such as cystic fibrosis, idiopathic pulmonary fibrosis, chronic obstructive pulmonary disease, or asthma.

P1550/B685

Localization of Critical Endocytic Molecules Needed for Gap Junction Plaque Internalization and an nular Gap Junction Formation.

T. Shakespeare[1], A. L. Long[2], J. D. Quezada[2], **S. A. Murray**[2]; [1]Savannah State University, Savannah, GA, [2]University of Pittsburgh Sch Med, Pittsburgh, PA.

Gap junction channels facilitate the communication of molecules between two neighboring cells. Gap junction-mediated communication plays a key role in regulating cell activity during cell development, wound healing, and many other cellular processes. Gap junction channels, which are clustered into gap junction plaques, are eliminated from the cell surface by an internalization process that results in the formation of annular gap junction vesicles. Alterations in the rate of gap junction plaque internalization have been indicated to have profound consequences on intercellular communication and play a pivotal role in disease development. While the components of this internalization process are still insufficiently understood, it has been demonstrated that internalization involves a clathrin-mediated gap junction membrane invagination, which results in a dynamin-dependent release of annular gap junction vesicles into the cytoplasm of one of two contacting cells. We hypothesize that for internalization to occur, endocytic molecules would need to align with the gap junction surface in only one of the two contacting cells. To test this hypothesis, the relative locations of the clathrin and its adaptor protein (AP-2) with gap junction plaques were visualized in contacting cells. Immunocytochemistry, transmission electron microscopy (TEM), and 3D computer-assisted reconstruction methods were used to study gap junction plaque internalization in a human adrenocortical tumor cell line that expresses connexin 43 gap junction protein. We demonstrated the preferential association of clathrin and its adaptor protein (AP-2) with the gap junction plaque face in one of the two adjacent cells. Specifically, the association of AP-2 with the surface of gap junction plaques in one cell (70 ± 10% SEM) was more prevalent than the association with both faces of the gap junction plaques in the two contacting cells (30 ± 8% SEM). These findings, along with the corresponding observations made with TEM in which most annular gap junction vesicles were devoid of material adjacent to their inner (luminal) membrane, are consistent with the preferential attraction of clathrin and AP-2 to the gap junction plaque membrane in one of the two neighboring cells. Further, we suggest that there is a repulsion of these endocytic molecules in the adjacent cell. The attraction of endocytic molecules to one face of the gap junction plaque and exclusion from the other face would thus facilitate gap junction plaque internalization. Understanding the mechanisms of gap junction plaque removal from the cell surface will expand our knowledge of gap junction protein trafficking, turnover, and cell-cell communication. Supported by NSF Grant #MCB-1408986

P1551/B686

Endocytosis Across the Gap Junction Connexin Protein Family.

C. G. Fisher, **M. M. Falk**; Lehigh University, Bethlehem, PA.

Proteins fated to be internalized by clathrin mediated endocytosis require an endocytic motif where AP-2 or other adaptors can bind and recruit clathrin. Tyrosine and di-leucine based sorting signals have been characterized to be such canonical motifs. Studies by us and others have shown that Cx43 has two canonical tyrosine based endocytic motifs that recruit clathrin and mediate its endocytosis. Here, we have examined amino acid sequences across the connexin protein family to identify canonical and possible non-canonical endocytic motifs to determine how non-Cx43 gap junctions might be

endocytosed. An alyses showed that surprisingly, quite a number of mammalian connexins do not contain any recognizable endocytic motifs. Moreover, through Clustal Omega sequence alignment, we have shown that unexpectedly, there is very little conservation of endocytic motifs between connexins, except for between Cx30 and Cx32. While most connexins that have recognizable endocytic motifs have them located in the C-terminal portion, some have canonical signals instead located in the intracellular loop (e.g. Cx36). We then demonstrate through an assortment of GFP-tagged connexins that either contain or do not contain recognizable endocytic motifs and video microscopy, that even endocytosis of connexins without recognizable endocytic motifs can occur; even in cells that do not express any other connexin type (HeLa, MDCK2 cells). Thus, the endocytic mechanisms that are embodied across the connexin protein family are unexpectedly diverse and needs to be investigated further. The reason for this diversity currently is not known, but it is tempting to speculate that it correlates with connexin-species function, and/or the tissue the connexin type is expressed in. An alyses towards this end are currently under way.

P1552/B687

Unveiling Disease Relevance in Gap Junction Turnover.

C. A. Hyland, M. Falk, K. Iovine; Lehigh University, Bethlehem, PA.

Mutations in the gap junction (GJ) forming proteins, connexins (Cxs) are known to cause a diverse array of severe human diseases, including hearing loss, neuropathies, skin disorders, and cancer. Interestingly, the half-life of GJ channels is short (1-5 hours) suggesting that regulated turnover plays an important role in GJ function. Over the past years we have characterized in great detail the molecular machinery that turns over GJs, and we identified a number of specific amino acid residues in the Cx43 (the most widely expressed and best studied GJ protein) C-terminal tail that are critical regulators of GJ turnover. To test the hypothesis that mutations on these critical sites could function as a disease mechanism, we established the CRISPR/Cas9 gene-editing technology in the zebrafish model organism. We expect that our analyses will show whether mutations on turnover-relevant residues can lead to disease and to what phenotypes; an important unaddressed yet likely disease mechanism. As impaired GJ turnover should negatively affect cell migration that is particularly critical during development, we expected primarily developmental phenotypes (including embryonic lethality). Our hypothesis is supported by the fact that a large number of healthy humans (over 60,000 individuals represented in the ExAC data base) do not exhibit mutations of any of the residues that we have identified. We began by replacing wild type Cx43 with a mutant in which all of the identified amino acid residues critical for endocytosis were deleted (Cx43ΔCT). However, this mutant still expresses the critical residues that allow it to be trafficked to the plasma membrane and form gap junction channels. Surprisingly, Cx43ΔCT homozygous zebrafish develop to adulthood, but show a significant increase in their heart rate, abnormal hematopoiesis, and a significant lengthening of fin segments, indicating mis-regulated development in organs known to be affected by Cx43 mutation. In addition, a more specific Cx43 mutation (Cx43Δ256-289) which deletes only some of the critical residues involved in gap junction turnover shows different phenotypes, such as a decrease in heart rate and normal fin segment lengths. Currently, we are testing whether the surviving fish are rescued by another connexin type that takes over the functions of Cx43, e.g. Cx40.8. Cx40.8 is a close relative of Cx43 that is the relict of a gene duplication that occurred in pre-historic time in the teleost family. We are also testing the causes of these phenotypes by analyzing the molecular properties of these mutated gap junction channels and how they affect the function of the cells and tissues that rely on them.

Complex Processing of Internalized Gap Junctions.

R. Norris, M. Terasaki; UConn Health, Farmington, CT.

Gap junctions connect cells of nearly all tissues in both vertebrates and invertebrates. While they are traditionally thought of as stable, long-lived structures, gap junctions are actually very dynamic in some tissues, turning over within a few hours after they form. The best-described mode of turnover is when one of the two connected cells engulfs the entire gap junction along with cytoplasm and membrane from the neighboring cell to form a double membrane vesicle, commonly referred to as a connexosome. The processing of connexosomes is poorly understood and is of interest in light of evidence that connexins have functions in addition to forming cell-cell channels. We are studying the ultrastructure of connexosomes within ovarian granulosa cells, which have a large number of these vesicles after cells are stimulated with luteinizing hormone. Using 3D electron microscopy with immunogold labeling, we have categorized and measured around 200 such internalized structures that contain Cx43 in a defined volume of tissue. We find that these structures have a wide variety of features. While slightly more than half fit the definition of a connexosome, many complex structures contain membrane regions that lack Cx43. Several structures contain intraluminal vesicles like those found in maturing endosomes, while a few contain whole organelles including mitochondria. An other subset appears to be undergoing lysosomal degradation. Notably, we have found similar double membrane vesicles in liver comprised in part of Cx32 gap junctions. Our ultrastructural study shows that by way of internalization, gap junctions can transfer bulk cargo to neighboring cells. The fascinating array of vesicles comprised of connexins shares structural similarities with both autophagosomes and endosomes. In essence, our studies provide insight as to how connexins and gap junctions could function beyond the plasma membrane.

P1554/B689

Phosphorylation Opens Up the C-terminal Domain Packing of Connexin43 Giving Enzymes and Endocytic Machinery Components Access to Aid in Gap Junction Endocytosis: Evidence by Molecular Modeling.

M. Falk, Y. Gao, W. Im; Lehigh University, Bethlehem, PA.

Gap junctions have a surprisingly short half-live of only a few hours, an unusual and not well understood feature for a membrane channel that can be regulated by gating. The short half-live suggests that gap junction channels, soon after accrual to the plaque reach a stage where they no longer can fully function, and hence need to be endocytosed and replaced with functional channels. Using live-cell photobleaching, Dendra2-photoconversion, and successive FlAsH/ReAsH staining techniques combined with time-lapse imaging provided evidence for such a fast turnover, as well as accrual of newly synthesized gap junction channels predominantly along plaque peripheries and a simultaneous internalization of older channels from plaque centers. To better understand gap junction endocytosis, we have characterized in detail the molecular events that lead to gap junction internalization. We found that a series of post-translational modifications, ZO-1 binding and release, phosphorylation/de-phosphorylation on specific Cx43 C-terminal residues, as well as K63-poly-ubiquitination transitions functional into non-functional channels that then can interact with AP-2/clathrin and be endocytosed. We showed that ZO-1 - probably because of its huge size sterically hindering access of kinases, phosphatases, and E3-ubiquitin ligases to the Cx43-CT - needs to be removed from Cx43 before

endocytosis of gap junction channels can occur. We also showed that phosphorylation, on critical serine residues (e.g. S368, S279/S282), and ubiquitination needs to occur before AP-2/clathrin can bind and internalize Cx43-based gap junction channels. Based on Solan, Lampe, and Sorgen work showing that S365 de-phosphorylation/S368 phosphorylation causes a conformational alteration of the Cx43 C-terminal domain, we hypothesized that phosphorylation opens up the packing of the C-terminal domains to allow access of the endocytic machinery to the Cx43-CT, and to internalize gap junction channels. We built a hybrid-Cx model consisting of the low-energy solution structure of the Cx43-CT (published by the Sorgen lab) fused to the atomic resolution structure of Cx26 (published by the Tsukihara lab) and used CHARMM-GUI membrane builder software to model gap junction channels with un-phosphorylated and phosphorylated (S368, S279/S282) C-termini. Modeling demonstrates that phosphorylation indeed opens up the cytoplasmically located Cx43-C-terminal domains providing support for our hypothesis, and a molecular mechanism for how endocytosis of Cx43-based gap junction channels is regulated.

P1555/B690

Connexin43 (Cx43), Fin Regeneration and Bone Composition and Density in Zebrafish.

A. D. Hoptak-Solga; Kutztown University, Kutztown, PA.

Zebrafish have the remarkable ability to regenerate missing caudal fin tissue. This ability provides a model system to study the mechanisms responsible for the control of bone growth. During the growth process, new bony segments and joints are added to the distal tip of the caudal fin. This process is affected in several fin length mutants, including the *short fin* (*sof*) and *long fin* (*lof*) mutant. In the *sof* mutant, the number of segments produced is similar to wild type, however, the size of the segments is shorter; whereas, the *lof* mutant produces segments similar in size to wild type, but the number of segments produced is greater. The *sof* mutants develop short fins due to mutations in the gap junction gene *connexin43* (*cx43*). Mutations in human Cx43 can cause Oculodentodigital dysplasia (ODDD), a disorder characterized by craniofacial and skeletal malformations. Connexins are subunits of gap junctions which serve as intracellular passageways for the exchange of molecules between cells, including the exchange of signals between osteoblasts that may coordinate bone growth. Gap junctional intercellular communication (GJIC) between these cells may be responsible for regulating segment length. We have shown that short fin mutants have fins that are half the length of wild-type fins, reduced levels of *cx43* mRNA and a reduction in the amount of cell proliferation in the mesenchyme of regenerating cells. Using a novel technique of targeted gene knockdown of *cx43* in regenerating fins, we were able to recapitulate the segment length defect as well as the cell proliferation defect in the *sof* mutants. We hypothesize that the level of intercellular communication via gap junctions in the population of dividing cells in the regenerating fin may regulate bone growth by regulating the level of cell proliferation. Defects in Cx43 may also affect gap junction channel structure which may affect channel function and GJIC. Differences in channel structure were visualized using electron microscopy (EM), Energy-dispersive X-ray spectroscopy (EDS) and Quantitative backscatter imaging (qBEI). Chemical composition differences including calcium and bone density variations between newly formed bone post amputation and old bone was examined to better understand the self-repairing nature of fracture healing. Naturally, as humans age or enter microgravity conditions, overall bone density decreases, therefore understanding the role Cx43 plays in cell-cell communication in coordinating a response to re-grow missing tissue combined with bone composition analysis in zebrafish can help to better understand bone fracture healing in humans.

P1556/B691

Reciprocal Relationships between Gap Junction Nexus Morphology and Cell Physiology.

R. F. Stout, Jr[1], S. McCutcheon[2], D. Tanis[1], M. Gleeson[1], H. Jani[3], Y. Nori[3], D. C. Spray[2]; [1]New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, [2]Dominick P. Purpura Department of Neuroscience, Albert Einstein College of Medicine, Bronx, NY, [3]New York Institute of Technology, Old Westbury, NY.

Vertebrate gap junctions are formed by multimeric transmembrane connexin proteins. Connexins are required in all human organs. The 21 human connexin isoforms are expressed in cell-type specific combinations. Our current research is focused on gap junction isoforms Cx43 and Cx47 which are expressed in astrocytes and oligodendrocyte cells of the brain along with other organs. Genetic deletion of either connexin can lead to dysfunction of the human nervous system. We previously found that the gap junction supramolecular complex known as the Nexus can exist in strikingly divergent stable or fluid states. Nexus fluidity was altered by redox levels, carboxyl-terminus sequence, and importantly, by addition of a fluorescent protein tag. *New research reported here is aimed at testing how the gap junction Nexus controls subcellular morphology and physiology outside of the gap junction plaque.* We found that gap junction plaques profoundly alter localization of other proteins in the vicinity of the junctional membrane area. Transgene expression and mutation studies indicated that the effects of gap junctions on cell morphology are generated by two or more distinct mechanisms. We will also describe new fluorescent protein tagging strategies that allowed us to circumvent long-standing impediments to gap junction cell research and new image analysis methods we developed to quantify experimentally induced changes to Nexus morphology. Additionally, we report results of confocal microscopy and single-molecule localization microscopy that confirm and extend previous reports by other groups of spatially-differential posttranslational modifications to connexins within the gap junction Nexus and a spatial association of endoplasmic reticulum to gap junction plaques. Based on these and other findings, we hypothesize that Nexus fluidity alters intercellular calcium signaling. Variability in size and shape of gap junctions makes testing this hypothesis difficult- even in cell culture- so we turned to mesoscale computational modelling. We are currently testing if Nexus fluidity alters intercellular calcium signaling by using computational simulations in which gap junction channel number and mobility can be precisely controlled and experimentally modified. In *general, the results we present reveal new aspects of gap junction control over cell morphology and intercellular signaling.*

Low Adhesive Scaffold Type I Collagen Prepared from Porcine Skin Regulates the Expression of Genes Relating to Osteocyte Differentiation.

S. Kunii, K. Morimoto; Kindai University, Kinokawa, JAPAN.

[Background] Collagen has biocompatibility and biodegradability with tissue or organ, therefore, collagen is the most promising material for tissue engineering. In general, the binding of rat marrow mesenchymal cells (rMMCs) to collagen scaffold is considered an effective to promote osteocyte differentiation. However, it is not clear why collagen is a suitable scaffold. At the ASCB&EMBO 2017

Congress, we showed that low adhesive scaffold type I collagen (LASCol) has marvellous ability to induce osteocyte differentiation in short term. In this study, we report the ability of LASCol scaffold by analyzing focused genes of osteogenesis. [Methods] Rat MMCs ($5x10^4$ cells/dish) were cultured on LASCol coated-dish with osteogenic basal medium. The alkaline phosphatase (ALP) activity of rMMCs cultured on the LASCol coated dish was observed. To evaluate osteogenic differentiation, mature RNA was isolated and reverse transcribed, subsequently the cDNA was analyzed with the real-time RT^2 Profiler™ PCR Array Rat Osteogenesis (QIAGEN). In addition, the up-regulated genes were further validated by qRT-PCR with specific primers. [Results] Rat MMCs on the LASCol coated-dish formed spheroid bodies and most of them showed ALP activity. However, on the other scaffolds only 60%-70% of cells had the ALP activity. Thus, the contact with LASCol might increase the ratio of osteocyte differentiation. Interestingly, after three days culture only a few genes of 84 genes showed increasing or decreasing. Though the genes such as *Col2a1*, *Bglap*, and *Phex* up-regulated, the threshold cycle of *Runx2* gene was similar. In particular, *Phex* might be an important gene because of the relative expression was high. Probably, LASCol would have the ability to induce osteocyte differentiation of rMMCs by the different gene expression. [Funding] This work was supported by the Adaptable and Seamless Technology Transfer Program through target-driven R&D (AS2715177U to K.M.). We thank Nitta Gelatin Inc. that provided the collagen materials.

Tenascin-c Prolongs Inflammation and Edema by Inhibiting Lymphangiogenesis.

D. Katoh, Y. Shiraki, T. Yoshida, K. Imanaka-Yoshida; Mie university, Tsu, JAPAN.

<Introduction>Tenascin-C (TNC), an extracellular matrix protein, is well known to activate inflammation responses via activating inflammatory cells or promoting angiogenesis. The purpose of our study was to examine the relationships between TNC and lymphangiogenesis, because recent studies have showed lymphatic vessels are associated with the resolution of inflammation.<Methods>We used a mouse tail lymphedema model in vivo, and human dermal lymphatic endothelial cells (HDLEC) in vitro.<Results>TNC-knock out (KO) mouse revealed decreasing lymphedema compared to WT mice. Deletion of TNC promoted the growing of lymphatic vessels and reduced the accumulation of macrophages in inflammatory lesions. Furthermore, the number of lymphatic vessels were significantly increased in TNC-negative area, compared to TNC-positive area in WT mice. To assess the lymphatic function, we injected Evans blue dye (EB dye) intradermally at the tip of the tail and measured the concentration of EB dye in the drainage lymph node. The concentration was significantly higher in TNC-KO mouse, indicating the better flow of lymph fluid in TNC-KO. These results suggested lymphatic vessels were increased in TNC-KO; in other words, TNC may inhibit lymphangiogenesis. Therefore, we examined the direct interaction of TNC and lymphatic vessels in vitro using HDLEC. We found that TNC significantly decreased the number of HDLEC. In addition, TNC decreased the proliferative cells and increased the apoptotic cells. TNC also disturbed the tube formation ability of HDLEC. Thus, TNC has negative effects on HDLEC and, therefore, we next examine how TNC affects on HDLEC. We found that TNC increased the phosphorylation levels of p38 MAPK and ATF-2. In addition, phospho-ATF-2 positive nucleus were significantly increased after TNC addition. Inhibition of p38 MAPK completely suppressed the TNC-induced effects on HDLEC. Thus, p38 MAPK/ATF-2 is critical for TNC function. Furthermore, inhibition of TGF-β receptors completely suppressed the phosphorylation of p38 MAPK and TNC-induced effects on HDLEC. However, interestingly, SMAD inhibitor did not suppress the phosphorylation of p38 MAPK and TNC-induced effects on HDLEC, although TNC increased the phosphorylation levels of

SMAD2/3 in HDLEC. Therefore, we focused on the non-canonical TGF-β signaling. TNC increased the phosphorylation level of TAK1, known as one of the non-canonical pathway. Inhibition of TAK1 suppressed the phosphorylation of p38 MAPK and TNC-induced effects on HDLEC. Thus, non-canonical TGF-β signaling was associated with the effects of TNC on HDLEC.<Conclusion>TNC inhibits lymphangiogenesis and prolongs inflammation and edema. TNC suppresses proliferation and promotes apoptosis of HDLEC via TGF/TAK1/p38/ATF-2 signaling pathway.

Matrix Fibulin-1 Association with Epidermal Growth Factor Receptor Inhibits Its Activation and Function in Lung Cancer.

K. Harikrishnan, 411008, N. Balasubramanian; Indian Inst Science Education/Res (IISER), Pune, INDIA.

Epidermal Growth Factor Receptor (EGFR) is a known promoter of tumor progression and is overexpressed in lung cancer. Growth factor receptors (including EGFR) are known to interact with extracellular matrix (ECM) proteins, which regulate their activation and function. Fibulin-1 (FBLN1) is a major component of the ECM in lung tissue, and its levels are known to be downregulated in non-small cell lung cancer (NSCLC). To study the role Fbln1 could have in regulating EGFR signaling and function in lung cancer, we performed siRNA mediated knockdown of FBLN1 isoforms FBLN1C and FBLN1D in NSCLC cell line (Calu-1). This while not affecting net EGFR levels did significantly increase basal and EGF mediated EGFR activation. Overexpression of FBLN1C and FBLN1D accordingly is seen to inhibit EGFR activation as well in Calu-1 cells. Loss of FBLN1C/FBLN1D and resulting EGFR activation promotes migration of these cells in wound healing assays. This is confirmed by inhibition of EGFR using Erlotinib. Mechanistically, both FBLN1 isoforms interact with EGFR, though their association is not dependent on its activation. Notably, we discovered this association is detectable in cell-derived matrix (CDM) of lung cancer cells. Calu-1 cells plated on CDM's derived from FBLN1C/FBLN1D knockdown cells interestingly show a significant increase in EGF mediated EGFR activation. This promotes cell adhesion and spreading on CDM derived from knockdown cells, which is inhibited by Erlotinib. This also reflects in a distinct increase in the membrane localization of activated EGFR in spreading cells. Together, our findings show FBLN1 as part of the ECM can bind and regulate EGFR activation and function in NSCLC cells, highlighting the importance of tumor ECM microenvironment in influencing cellular behavior of EGFR dependent cancers.

Sculpting of Tissues by Tension-suppressed Degradation.

K. Saini[1], M. Tiwari[1], S. Cho[1], A. Jalil[1], J. Irianto[1], M. Vashisth[1], C. Pfeifer[1], L. Dooling[1], C. Alvey[1], A. Kasznel[1], D. Chenoweth[1], K. Yamamoto[2], D. Discher[1]; [1]University of Pennsylvania, Philadelphia, PA, [2]University of Liverpool, Liverpool, UNITED KINGDOM.

Development of tissue morphology generally depends on matrix and reflects a balance of synthesis and degradation of matrix proteins. Homogeneously tensed tissues and collagenous materials have suggested that collagen degradation is suppressed by strain, but tissues often sustain non-uniform strains that could in principle sculpt the mechanics and morphology of tissue. Here we study such processes in beating embryonic chick hearts and in isolated mice tail tendons. Normal beating hearts are subjected to ~5% peak strain in a spatiotemporally coordinated contractile wave, and the hearts maintain their collagen mass until the contractile strain is suppressed by inhibition of myosin-II.

Endogenous MMPs then degrade the collagens of contractility-inhibited embryonic chick hearts within ~30-60 minutes based on addition or not of MMP inhibitors and quantitation by calibrated mass spectrometry. In tendon fascicles, collagen fibrils primarily orient along the tension axis of the tissue but heterogeneous strains and gradients were induced using three-point, adherent bending, with patterned photo-bleaching of a fluorescent dye and collagen-binding peptide on fascicles used to measure strain. Microstructure of "cell-free" fascicles was simultaneously imaged using Second Harmonic Generation (SHG) signal while deformed fascicles were exposed to collagenases i.e. purified MMP-1 or Bacterial collagenase. Within physiological strain limits (i.e. ~5-8%), the decrease in fascicle degradation rate (relative to strain-free) was nearly independent of collagenase type despite different cleavage mechanisms, and tissue locations sustaining higher strains showed the degradation rate became almost independent of strain magnitudes. Sequestration of collagen's cleavage sites by strain is likely because permeation and mobility of fluorescent collagenase and dextran are strain-independent up to ~5-8% strains. Both tissue systems under heterogeneous strains indicate a degradative loss and sculpting of tissue locations that sustain the lowest strains.

P1561/B696

Type I Collagen Expression After Thermal Injury in Larval Zebrafish.

R. T. Burke, A. Huttenlocher; University of Wisconsin-Madison, Madison, WI.

Burn injuries are a prominent clinical issue often complicated by systemic inflammation and risk of infection. However, few models have been developed to address the molecular mechanisms that regulate burn injury healing. We have recently developed a zebrafish burn injury model to study burn injury healing, and have shown that collagen fibers are undetectable by second harmonic generation imaging (SHG) rapidly after thermal injury. Many experimental therapies have been designed to repair the extracellular matrix including applying collagen-based matrices over the healing wound. However, the regulation of endogenous collagen reorganization or repair is not well understood. Here, we have identified that different populations of cells are activating expression of type I collagen after either burn injury or fin amputation. We have expressed fluorescent reporters under control of putative promoters of type-I collagen subunits: *col1a1a, col1a1b and col1a2*. Larval zebrafish are either burned using an electric cauterizer or the caudal fin is transected with a surgical blade. Fish are then longitudinally followed during repair, and activation of type I collagen is assessed by fluorescent protein expression. In unwounded developing tails, *col1a1a and col1a1b* are expressed by elongated cells on the interior of the fin. In addition, *col1a1a* is expressed in the notochord and nervous tissue in the developing fin. Expression of *col1a2* is primarily in epithelial cells. Following both burn injury and tail transection, *col1a1a and col1a1b* are expressed in expanding cell populations on the interior of the regenerating fin. In contrast, *col1a2* is expressed in epithelial cells along the wound edge, and in cells surrounding collagen projections that have been previously identified during tail regeneration. Overall, here we present a new model in which to study the regulation of collagen regeneration during burn wound healing. Further studies are exploring the signaling that regulates collagen expression and timing during burn injury regeneration.

P1562/B697

Regulation of Extracellular Matrix Gene Expression by Desmosomal Cadherins.

H. R. Alexander[1], A. K. Godwin[1], D. E. Conway[2], A. D. Dubash[1]; [1]Furman University, Greenville, SC, [2]Virginia Commonwealth University, Richmond, VA.

Desmosomes are protein complexes crucial for maintaining cell-cell adhesion and integrity of tissues. These complexes are made up of proteins from three families: transmembrane cadherins (Desmoglein and Desmocollin) link adjacent cells in the extracellular space, armadillo proteins (Plakophilin and Plakoglobin) stabilize the intracellular plaque, and the cytolinker Desmoplakin (DP) connects the plaque to the intermediate filament network. Desmosomal proteins have also been shown to coordinate gene expression pathways required for processes such as proliferation, differentiation and cell migration. In particular, several lines of evidence have linked desmosomal proteins to gene expression of extracellular matrix (ECM) proteins. Loss of Plakophilin-2 or Desmoplakin causes increases in expression of fibronectin and collagen, while in contrast, loss of plakoglobin results in a significant decrease in expression of fibronectin. These data indicate that individual components of the desmosomal complex control ECM gene expression via distinct cellular signaling networks. In our study, we sought to investigate the role of desmosomal cadherins in ECM gene expression, via use of A431 cells lacking either Desmoglein-2 or Desmocollin-2, generated via CRISPR-mediated knock-out (Dsg2 KO and Dsc2 KO, kindly provided by Dr. Daniel Conway). Compared to control cells, Dsg2 KO cells demonstrated a dramatic (~10-fold) increase in expression of Fibronectin (Fn1), and relatively minor changes in expression of Collagen 1 (Col1a1) and Collagen 2 (Col2a1). In contrast, no major changes in expression of Fn1 was observed in Dsc2 KO cells. We show that loss of Dsg2 KO (but not Dsc2 KO) also caused a significant increase in expression of the pro-fibrotic signaling molecule transforming growth factor beta 2 (Tgfb2), but not Tgfb1 or Tgfb3. Increased expression of Fn1, Col1a1, Col2a1 and Tgfb2 was also observed upon siRNA-mediated knockdown of Dsg2 in A431 cells, verifying that these changes are not clone-specific or due to off-target CRISPR effects. While expression of other desmosomal proteins is unchanged in Dsg2 KO cells (mRNA and protein levels), the integrity of the junctional complex was expectedly perturbed, as observed via a significant increase in Triton-solubility of Plakophilin-2, Plakophilin-3, Plakoglobin and Desmoplakin. Nevertheless, siRNA-mediated knockdown of these proteins could not rescue Fn1 or Tgfb2 increases in Dsg2 KO cells, indicating that these changes are not due to mis-localization of other desmosomal components. Taken together, our study highlights a novel role for Dsg2 in mediating ECM gene expression, adding significant insight into the mechanisms by which desmosomal cadherins control the adhesive behavior of cancer cells.

P1563/B698

Identification and Structure Activity Relationship Study of an α-Dystroglycan Binding Peptide from the Laminin α2 Chain LG4-5 Modules.

K. Hamada, G. Zhang, Y. Yamada, A. Truong, Y. Kikkawa, M. Nomizu; Tokyo University of Pharmacy and Life Sciences, Hachioji, Tokyo, JAPAN.

Laminin is a major component of the basement membrane and has various biological activities. Laminin consists of α, β, and γ chains, in which 5α (α1-α5), 3β (β1-β3), and 3γ (γ1-γ3) chains have been identified. The laminin α2 chains are specifically expressed the in skeletal muscle, peripheral nerves, brain, and capillaries. The laminin α2 chain interacts with integrin α3β1, integrin α7β1, syndecan, and α-dystroglyan (α-DG). Specific binding of the laminin α2 chain with α-DG is critical to maintain the

structure and function of skeletal muscle, and genetic disruption of the laminin α2 chain causes muscular dystrophy. The laminin α2 chain binds to α-DG through its C-terminal globular module of LG (laminin globular) 4-5 modules. Previously, we developed an assay system to identify α-DG binding peptides using an Fc-tagged recombinant α-DG and peptide-chitosan matrices. We screened α-DG binding sequences of the laminin α2 chain LG4-5 modules using 42 peptides covering the entire sequence of the modules. The peptides were synthesized with a CGG residue on their N-terminus and conjugated on maleimidebenzoyloxy-chitosan to construct a peptide-chitosan matrix. Four peptide-chitosan matrices (A2G77-, A2G78-, A2G80-, and A2G95-chitosan matrices) demonstrated the Fc-DG binding. In this study, we focus on the A2G80 peptide (VQLRNGFPYFSY) and have performed a structure activity relationship study to obtain stronger binding peptides to α-DG. We synthesized a set of alanine-substituted peptides and evaluated α-DG binding activity. Initial results suggested that the side chain of three amino acid residues (Asn, Pro, Ser) does not affect α-DG binding activity of A2G80. Based on these results, we synthesized an additional 36 peptides focusing on two amino acid residues (Asn, Ser) and reevaluated α-DG binding activity. Some peptides significantly enhanced the activity compared with that of A2G80, suggesting that these substituted residues are critical for the α-DG binding. These results are useful for understanding α-DG binding mechanism of A2G80 and these peptides have a potential to be used as a drug delivery tool that are selective for the skeletal muscle.

P1564/B699

Force-dependent Extracellular Matrix Remodeling Results in Altered Exosome Diffusion by Cancer Cells and Activates Stromal Fibroblasts.

Y. Chen, 21218, W. Jung; Johns Hopkins University, Baltimore, MD.

It is known cancer cells secrete cytokines inducing normal fibroblasts (NFs) to become carcinoma-associated fibroblasts (CAFs). However, it is not clear how the CAF-promoting cytokines can effectively navigate the dense ECM, a diffusion barrier, in the tumor microenvironment to reach NFs during the early stages of cancer development. In this study, we devised an organoid system to investigate the possible mechanism of CAF induction at early stages of breast cancer. We found that in a force-dependent manner, ECM fibrils are radially aligned relative to the tumor spheroid. The fibril alignment enhances the diffusion of exosomes containing CAF-promoting cytokines towards NFs. Suppression of force generation or ECM remodeling abolishes the enhancement of exosome diffusion and the subsequent CAF induction.

P1565/B700

Nanoarchitecture and Size-exclusion Barrier Function of the Enteric Glycocalyx Examined by Freeze-etching Electron Tomography and Macromolecular Diffusion Assay.

W. W. Sun[1,2], E. S. Krystofiak[1], R. Cui[1], A. Sesso[3], R. Weigert[4], S. Ebrahim[4], B. Kachar[1]; [1]National Institute on Deafness and Other Communication Disorders, Bethesda, MD, [2]University of Maryland, College Park, College park, MD, [3]Institute of Tropical Medicine, University of São Paulo, São Paulo, BRAZIL, [4]National Cancer Institute, Bethesda, MD.

The intestinal epithelium is the largest interface between our bodies and the external environment and functions as a selective barrier for both endo- and exogenous materials, including pathogens. Directly adhering to the apical surface of the epithelium is an extensive layer of glycoprotein network—the glycocalyx—which has been hypothesized to function as a protective diffusion barrier to the underlying

epithelium. Visualization of the enteric glycocalyx by conventional transmission electron microscopy has revealed the presence of a layer of dense filamentous proteins situated atop the brush border that appear as a fuzzy coat. This appearance is due to inadequate preservation of glycocalyx native structure. In order to obtain an in-depth understanding of glycocalyx structure-function relationship, we performed freeze-etching electron tomography to visualize the enteric glycocalyx architecture of the rodent intestine in its native hydrated state in combination with Dextran-based diffusion experiment to probe its diffusion barrier property. We observed micrometer-long filamentous proteins emerging exclusively from the tips of microvilli. These filaments displayed extensive lateral contacts resulting in a dense three-dimensional columnar network with a 30 nm mesh. Strikingly, filament termini converge to form globular structures that are ~30 nm apart with liquid-crystalline packing organized into a plane. We then tested the functional relevance of these ultrastructurally derived dimensions by incubating rodent small intestine with different molecular weight fluorescent Dextran. We observed that 3 kDa Dextran with small Stokes radius at approximately 1.2 nm readily diffuses across the glycocalyx layer. On the other hand, the diffusion of 2000 kDa Dextran with an estimated Stokes radius at 27 nm was impeded by the surface coat. Our findings show that the enteric glycocalyx forms a continuous complex columnar network that traverses throughout the intestinal tract and physically segregates the apical cell surface from the lumen. In addition, inter-filament mesh size and filament termini spacing form the basis of a size-exclusion filter that allows passage of vital nutrients while preventing micrometer-scale bacteria access to the apical surface. Taken together, we have established a renewed structural understanding of the enteric glycocalyx and provide a foundation for future explorations on how the architecture of this surface coat correlates with intestinal physiology.

Identification of Biologically Active Site in Mouse Laminin Alpha3b Chain N Terminal Region.

F. Katagiri, M. Hashidume, N. Midorikawa, S. Hiraoka, K. Kimura, R. Takayanagi, K. Hozumi, Y. Kikkawa, M. Nomizu, Y. Yamada; Tokyo University of Pharmacy and Life Sciences, Hachioji, JAPAN.

Laminin α3 chain is a kind of laminin that is one of the components of extracellular matrix, and is highly expressed in the skin to promote skin regeneration and wound healing. Two types of isoforms with different N-terminal domains, α3A chain and α3B chain, have been identified for laminin α3 chain. Both laminin α3A chain and α3B chain are derived from the LAMA3 gene, and the α3B chain is a huge protein consisting of 1,800 amino acid residues with multiple globular domains at the N-terminus. On the other hand, the α3A chain has a structure in which most of the globular domain of the α3B chain is deleted. In this study, synthetic peptides covering the amino acid sequence of the N-terminal region of laminin α3B chain were prepared, and the biological activity of the peptides was evaluated for the purpose of elucidating the function of the N-terminal region of laminin α3B chain. A peptide consisting of 12 residues in length covering the amino acid sequence of the mouse laminin α3 chain N-terminal region was designed, and 188 peptides were synthesized. Human dermal fibroblasts (HDF) were used to evaluate the cell adhesion activity, and EDTA/heparin was added to the peptides that showed adhesion activity to identify the adhesion mode. In addition, neurite outgrowth activity was evaluated using rad adrenal pheoxhromocytoma cells (PC12). Twenty-one peptides showed adhesion activity to HDF, and 6 peptides showed neurite outgrowth activity. Of the 21 types that showed adhesive activity, 5 were heparin only, 3 were EDTA only, and 8 were both heparin and EDTA, and cell adhesion activity was inhibited. In addition, most of the active peptides were located in the globular domain of the laminin α3B chain. Many active peptides have been found in the globular domain at the C-terminal of laminin α3

chain. Similarly to laminin α3B chain, active sites are reported to be concentrated in the globular domain in laminin α1, α2, and α5 chains with N-terminal region, and they also play important functions in actual proteins. It has been suggested that the results of this study may provide useful information for elucidating the biological activity of laminin α3B chain.

Integrins and Cell-ECM Interactions

P1567/B702

The Pix Pathway Directs Assembly of Integrin Adhesion Complexes in Muscle.

J. C. Moody, H. Qadota, A. Reedy, D. Okafor, N. Shanmugam, C. Christian, Y. Matsunaga, E. Ortlund, G. Benian; Emory University, Atlanta, GA.

Integrin adhesion complexes (IACs) are called focal adhesions in non-muscle cells, and costameres in muscle cells. These sites are crucial for the adhesion of cells to ECM and are required for transmission of lateral forces between muscle cells. The composition of IACs is well established, however the mechanism that determines when and where IACs will form is unknown. *C. elegans* striated muscle has IACs at 3 locations: M-line, dense body, and attachment plaque at muscle cell boundaries. From a screen for mutants that disrupt the localization of IAC component PAT-6 (α-parvin), we discovered that loss of function of *pix-1* results in the absence of PAT-6 at muscle cell boundaries, but not at the M-lines and dense bodies. PIX-1 is the nematode ortholog of human β-PIX. Muscle-specific expression of wildtype PIX-1 cDNA rescues the muscle cell boundary phenotype. *pix-1* mutants lack additional IAC components at muscle cell boundaries and display reduced locomotion, yet sarcomere structure is normal. PIX-1 localizes to all 3 IAC structures in muscle. Mutations in genes encoding proteins at all known steps of the PIX signaling pathway show defects at muscle cell boundaries. Mutation of the highly conserved P190 residue in RhoGEF domain of PIX-1 causes defective boundary structures but yields normal levels of PIX-1 protein. A homology model of the RhoGEF domain of PIX-1, based on the known structure of human β-PIX, together with molecular dynamics simulations, indicates that the P190S mutation disrupts the structure of the RhoGEF domain, and enhances its interaction of GTP-bound (active) Rac, thus perhaps reducing the rate of the GTPase cycle. Rho GTPases function as molecular switches between active and inactive states, facilitated by GEF and GAP proteins, respectively. However, a GAP for PIX-1 in nematodes or β-PIX in mammals has not yet been identified. Based on previous studies it is hypothesized that the terminal phenotype of loss of function for a GEF and a GAP for a specific GTPase and cellular function are the same. In *C. elegans*, there are 30 genes encoding proteins harboring RhoGAP domains, and 18 of them are expressed in muscle. We obtained loss of function mutants for these 18 genes and conducted PAT-6 immunostaining. Mutations in 2 genes yield the same muscle boundary defect as *pix-1* mutants. Therefore, our results provide the first evidence that a PIX protein has an important function in muscle, and we have identified the first GAP protein for the PIX pathway.

Mechanisms Regulating the Differential Adhesion and Spreading Characteristics of Hela Cells, Seeded on Fibronectin, Galectin 8 Or a Mixture of the Two.

W. Li[1], A. Sancho Erkizia[2], J. Groll[2], A. Bershadsky[3,1], B. Geiger[1]; [1]Department of Molecular Cell Biology, Weizmann Institute of Science, Rehovot, ISRAEL, [2]Department of Functional Materials in Medicine and Dentistry and Bavarian Polymer Institute (BPI), University of Würzburg, Würzburg, GERMANY, [3]Mechanobiology Institute, National University of Singapre, Singapore, SINGAPORE.

Galectin-8 is a mammalian lectin, which specifically binds to β-galactoside residues. It is secreted, and has the potential of modifying cell-extracellular matrixes interactions. Galectin-8 is widely expressed in various tissues, and has roles in vascular and lymphatic angiogenesis, B-cell function, and cancer metastasis. However, how galectin-8 affects cell spreading and adhesion is still poorly understood. Here, we describe the differential cytoskeletal and adhesion dynamics of HeLa cells, spreading on rigid flat substrate functionalized by fibronectin or galectin-8, or a mixture of both proteins. Using interference reflection microscopy, we found that HeLa cells, plated on galectin-8, have a faster spreading rate and a larger cell area than cells seeded on fibronectin. Measuring the detachment forces by Single Cell Force Spectroscopy revealed that the detachment forces per unit area on galectin-8 were two-fold higher than on fibronectin. On fibronectin, paxillin-positive focal complexes formed in a few minutes after seeding, matured into focal adhesions (FA) in about half an hour. On galectin-8, fuzzy clusters of paxillin at the periphery of lamellipodia underwent transformation into narrow strips associated with thin actin bundles perpendicular to the cell edge. They moved centripetally, and eventually vanished. During the spreading process, the total intensity of paxillin clusters increased on fibronectin, but decreased on galectin-8. On fibronectin, after half an hour of spreading, actomyosin forms circumferential fibres, while on galectin-8, at the same time, dynamic aster-like actomyosin structures assembled in the center of the cell. The total myosin-II filament intensity was weaker on galectin-8 than that on fibronectin. Furthermore, the addition of soluble RGD reduces cell spreading on fibronectin, but does not affect cell spreading on galectin, while the addition of thiodigalactoside does not change cell spreading on fibronectin, but reduces cell adhesion and spreading on galectin-8. The difference between cell spreading on fibronectin and galectin was associated with differential regulation of small Rho GTPase activity by cells seeded on these two ligands. We then studied how a mixture of fibronectin and galectin-8 modulates cell adhesion and spreading. Galectin coated substrates promoted formation of filopodia more effectively than fibronectin, and the maximal formation of filopodia was observed in cells seeded on substrates coated with a mixture of both proteins. We consider the possibility that galectin-8, at high concentrations interferes with integrin mediated signaling and blocks FAs and stress fiber formation, while at low concentrations galectin can enhance the adhesion and thereby cooperate with integrin mediated signaling.

Spatiotemporal Regulation of Clathrin Containing Adhesion Complexes in Proliferating and Quiscent Cells.

U. Djakbarova[1], N. Willy[1], S. Shamiluulu[2], C. Kural[1]; [1]Ohio State University, Columbus, OH, [2]Verizon Wireless, Hilliard, OH.

Clathrin-mediated endocytosis is the most extensively studied trafficking pathway from the cell surface to membrane-bound organelles. Cells exhibit two major modes of endocytic clathrin coats: dynamic

clathrin-coated pits and large, long-lived clathrin lattices called plaques. Recent studies show that clathrin plaques mediate cell adherence to the extracellular matrix via integrins and act as molecular scaffolds for transmission of mechanical forces required for migration. Canonical cell adhesion complexes (i.e. focal adhesions) are tightly regulated in proliferating and quiescent cells. However, it is not known how clathrin containing adhesion complexes (i.e. plaques) are regulated in cells. Using fluorescence live cell imaging and single particle tracking analysis, we observed significant variation in dynamics and spatial density of clathrin plaques across different stages of the cell cycle. Clathrin plaque density is high during G1 and G2 phases and low during S phase, exhibiting negative correlation with focal adhesion density. Furthermore, treating cells with Cyclin D1 inhibitor, which reduces focal adhesion maturation, increased plaque formation. We also found that clathrin plaque density gradually increased as cells exit the cell cycle, peaked in quiescent cells, and reduced back upon stimulating cell cycle re-entry. These results show that clathrin plaques provide cell adhesion in coordination with focal adhesions and their cooperation is tightly regulated in proliferating and quiescent cells.

Identification of Context-specific Force-sensitive Protein Complexes within Focal Adhesions.

A. Tao, A. LaCroix, B. Hoffman; Duke University, Durham, NC.

Mechanical cues, such as applied loads or extracellular matrix (ECM) stiffness, activate specific cell signaling pathways to affect key cellular processes, such as migration and differentiation. Cellular detection of these physical cues is thought to be mediated by protein conformation changes and the formation of key force-induced protein complexes within focal adhesions (FAs), subcellular structures that mediate physical connections between the ECM and force-generating cytoskeleton. As the key constituents that comprise force-induced protein complexes are unknown, we developed a novel technique to identify them by probing for proteins, or phosphorylation states, that selectively localize to areas of high tension. We achieve this by combining a FRET-based molecular tension sensor that reports the loads across a key mechanical linker protein, vinculin, with standard immunofluorescence protocols to probe for protein localization and phosphorylation states. Using this technique, we identified ten FA proteins and six phosphorylation states that are preferentially and specifically recruited to areas of high vinculin tension, suggesting that they form different force-induced protein complexes. Furthermore, as FAs are diverse structures that contain vinculin in various biochemically-distinct and mechanically loaded states, we hypothesized that differential force-induced protein complexes form in various FA subclasses. To test this idea, we developed a machine learning algorithm to identify two FA subclasses, those associated with stress fibers or protrusions, and searched for distinct vinculin-based force-induced protein complexes. Interestingly, nine proteins and two phosphorylation states exhibited differential force sensitive protein complex formation based on their associated FA class. In total, this work develops and uses a new imaging-based approach to demonstrate the existence of context-specific force-induced signaling capabilities amongst different FA proteins. Our observation that vinculin forms a variety of force-induced protein complexes in various FA subclasses suggests that vinculin load may activate different mechanosensitive signaling pathways in various adhesions. Indeed, preliminary experiments suggest that force-induced protein complexes that form in different FA subclasses are required for directed migration in response to aligned ECM.

P1571/B706

Spatio-temporal Dynamics between BMP Receptor and Integrin to Control Cell Decision Making.

A. Guevara[1], L. Fourel[1], I. Bourrin-Reynard[1], P. Machillot[2], O. Destaing[3], C. Picart[2], **C. Albiges-Rizo**[1]; [1]Institute for Advanced Biosciences INSERM U1209 CNRS UMR5309, GRENOBLE, FRANCE, [2]LMGP, GRENOBLE, FRANCE, [3]Institute for Advanced Biosciences INSERM U1209 CNRS UMR5309, GRENOBLE, France, GRENOBLE, FRANCE.

Understanding how cells integrate multiple signals from the extracellular matrix to make a decision, achieve specific cell differentiation and acquire cell identity is a challenging question in cell biology. We have previously shown that integrins and BMPR are able to cooperate for the cell response to biophysical cues from the microenvironment. Whether the temporal dynamics of both receptors are coupled to their spatial gradients to guide pivotal intracellular processes and to generate diversity in cell response was the pending question. Our goal is to explore whether cell fate depends on the differential spatio-temporal distribution between BMP receptor and Integrins. Based on biomaterials, live cell imaging and optogenetic tools, we show that the specificity of cellular response to receptor stimulation is encoded by their spatial and temporal dynamics. First the cooperation between BMPR and integrins depends on a discrete organization into segregated spatial domain between BMPR and integrins at the cell surface. Second the temporal control between BMPR and integrins is sufficient to drive cell spreading, cell mechanics and cell differentiation. Finally we demonstrate that integrins and BMP receptors finely communicate in space and time to control cell decision making.

P1572/B707

Vitronectin Promotes Axon Specification of Cerebellar Granule Cells Via αvβ5 Integrin and Pi3-kinase/gsk3β Pathway.

Y. Oishi[1], K. Hashimoto[2], A. Abe[1], M. Kuroda[1], Y. Miyamoto[2]; [1]Div. Of Life Sci., Grad.Sch. Of Humani. An d Sci., Ochanomizu Univ., Tokyo, JAPAN, [2]Inst. For Human Life Innov., Ochanomizu Univ, Tokyo, JAPAN.

Mouse cerebellar granule cells (CGCs) are the most numerous cells in cerebellum. There are still many unknown parts in cerebellar development, the generation of CGCs is also one of the mysteries of cerebellar development. Vitronectin (VN), one of the extracellular matrix proteins, has been reported to be expressed in the developing cerebellum. We previously revealed that VN controls the maturation of CGCs through the promotion of the initial differentiation stage progress. αvβ5 integrin is a receptor for VN in CGCs and is involved in the progression of the initial differentiation stage in CGCs. In this stage, axon specification and progress of the initial differentiation has been known to happen simultaneously. This finding motivated us to address the function of VN on the axon specification of CGCs. In addition, previous studies have shown that the PI3K / GSKβ pathway is involved in axonal formation in the hippocampus. Therefore, we hypothesized that VN and αvβ5 integrin are involved in the axon specification of CGCs. The aim of our research is to confirm that VN and its receptors are involved in the axon specification of CGCs, and to show the involvement of the PI3K / GSK3β pathway. First, we analyzed the effects of VN on the axon specification of CGCs in VN knockout mice-derived CGCs. Immunofluorescent staining showed that the loss of VN increased the ratio of CGCs with no axon, and VN addition increased the ratio of CGCs with multiple axons. Next, to analyze whether αvβ5 integrin is served as a VN receptor in the axon specification of CGCs, the effect of β5 integrin knockdown on VN-dependent axon specification was examined. The knockdown of β5 integrin failed to up-regulate the ratio of cells with multiple axons by VN addition. Furthermore, to examine the signal pathway of the

axon specification, we analyzed the effect of PI3K and GSK3β inhibitors on the VN-dependent axon specification. Wortmannin, a PI3K inhibitor, suppressed multiple-axon formation. Similarly, LiCl, a GSK3β inhibitor, promoted multiple axon-formation. In addition, we observed that the addition of VN to Neuro2a cells up-regulated the phosphorylation level of GSK3β using Western blotting. Taken together, our results indicate that VN promotes the axon specification of CGCs via αvβ5 integrin and PI3K / GSK3β pathway in the developing cerebellum.

P1573/B708

An In-depth an alysis of Cardiomyocyte Rigidity Sensing through Quantitative Imaging of Cardiomyocyte Forces and Integrin Mechanosensing Using PDMS Nanopillar and DNA Origami Nanoarrays.

W. Hawkes, P. Pandey, **T. Iskratsch**; Queen Mary University of London, London, UNITED KINGDOM.

Mechanical properties are cues for many biological processes in health or disease. In the heart, changes to the extracellular matrix composition and cross-linking results in stiffening of the cellular microenvironment during development. Moreover, remodelling after myocardial infarction, or in cardiomyopathies lead to fibrosis and a stiffer environment. Previous studies established a direct relationship between rigidity and the contractile forces of cardiomyocytes. However, it is still elusive how cardiomyocytes sense matrix stiffness. By combining nanopillar arrays, PDMS gels with defined stiffness and FRET molecular tension sensors, we identify here a fundamental mechanism for cardiomyocyte rigidity sensing, whereby single cardiomyocyte adhesions sense simultaneous (fast oscillating) cardiac and (slow) non-muscle myosin contractions. Together this leads to oscillating tension on the mechanosensitive adaptor protein talin on substrates with a stiffness of healthy adult heart tissue, compared to no tension on embryonic heart stiffness and continuous stretching on fibrotic stiffness. To further investigate the mechanosignalling pathways downstream of cardiomyocyte integrins, we designed DNA origami nanoarrays, which enable the display of receptor ligands in a highly customisable manner, with modifiable parameters including ligand number, ligand spacing, inter-cluster spacing and multivalency. Combining the nanoarrays with various imaging techniques (FRET/FLIM, FRAP, SIM), we find distinct clustering behaviour of cardiomyocyte integrins as well as the involvement of additional cytoskeletal proteins in the regulation of cardiomyocyte rigidity sensing.

Tenascin-C Evokes Phenotypic Changes in Human Mammary Fibroblasts to Myofibroblasts with High Contractility Via Integrin αvβ1/TGF-β/SMAD Signaling Axis.

D. Katoh, Y. Kozuka, A. Noro, T. Ogawa, K. Imanaka-Yoshida, T. Yoshida, 5148507; Mie University Sch Med, Tsu, JAPAN.

Tenascin-C (TNC) is strongly expressed in the fibroblasts and cancer cells of breast cancer tissues. We examined phenotypic changes in human mammary fibroblasts (HMFs) after a treatment with TNC. The addition of TNC induced the aggregated cluster formation of cultured HMFs, similar to the “hill-and-valley” appearance of smooth muscle cells. The protein expression of α-smooth muscle actin (SMA) and calponin was significantly up-regulated. TNC increased the number of α-SMA- and/or calponin-positive cells with well-developed stress fibers in immunofluorescence, which enhanced contractile ability in the collagen gel contraction assay. TNC significantly up-regulated itself at the mRNA and protein levels, whereas the gene expression of *COL1A2*, *COL3A1*, *and FN1* remained unchanged. Double

immunofluorescence of human breast cancer tissues showed α-SMA and/or calponin-positive myofibroblasts in the TNC-deposited cancer stroma. Among several receptors for TNC, the protein levels of the αv and β1 integrin subunits significantly increased after the TNC treatment, while the gene expression of β3 significantly decreased. Immunofluorescence showed the augmented co-localization of αv and β1 at focal adhesions after the TNC treatment. Immunoprecipitation using an anti-αv subunit antibody revealed a significant increase in co-precipitated β1 levels with TNC in lysates. The addition of TNC induced the phosphorylation of SMAD2/3, and the nuclear translocation of SMADs was observed. SB-505124 and SIS3 blocked myofibroblast differentiation by TNC. Thus, TNC enhances its synthesis by forming a positive feedback loop and increases the levels of integrin αvβ1 heterodimers, which are known to activate TGF-β signaling. This was followed by a change to highly contractile myofibroblasts. TNC may contribute to the cancer stroma formation characteristic of breast cancer tissues.

P1575/B710

Galectin-8 Mediates Cyclosporine-induced Fibrogenesis in Human Gingival Fibroblasts.

P. Smith[1], C. Metz[2], A. de la Peña[2], C. Oyanadel[2], P. Avila[3], R. Arancibia[3], L. Vicuña[3], C. Retamal[4], A. González[4], **A. Soza**[4]; [1]Pontificia Universidad Católica de Chile, Santiago, CHILE, [2]Universidad San Sebastián, Santiago, CHILE, [3]Universidad Catolica de Chile, Santiago, CHILE, [4]Universidad San Sebastian, Santiago, CHILE.

Galectins are glycan-binding proteins that modulate a variety of cellular processes including fibrosis in several organs. Galectin-8 (Gal-8), one of the most widely expressed galectins, has two carbohydrate recognition domains (CRDs) through which can bind and activate selected β1-integrins and transforming growth factor-beta receptor TGFβRI, crucially involved in fibrogenesis. We recently described that Gal-8 induces partial epithelial mesenchymal transition (EMT), which included an increased expression of fibronectin, as is characteristic of fibrogenesis. Here we study the role of Gal-8 in the response of gingival connective tissue cells to cyclosporine, which unwanted effects include gingival overgrowth and disruption of gingival connective tissue homeostatic balance, leading to pathogenic fibrosis. In human gingival fibroblasts (HGF), we show that Gal-8 stimulates the expression of type I collagen and fibronectin, potentiates the expression of CTGF induced by TGF-β, interacts with α5β1 integrin and type II TGF-β receptor, activates β1-integrins and stimulates Focal adhesion kinase (FAK) but not Smad2/3 signaling. Cyclosporine and the proinflammatory tumor necrosis factor alpha both increased Gal-8 expression. Experiments in NIH3T3 fibroblasts silenced for Gal-8 with siRNA, demonstrated that cyclosporine-induction of fibronectin expression requires Gal-8. Taken together, these results reveal Gal-8 as a fibrogenic stimulus involving β1-integrins/FAK pathways in human gingival fibroblasts. Gal-8-mediated fibrogenesis can be triggered by cyclosporine and, afterwards, might be exacerbated by the inflammatory condition that usually accompanies a fibrotic process. Thus, Gal-8 emerged as mediator of cyclosporine-induced fibrogenesis and can offer new opportunities to ameliorate an unfortunate collateral problem of this otherwise highly effective immune-suppressive drug. Alpha 6 Integrins Regulate the Expression of Laminin-511 and Cxcr4 to Promote Endothelial Tubular Morphogenesis.

H. Xu, S. LaFlamme; Albany Medical Center, Albany, NY.

During angiogenesis, endothelial cells engage components of the extracellular matrix through integrin-mediated adhesion. Endothelial cells express laminin-411 and laminin-511 that bind to integrins, including the α6 integrins, α6β1 and α6β4. However, little is known about the contribution of these laminins to endothelial tubular morphogenesis and stability. We used two organotypic angiogenesis assays in conjunction with RNAi approaches to demonstrate that endothelial depletion of either the α4 chain of laminin-411 or the α5 chain of laminin-511 inhibited sprouting and tube formation. Depletion of α6 integrins resulted in similar phenotypes. Interestingly, depletion of α6 integrins also inhibited the expression of laminin-511, which correlated with the loss of tubular stability. Loss of either α6 integrins or laminin-511 resulted in the inhibition of the expression of CXCR4, a gene previously associated with sprouting endothelial cells. Pharmacological inhibition of CXCR4 signaling suppressed endothelial sprouting and morphogenesis, suggesting that the interaction of α6 integrins and laminin-511 regulate of endothelial tubular morphogenesis in part by regulating the expression of CXCR4. Taken together, our results suggest that α6 integrins regulate gene expression to promote both early events in tubular morphogenesis, as well as the stability of established endothelial tubes.

P1577/B712

Ultra Dilution of *Rhus Toxicodendron* Induced Cell Adhesion in Mouse Preosteoblast Cell Line.

Y. Kim[1], S. Chae[2], **M. Yeo**[2]; [1]Department of Medicine, University of Ulsan College of Medicine, Seoul, KOREA, REPUBLIC OF, [2]Department Integrative Medical Sciences, Nambu University, Gwangju, KOREA, REPUBLIC OF.

Background: Ultra dilution of *Rhus toxicodendron* (*R. Tox*) has been used as a homeopathic remedy and treatment of anti-inflammatory conditions. Previously, we reported that *R. Tox* showed modulate the inflammation in mouse chondrocyte and preosteoblastic MC3T3-e1 cell line. During the inflammation process, cells adhere to the extracellular matrix (ECM) and then migrate to the inflammation site. Here we examine the cell adhesion process after treatment of *R. Tox* using MC3T3-e1 cells. **Methods:** the cells are stimulated with *R. Tox*, cell adhesion improved comparing with fibronectin (FN) and gelatin stimulations. To access the cell adhesion assay, cells are starved, cultured and detached using EDTA containing media. Adhesive cells were measured using WST(water-soluble tetrazolium salt)-8 assay. To examine the intracellular signals after stimulation of *R. Tox*, the tyrosine phosphorylation of FAK, Src, and Paxillin analyzed and identified phosphorylation of FAK, Src, and Paxillin using phosphor-specific antibodies by immunoblot assay. The focal adhesion formation examined by immunocytochemistry assay **Results:** the cell adhesion increased after stimulated with *R. Tox* (FN:20.50%, *R. Tox*:44.80%, Gelatin:17.11%). The tyrosine phosphorylation of FAK was increased compare with FN and gelatin, and also Paxillin and Src phosphorylation when stimulating with *R. Tox*. Additionally, *R. Tox*-stimulated MC3T3-e1 cells also formed focal adhesions. **Conclusions:** *R. Tox* has roles of ECM like FN which has an Arg-Gly-Asp (RGD) motif and then transduces the extracellular signals into intracellular.

P1578/B713

Investigating Integrin α3β1-mediated Regulation of Transcription Factor Brain-2 (brn-2/ Oct-7/ N-oct3) in Breast Cancer Cell Invasion.

R. Miskin, C. DiPersio; Albany Medical College, Albany, NY.

Tumor cells receive extracellular signals from the tumor microenvironment that play a critical role in regulating gene expression that drives malignant progression and invasion; however, roles for integrins in this process remain underexplored. The laminin-binding integrin, α3β1, is a heterodimeric cell surface protein that promotes tumor growth, progression and metastasis in murine models of breast cancer, and our lab and others have demonstrated a role for α3β1 in promoting breast cancer cell invasion. To explore mechanisms of α3β1-mediated effects on cell invasion, we mined data from our previously published microarray analysis in which we compared the transcriptomes of MDA-MB-231 cells (a triple-negative human breast cancer cell line) that express either non-targeting shRNA (control cells) or α3-targeting shRNA (α3-knockdown cells). We showed that knockdown of α3 leads to the suppression of the mRNA encoding the transcription factor, Brain-2 (BRN-2). BRN-2 is a master regulator of invasive phenotype in melanoma; however its role in breast cancer is unknown. We hypothesize that integrin α3β1-dependent regulation of BRN-2 expression in breast cancer cells promotes invasion. Here we confirm that RNAi-mediated targeting of α3β1 in MDA-MB-231 cells reduces BRN-2 mRNA and protein levels. Additionally, microarray data confirm downregulation of several predicted BRN-2 target genes in α3-knockdown cells compared to control cells. To investigate if integrin α3β1 regulates BRN-2 gene transcription we are performing BRN-2 promoter reporter assays in control and α3-knockdown cells. RNAi-mediated suppression of BRN-2 in MDA-MB-231 cells followed by Transwell invasion assay showed decreased invasion of BRN-2 knockdown cells, confirming a pro-invasive role for BRN-2 in these cells. In summary, our work identifies a novel role for integrin α3β1 in the regulation of BRN-2, revealing a potential mechanism of gene regulation that affects breast cancer cell invasion.

P1579/B714

Investigating the Roles of Laminin-binding Integrins in Breast Cancer Cell Invasion.

J. Kenney, M. DiPersio; Albany Medical Center, Albany, NY.

Integrins are αβ heterodimeric receptors on the cell surface that mediate cell adhesion to the extracellular matrix and are involved in cell signaling. The laminin-binding integrin α3β1 is expressed in all epithelial tissues, including the epidermis of skin and the breast epithelium, where it has important roles in regulating cell survival, migration and proliferation. Our group and others have previously linked α3β1 signaling and adhesion functions to tumor growth, invasion and metastasis in models of skin and breast cancer. Two other laminin-binding integrins, α6β1 and α6β4, have also been implicated in the regulation of cancer cell invasion. To investigate roles of α3β1 in cell invasion, and to explore its potential interactions with α6 integrins, we used a genetic approach of CRISPR technology to knock out the ITGA3 gene (encoding the integrin α3 subunit) in the triple-negative breast cancer cell line, MDA-MB-231 (i.e., α3KO cells). Flow cytometry confirmed complete loss of α3β1 expression from the cell surface of α3KO cells. However, we observed a shift in surface expression of α6 integrins, where α6β4 levels decreased while levels of α6β1 appeared to increase. This shift presumably resulted from partnering of the α6 subunit with excess β1 subunit following the CRISPR-mediated ablation of α3. As α6β1 has also been shown to promote cell invasion in breast cancer cells, we next tested whether or not the increased surface levels of α6β1 in α3KO cells partially compensates for the loss of α3β1 during cell

invasion. Towards this goal, we used siRNA to target the ITGA6 mRNA (encoding the integrin α6 subunit) in α3KO cells, or in parental MDA-MB-231 cells as a control, then compared invasion using Transwell Matrigel assays. Initial results showed that loss of either the α3 or α6 integrin subunits alone reduced migration to a similar extent, and we did not observe a synergetic effect upon loss of both α3 and α6 subunits. These results suggest that α3β1 and α6 integrins both promote cell invasion, but that neither alone is sufficient in MDA-MB-231 cells to achieve baseline invasion levels. Studies are underway to determine whether α6 integrins can compensate for the loss of α3β1 with regard to other α3β1-dependent functions that we have identified in MDA-MB-231 and other breast cancer cells.

P1580/B715

Cell-ECM Attachment Facilitates Inflammatory Signaling by Suppressing Interleukin-1 Receptor Endocytosis.

S. Yang, C. Tuo, S. V. Plotnikov; University of Toronto, Toronto, ON, CANADA.

Interactions between cells and their extracellular matrix (ECM) mediate a plethora of cellular processes such as development and tissue repair. Such interactions are largely mediated by focal adhesions - integrin-based adhesion complexes that enable cells to sense immobile cues and correctly respond to mechanical properties of their microenvironment. In addition, focal adhesions are also known to mediate responses to soluble cues such as interleukin-1 (IL-1), yet the mechanism is unknown. Here we show that focal adhesions indirectly regulate IL-1 receptor (IL-1R) surface expression and IL-1 signaling through modulation of cortical tension. To test whether focal adhesions are important for IL-1 signaling, we plated primary human fibroblasts on surfaces that either suppressed or promoted focal adhesion assembly. We found an increase in both IL-1 receptor surface expression and downstream signaling events in cells that assembled focal adhesions, suggesting that focal adhesions are indeed important for IL-1 signaling. Interestingly, we found that IL-1 signaling can also be suppressed by pharmacological perturbations that attenuate myosin contractility without affecting integrin signaling and focal adhesion assembly, suggesting an indirect regulation of IL-1 signaling by focal adhesions. Thus, we hypothesized that cortical tension, a factor that focal adhesions contribute to, may play a role in regulating IL-1 signaling. To test whether cortical tension modulates IL-1 signaling through IL-1R surface expression, we locally modulated cortical tension by plating cells on patterned surfaces of defined shapes and showed that IL-1R is consistently enriched in areas of high cortical tension. Furthermore, inhibition of endocytosis abolished heterogenous receptor distribution and rescued IL-1 downstream signaling events in cells with suppressed cortical tension, suggesting that cortical tension modulates IL-1 signaling through endocytosis of its surface receptor. To understand the biological role of cortical tension-regulated IL-1 signaling, we plated cells on ECMs of different stiffness that are physiologically and pathologically relevant. By combining immunofluorescence and biochemical assays, we found that both receptor expression and IL-1 signaling are significantly upregulated on the stiffer ECM. Since cells in pathological environments, such as fibrotic tissues, are often under high cortical tension, our results provide insight into a possible molecular link between mechanical properties of cell microenvironment and inflammatory signaling.

P1581/B716

The LTB_4-BLT1 Signaling Axis Coordinates Actomyosin Dynamics and Beta-2 Integrin Trafficking to Drive Intravascular Neutrophil Response to Infection.

B. Subramanian[1], N. Melis[1], D. Chen[1], W. Wang[1], D. Gallardo[1], R. Weigert[1], C. Parent[2]; [1]National Cancer Institute, NIH, Bethesda, MD, [2]University of Michigan, an n Arbor, MI.

The eicosanoid Leukotriene B_4 (LTB_4), relays chemotactic signals to direct neutrophil interstitial migration in response to injury through its receptor, BLT1. However, whether the LTB_4-BLT1 axis relays signals during intravascular neutrophil response has not been directly addressed. To test this issue, we developed a sterile bacterial infection model in the mouse footpad and used intravital microscopy to directly visualize the impact of LTB_4-BLT1 axis on the intravascular neutrophil dynamics. Here, we report that LTB_4 produced by neutrophils acts as an autocrine/paracrine signal via BLT1 to drive their recruitment, arrest, and extravasation during infection in living mice. To understand the mechanism behind these findings, we utilized Intravital Subcellular Microscopy (ISMic) and discovered that LTB_4 elicits cell adhesion and polarization during neutrophil arrest in *vivo*. Specifically, LTB_4 signaling coordinates the dynamic redistribution of - 1) non-muscle Myosin IIA (NMIIA) to the back of cells, and 2) $ß_2$-integrin (Itgb2) to the neutrophil-endothelial interface, whose retention on the cell surface promotes neutrophil arrest and subsequent extravasation. Additionally, using an in *vitro* adhesion assay, we found that blocking LTB_4-BLT1 signaling or NMIIA activation results in a reduction of Itgb2 recycling to the plasma membrane in primary human neutrophils. Notably, we also discovered that neutrophils shed extracellular vesicles (EVs) in *vivo* and that blocking their biogenesis/release prevents the autocrine/paracrine actions of LTB_4 signaling therefore inhibiting neutrophil arrest and extravasation response. Overall, our study unravels a crucial function for LTB_4 in promoting neutrophil communication in the vasculature during early response to infection.

P1582/B717

Using Phosphoproteomics to Decipher Syndecan-3 Mediated Signaling Events in Myoblasts.

F. Jones; Stony Brook University, Stony Brook, NY.

Muscle satellite cells are quiescent muscle progenitors residing within the muscle tissue which are required for skeletal muscle maintenance and regeneration. The signalling networks that regulate satellite cell fate decisions are not fully understood. Particularly it is still unclear how satellite cells are maintained quiescent, but it is thought that proteoglycans found within the satellite cell niche play a critical role. Previous studies have shown that genetic ablation of the transmembrane proteoglycan syndecan-3 in mice dramatically improves muscle health and regenerative potential in ageing and in pathological conditions such as muscular dystrophy. Primary myoblasts from syndecan-3 null mice show a global upregulation of phosphorylated-tyrosine. Therefore, we hypothesised that syndecan-3 is involved in the regulation of several signalling pathways simultaneously. To test this hypothesis, we used a phosphoproteomics-based approach to identify proteins that are differentially phosphorylated when syndecan-3 expression is knocked-down in proliferating myoblasts. We then employed functional enrichment analysis to identify the signalling pathways that were affected by syndecan-3 knockdown in myoblasts. Pathway enrichment analysis identified insulin/PI3K/mTOR as one of the pathways regulated by knock-down of syndecan-3. Results from insulin stimulation experiments in C2C12 and primary satellite cell-derived myoblasts further confirmed that syndecan-3 is a regulator of the insulin signalling

pathway, likely in an AKT-dependant mechanism. These results indicate that syndecan-3 regulates the balance between myoblast proliferation and differentiation.

Cell Death: Alternative Death Pathways

P1583/B719

Pannexin-1 Limits the Production of Proinflammatory Cytokines during Necroptosis.

T. Douanne, **N. BIDERE**; INSERM, Nantes, FRANCE.

The activation of mixed lineage kinase-like (MLKL) by receptor-interacting protein kinase-3 (RIPK3) controls the execution of necroptosis, a regulated form of necrosis that occurs in apoptosis-deficient conditions. Active oligomerized MLKL triggers the exposure of phosphatidylserine residues on the cell surface and disrupts the plasma membrane integrity by forming lytic pores. MLKL also governs endosomal trafficking and biogenesis of small extracellular vesicles as well as the production of proinflammatory cytokines during the early steps of necroptosis, however the molecular basis continues to be elucidated. Here, we find that MLKL oligomers activate Pannexin-1 (PANX1) channels, concomitantly to the loss of phosphatidylserine asymmetry. This plasma membrane “leakiness” requires the small GTPase RAB27A and RAB27B isoforms, which regulate intracellular vesicle trafficking, docking and fusion with the plasma membrane. Although cells in which PANX1 is silenced or inhibited normally undergo necroptotic death, they display enhanced production of cytokines such as interleukin-8, indicating that PANX1 may tamper with inflammation. These data identify a novel signaling nexus between MLKL, RAB27, and PANX1, and propose ways to interfere with inflammation associated with necroptosis.

Reversal of Ferroptotic Cell Death Process by an astasis.

H. Tang[1], H. Tang[2]; [1]Johns Hopkins University School of Medicine, Baltimore, MD, [2]The Chinese University of Hong Kong, Hong Kong, HONG KONG.

Anastasis (Greek for “rising to life”) is a natural cell survival mechanism to allow recovery of dying cells from the brink of death. The classical view of programmed cell death has long assumed that once initiated the dying process is irreversible. Overturning this general assumption, our earlier studies demonstrated that the apoptotic form of programmed cell death is reversible. This observation on apoptosis reversal raises an intriguing question: which forms of programmed cell death can be reversable? by time-lapse live-cell microscopy, we made a new discovery that ferroptosis, the non-apoptotic iron-dependent form of programmed cell death, is also reversible. Ferroptotic cell death can be induced by natural stimuli such as the neurotransmitter glutamate, or by synthetic agents such as the small molecule erastin. Unlike apoptosis reversal, removal of ferroptosis inducers is insufficient to allow ferroptotic dying cells to reverse the initiated cell death process such as lipid peroxidation. However, by removing the cell death inducer and also restoring the intracellular reducing environment with pharmacological approach such as by providing the reduced form of glutathione or the radical-trapping antioxidant ferrostatin-1, ferroptotic dying cells can be rescued and promoted to recover. Interestingly, although potent ferroptotic inhibitors such as aminooxyacetic acid, deferoxamine, dopamine, and vitamin C can prevent initiation of ferroptosis, added alone they are unable to rescue the ferroptotic dying cells. This indicates the regulatory distinctions between preventing and reversing ferroptosis.

Taken together, these results demonstrate that ferroptosis is reversible, and suggest strategies to mediate the reversibility of ferroptosis, with physiological, pathological, and therapeutic potentials in which involvements of ferroptosis are beginning to emerge.

P1585/B721

Gallic Acid Triggers Iron-dependent Apoptotic, Ferroptotic and Necroptotic Cell Death Mechanism.

H. Tang, P. Cheung; Chinese University of Hong Kong, Hong Kong, HONG KONG.

Gallic acid (GA) is a natural anticancer phenolic compound that can be found in many food sources including edible mushrooms, fruits, herbs, teas and vegetables. Studies generally attribute the anticancer activity of GA to the induction of apoptosis. Interestingly, we found that GA activates apoptotic, ferroptotic and necroptotic mechanisms simultaneously in the same cancer cells. By time-lapse live-cells confocal microscopy, we discovered that GA can trigger multiple types of cell death pathways including apoptosis characterized by mitochondrial cytochrome *c* release to cytosol and caspase-3 activation, ferroptosis by lipid peroxidation, and necroptosis by MLKL activation and loss of plasma membrane integrity. By pharmacological approach, we found that this form of cell death can be suppressed by iron chelator such as deferoxamine (DFO), indicating that it is an iron-dependent cell death. However, this GA-induced cell death cannot be suppressed by apoptosis inhibitor such as the potent pan-caspase inhibitor Z-VAD-FMK, ferroptosis inhibitors such as ferrostatin-1 (Fer-1) and aminooxyacetic acid (AOA), as well as necroptosis inhibitors such as necrostatin-1 (Nec-1) and MLKL inhibitor necrosulfonamide (NSA), when they are applied either alone or in combinations. This indicates that GA can also trigger the unidentified cell death mechanism(s), which is mediated by an iron-dependent pathway. Interestingly, NSA exerts a synergistic effect by enhancing the sensitivity of various cancer cells upon GA induction. Taken together, these results suggest potential new strategies to enhance the efficacy of this natural anticancer substance, and also provide a useful model for studying the crosstalk between apoptosis, ferroptosis, and necroptosis.

P1586/B722

Unc-53/nav2 Inhibits the Phagocytosis of Apoptotic Cells in *Caenorhabditis Elegans*.

C. Lehman[1], M. Kinkaid[1], S. Mast[1], D. Afful[1], E. Stringham[2], **K. L. Schmidt, 22802**[1]; [1]Eastern Mennonite University, Harrisonburg, VA, [2]Trinity Western University, Langley, BC, CANADA.

The nematode *Caenorhabditis elegans* has been used to unravel the signalling processes controlling apoptosis and cell corpse engulfment. The engulfment of apoptotic cells is mediated by three signalling pathways: (i) CED-1/SREC, CED-6/GULP, CED-7/ABC1, DYN-1/Dynamin and (ii) CED-2/CrkII, CED-5/DOCK180, CED-10/RAC, CED-12/ELMO and (iii) ABI-1/ABI and ABL-1/ABL. CED-1,6,7 activate DYN-1 to control membrane dynamics while CED-2,5,12 activate CED-10 to altered actin polymerization. ABI is an adaptor protein for the oncoprotein ABL and participates in cell adhesion and migration as well as cancer signalling. ABI-1 is required for ABL-1 mediated suppression of cell corpse engulfment. ABI-1 interacts physically and genetically with the protein UNC-53 to control cell migration and actin-mediated outgrowth. UNC-53 is a cytoskeletal binding protein homologous to the mammalian Neuron Navigator genes (NAV-1,2,3), a gene family with diverse functions including contributions to the growth and development of tumorigenic cells. In this study we used *C. elegans* to examine the role of UNC-53 in apoptotic cell corpse engulfment and the related process of distal tip cell (DTC) migration. We constructed double mutants between loss of function *unc-53* mutants and mutant *ced-1*, *ced-2*, *ced-5*,

and *ced-10* animals. *unc-53* suppressed cell corpse engulfment and distal tip cell migration of *ced-1*, *ced-2*, and *ced-10* but not *ced-5* mutants, placing *unc-53* outside of a *ced-1* pathway but not entirely independent of *ced-2* and *ced-5*. To determine if *unc-53* is involved in apoptosis directly or through engulfment we examined *unc-53* alongside *ced-3*/Caspase mutants and found that *unc-53* does enhance *ced-3* and is likely not involved in apoptosis directly. *unc-53* also does not affect the timing, number or morphology of cell corpses, arguing for a role in engulfment processes. We also show that *unc-53* is expressed after the comma stage, when programmed cell death is complete, suggesting a role for *unc-53* in engulfing rather than engulfed cells. In the process of DTC migration *unc-53* strongly suppresses the cell guidance defects of *ced-10* and *mig-2*/Rho by eliminating anteroposterior polarity reversals. Our current model is that *unc-53* suppresses cell engulfment in a pathway through its physical interactions with ABI-1, possibly through its activity in cell polarity decisions.

P1587/B723

Necrosome-mediated Control of Immune Response by Canonical Nf-kb Activation.

E. Ju, M. Won, K. Kang, S. Lee, X. Piao, J. Hong, G. Hur; Department of Pharmacology and Medical Science, School of Medicine, ChungnamNational University, Deajeon, KOREA, REPUBLIC OF.

Unlike apoptotic cell death, the release of inflammatory mediators called damage-associated molecular patterns (DAMPs) from necroptosis promotes inflammation and innate immune responses. However, its ability to regulate adaptive immune responses as well as the underlying mechanism, remains largely unknown. Here, in RIP3 expressing cells and FADD null cells, we found that TNF induced persistent activation of NF-κB signaling cascades under the condition of necroptosis, but not of apoptosis independently of DAMPs liberation. Furthermore, we observed that TNF-induced necroptosis resulted in drastic up-regulation of pro-inflammatory cytokines, and such enhanced cytokine expression was completely abrogated by pharmacological inhibition or genetically abolishment of IKKβ. An alysis of the signaling molecules composed of necrosome revealed that upstream NF-κB components were associated with receptor interacting protein kinase 1 (RIP1)-RIP3 complex under the necroptotic conditions. Together, these results suggest that necroptosis up-regulates autonomous cytokine production by canonical NF-κB activation, and thus our study uncovers the signaling crosstalk between necroptosis and inflammatory responses to elicit adaptive immune response.

P1588/B724

Rip3-independent Function of Mlkl in Trail-induced Cancer Cell Death.

H. Park, S. Park, H. Noh, Y. Ha, M. Kim, Y. Lee, Y. Kim; Ajou University, Suwon-si, KOREA, REPUBLIC OF.

Mixed Lineage Kinase Domain-like (MLKL) is the essential molecule of programmed necrotic cell death, Necroptosis. To induce necroptosis, MLKL is phosphorylated by upstream partner, Receptor Interacting Protein Kinase-3 (RIPK3 or RIP3) and then translocate cellular membrane to disrupt membrane integrity. Recent data suggests that function of MLKL in RIP3-indendent manner in the effective generation of intraluminal and extracellular vesicles as well as in myelin sheath breakdown to promotes sciatic nerve regeneration. In this study, we investigated that whether MLKL play a role in link between TRAIL receptor endocytosis and apoptosis. Depletion of MLKL enhances TRAIL-induced cell death in various cancer cell lines and enhancement of cell death is RIP3-independent manner. TRAIL-induced cytotoxic signals are further increased by preventing endocytosis and MLKL depletion facilitates degradation of TRAIL-DR5. TRAIL-induced intracellular downstream signals were prolonged by depletion of MLKL and

then prolonged cytotoxic signals promote cell death. Our data indicate that defect of the intracellular trafficking of TRAIL-DR5 by depletion of MLKL enhances cancer cell death. Based on our findings, it is tempting to speculate that to promote death receptor signals, it may effective to reduced MLKL expression and to prevent survival receptor signal, upregulated MLKL expression contribute to abolish the intracellular signal through the MLKL-dependent extracellular vesicles secretion. Although the processes that regulate these pathways require further elucidation for detail molecular mechanisms, both ways will be the potent therapeutic strategies to target cancer.

P1589/B725

Waiting to Die: Nucleation-limited Signalosome Assembly Renders Human Cell Fate Decisions Inevitable.

R. Halfmann[1,2], A. Rodriguez Gama[1], T. Kandola[1], S. Venkatesan[1], J. Wu[1,2], M. Hu[1]; [1]Stowers Institute for Medical Research, Kansas City, MO, [2]University of Kansas Medical Center, Kansas City, KS.

Multiple signaling proteins of the innate immune system exert their cellular activities by assembling into large macromolecular complexes known as signalosomes. We previously discovered that two such proteins - the pyroptosome scaffold ASC, and the antiviral signaling protein MAVS - each assemble through self-templating polymerization that is reminiscent of infectious protein particles known as prions (Cai et al. 2014; PMID: 24630723). More recently we revealed that prion-like activity broadly arises from structurally encoded kinetic barriers to nucleation - the probabilistic formation of a self-templating multimer de novo (Khan et al. 2018; PMID: 29979963). For proteins like MAVS and ASC, the nucleation barrier is so high that their soluble inactive states persist despite physiological concentrations that are highly supersaturated with respect to the assembled active state. To identify other innate immune signaling proteins that may function in this manner, we used DAmFRET, a flow cytometric cell-based assay of nucleation barriers, to screen 138 candidate prion-like modules from 129 human proteins that broadly function in programmed cell death and innate immune signaling. We discovered 36 of these proteins that are inherently capable of supersaturation and switch-like self-templating activation in living cells. We have further discovered a network of nucleating interactions between them, wherein polymerization of one protein nucleates the polymerization of specific additional proteins, resulting in a cascade of irreversibly activating protein switches. This widespread kinetic control over cell fate indicates that cells are literally waiting to die -- pyroptosis, necroptosis, and alternative cell fates downstream of these proteins are thermodynamically favored, and therefore inevitable with time. Surveying known disease-associated mutations in one such signalosome, we show that the nucleation barrier for BCL10 is balanced between hypo-activation and immunodeficiency on the one hand, and hyper-activation and lymphoma on the other. Finally, I will discuss our investigations into the implications of this phenomenon for aging-associated inflammation and innate immune memory in human monocytes.

P1590/B726

A Novel Ca^{2+}Influx Pathway during Clearance of Apoptotic Cells.

D. KIM; Gwangju Institute of Science and Technology (GIST), Buk-gu, Gwangju, KOREA, REPUBLIC OF.

A tons of apoptotic cells are generated by diverse stimulations in adults everyday. However, phagocytes clear apoptotic cells quickly and efficiently. This process is named efferocytosis. Successful efferocytosis can maintain tolerance of immune responses through secretion of anti-inflammatory cytokines such as

IL-10 and TGF-beta[1)]. If apoptotic cells are not removed accurately, they undergo secondary necrosis and damage to neighboring normal cells. Finally, it evokes serious diseases such as autoimmune disease and atherosclerosis etc[2,3)]. As a result, exquisite efferocytosis is important to prevent from abnormal immune responses. Although many factors related with efferocytosis have been studied, all mechanisms are not fully understood. Ca^{2+} is associated with many cellular functions including proliferation, migration, cytoskeleton rearrangement and phagocytosis[4)]. In addtion, it has revealed that extra/intracellular Ca^{2+} is important to engulf apoptotic cells[5,6)]. However, all mechanisms associated with Ca^{2+} influx during efferocytosis is elusive. We found that interaction between Stim and Orai is enhanced during clearance of apoptotic thymocytes. This interaction is specific to apoptotic cells, not live thymocytes. In addition, apoptotic cell itself induced the interaction between Stim and Orai. Overexression of Stim and Orai increased engulfment of apoptotic cells. These results suggest a novel Ca^{2+} influx pathway during efferocytosis. Our findings will help to understand efferocytosis in detailed and develop a new drug for diseases generated by defect of efferocytosis. **References** 1)Fadok VA *et al.* Macrophages that have ingested apoptotic cells in vitro inhibit proinflammatory cytokine production through autocrine/paracrine mechanisms involving TGF-beta, PGE2, and PAF. *J Clin Invest*. 101: 890-898. Mitochondrial Targeting Sequence of Telomerase Reverse Transcriptase Acts as a Cell Death Regulator.

H. EBATA, T. Shima, Y. Shirasaki, S. Uemura; the University of Tokyo, Tokyo, JAPAN.

Telomerase reverse transcriptase TERT is a major component of telomerase that elongates telomere region at chromosomal ends. Recently, TERT has been reported to localize also in mitochondria that lack telomere region. Based on the observation that TERT accumulates in mitochondria under oxidative stress, mitochondrial TERT has been predicted to participate in the regulatory process of apoptotic cell death. However, the role of mitochondrial TERT in the process remains controversial mainly because of the absence of information about the real-time dynamics of TERT localization. Here, we developed a new TERT probing method that did not disturb TERT activity and localization. Using this method, we simultaneously observed the temporal dynamics of TERT localization with apoptosis process induced by oxidative stress. Mutations in mitochondrial targeting sequence of TERT changed the cell death reaction of HeLa cells, suggesting that the sequence acts as a cell death regulator.

In mammalian cells, mitochondrial dysfunction triggers the integrated stress response (ISR), in which eIF2α phosphorylation upregulates the transcription factor ATF4. However, how mitochondrial stress is relayed to the ISR is unknown. We found that HRI is the eIF2α kinase necessary and sufficient for this relay. Using an unbiased CRISPRi screen, we identified factors upstream of HRI: OMA1, a mitochondrial stress-activated protease, and DELE1, a little-characterized protein we found to be associated with the inner mitochondrial membrane. Mitochondrial stress stimulates the OMA1-dependent cleavage of DELE1, leading to its accumulation in the cytosol, where it interacts with HRI and activates its eIF2α kinase activity. Blockade of the OMA1-DELE1-HRI pathway is beneficial during some, but not all types of mitochondrial stress, and leads to an alternative response that induces specific molecular chaperones. Therefore, this pathway is a potential therapeutic target enabling fine-tuning of the ISR for beneficial outcomes in diseases involving mitochondrial dysfunction.

P1593/B729

Therapeutic Genetic Variation Revealed in Diverse Hsp104 Homologs.

Z. March, J. Shorter; Perelman School of Medicine at University of Pennsylvania, Philadelphia, PA.

Aberrant protein folding and aggregation underpins several fatal neurodegenerative diseases. Protein disaggregases, such as the AAA+ protein Hsp104, which directly counteract protein aggregation, represent an innovative technology to reverse these deleterious protein misfolding events. Indeed, engineered Hsp104 variants potently suppress toxicity associated with TDP-43 and αSyn in yeast and metazoa. But, these artificial disaggregases can have damaging off-target effects that might restrict their therapeutic potential. Thus, uncovering other therapeutic Hsp104s with diminished propensity for off-target effects remains a key objective. Hsp104 is conserved among all nonmetazoan eukaryotes and eubacteria, yet natural Hsp104 sequence space remains largely unexplored, raising the possibility that natural sequences exist with divergent enhanced and selective activity against neurodegenerative disease substrates. Here, we survey a cross-kingdom collection of Hsp104 homologs for their ability to suppress proteotoxicity of several proteins implicated in neurodegenerative disease. Surprisingly, nearly half of these selectively suppress TDP-43 or αSyn toxicity. Mechanistic studies and mutational analysis

suggest that these activities are traceable to genetic variation that impacts passive chaperone activity of Hsp104 homologs for select substrates. Our results suggest that natural Hsp104 homologs can have therapeutic-disaggregase activity, and that sequence variation among Hsp104 homologs may be a valuable resource for engineering therapeutic disaggregases to counter disease.

P1594/B730

Signal Peptide Processing Regulates Unfolded Protein Degradation in Mammalian Cells.

R. Yan[1], K. Chen[1], K. Xu[1,2]; [1]UC Berkeley, Berkeley, CA, [2]Chan Zuckerberg Biohub, San Francisco, CA.

It is estimated that in eukaryotic cells, about one third of the proteome is synthesized and matured inside the endoplasmic reticulum (ER) lumen. Efficient degradation of unfolded proteins is hence crucial to the maintenance of protein homeostasis and normal cellular functions. Although ER-associated degradation (ERAD) via proteasomes has been extensively studied and its significance underscored, knowledge about alternative protein degradation mechanisms is scarce. Using ER lumen-targeted, hard-to-fold fluorescent proteins as reporters, we discovered a signal peptide-mediated degradation mechanism of unfolded proteins. Specifically, by examining point mutations of the first amino acid residue (P1') downstream to the signal peptidase (SPase) cleavage site of the human calreticulin signal peptide, we found small, hydrophobic residues (A/G) drastically compromised the expression level as compared to naturally occurring negatively charged residues (D/E). The amount of difference in expression level depended on the protein following the signal peptide, with the more misfolding-prone ones exhibiting larger differences. Inhibition of SPase by a genetically encoded inhibitor abolished the difference, highlighting the critical role of signal peptide processing in this mechanism. On the cellular level, a type of extremely slim, recycling endosome-like organelle, together with many vesicles in the secretory pathway, emerged in cells with A/G but not D/E, implying degradation via vesicular transport. The ER-Golgi trafficking inhibitor brefeldin a and lysosomal inhibitor bafilomycin A1, but not the proteasome inhibitor MG132, suppressed the formation of such organelles in A/G as well as increased the fluorescent protein level, which corroborated a non-ERAD mechanism of unfolded protein clearance. In conclusion, we revealed an unexpected function of signal peptide processing on the sensitivity to unfolded protein degradation through secretory pathways, with negatively charged residues conferring more tolerance to unfolded proteins and thus higher protein levels in the ER.

P1595/B731

The Role of the Endoplasmic Reticulum in Quality Control of Non-Imported Mitochondrial Membrane Proteins.

T. Xiao, V. P. S. Shakya, A. L. Hughes; Department of Biochemistry, University of Utah School of Medicine, Salt Lake City, UT.

Mitochondria contain over 1,000 proteins, the vast majority of which are encoded in the nucleus and translated in the cytoplasm. These precursor proteins are imported into mitochondria by translocase complexes located on mitochondrial membranes, and this process depends on the inner mitochondrial membrane potential. As a consequence of mitochondrial dysfunction, mitochondrial protein import is impaired. Recent studies found that non-imported mitochondrial proteins cause mitochondrial precursor overaccumulation stress, which is highly toxic to the cell. To determine how cells process non-imported mitochondrial proteins as a protective protein quality control mechanism, we systematically screened the localization and abundance of yeast non-imported mitochondrial proteins by microscopy

and western blot, respectively. We identified at least five distinct fates of non-imported mitochondrial proteins. A number of these proteins localized to the endoplasmic reticulum (ER) when mitochondrial protein import was blocked by depolarization of mitochondria or genetic impairment of mitochondrial translocases. We found that the guided entry of tail-anchored proteins (GET) complex, a known post-translational ER protein import machinery, is required for the ER-targeting of non-imported mitochondrial membrane proteins. In the absence of a functional GET pathway, non-imported proteins destined for the ER are sequestered into protein aggregates that co-localize with Hsp104 and are associated with both mitochondria and the ER. Overall, these results uncover an important role for the GET complex in preventing aggregation of non-imported mitochondrial membrane proteins, and identify the ER as a major destination for non-imported mitochondrial membrane proteins.

P1596/B732

Regulation of ER Stress Resistance by Tauroursodeoxycholic Acid in Yeast.

S. R. Chadwick[1], R. D. Moir[2], I. M. Willis[2], E. L. Snapp[3], P. Lajoie[1]; [1]University of Western Ontario, London, ON, CANADA, [2]Albert Einstein College of Medicine, New York City, NY, [3]Janelia Research Campus, Howard Hughes Medical Institute, Ashburn, VA.

Accumulation of toxic misfolded secretory proteins in the endoplasmic reticulum (ER stress) is linked to several human diseases. Cells respond to ER stress through activation of signaling pathways such as the Unfolded Protein Response (UPR), which adapt the ER folding environment upon changes in misfolded protein burden. Small molecules called chemical chaperones have been shown to attenuate the UPR under stress conditions and improve folding and trafficking of specific mutant proteins. Here, we aimed to identify the effects of a chemical chaperone, the bile acid tauroursodeoxycholic acid (TUDCA), in yeast. Despite promising results in multiple models of protein folding diseases, TUDCA's mechanism of action remains unclear. We found that TUDCA significantly improves growth of yeast subjected to ER stress caused by tunicamycin (Tm). Interestingly, the ability of TUDCA to rescue growth in presence of Tm was independent of the UPR. Moreover, TUDCA could not attenuate UPR activation associated with deletion of genes involved in protein quality control, suggesting that it may act by increasing cell resistance to pharmacological stressors. Using genome-wide screens, we have linked the ability of TUDCA to rescue Tm-induced stress to the regulation of yeast cell wall integrity. Cells lacking the MAP kinase Slt2, a protein essential to signal transduction through the cell wall integrity (CWI) pathway, were hypersensitive to TUDCA. This suggests that TUDCA treatment results in cell wall remodeling, thereby requiring CWI signaling. Likewise, using quenching assays, we were able to demonstrate that TUDCA decreases cell wall porosity and increases cell resistance to the cell wall-targeting agent and ER stress inducer, caspofungin. Thus, we characterized a novel mechanism of action of TUDCA in increasing ER stress resistance by regulating cell wall integrity and presumably affecting drug uptake. Supported by NSERC.

Hsp104/70/40 Disaggregation System Disperses Heat-induced Poly(a)-binding Protein Aggregates.

H. Yoo, E. Pilipenko, D. Drummond; University of Chicago, Chicago, IL.

All cells produce an adaptive response to environmental stresses, including heat. Two highly conserved features of the cellular heat shock response are 1) an increased production of heat shock proteins, many of which are molecular chaperones, and 2) aggregation of protein and mRNA molecules into stress

granules (SGs). During the recovery period, a set of molecular chaperones (Hsp104/70/40) disperses the constituent SG proteins back to the cytosol. We previously demonstrated that poly(A)-binding protein (Pab1 in budding yeast; PABPC1 in human), a classic SG marker, demixes in vitro upon exposure to physiological stress conditions. Pab1 demixing involves phase separation and gelation without global unfolding. Although the Hsp104 disaggregation system has been shown to be important for the timely dispersal of SGs in vivo, no direct demonstration of Hsp104/70/40-mediated dispersal of endogenous, stress-induced aggregates has been done. Here, using Pab1 as model substrate, we demonstrate that Hsp104 disaggregation system can disperse endogenous stress-induced aggregates. We introduce a fluorescence anisotropy assay for kinetic monitoring of the conversion of inert Pab1 aggregates into soluble RNA-binding Pab1 monomers. Pab1 dispersal requires co-chaperone Sis1 but not Ydj1. Unlike in the case of misfolded substrates, no synergy between Sis1 and Ydj1 is observed with Pab1. The high resolution of our assay and the substoichiometric concentration of molecular chaperones required for Pab1 dispersal make our system a useful tool for studying molecular chaperones in the context of disaggregating RNA-binding protein aggregates. We intend to exploit our system to address important questions as to the mechanisms by which the disaggregation system recognizes Pab1 and the molecular features, e.g. phosphorylation, which control the efficiency of molecular dispersal of distinct stress-induced structures.

P1598/B734

Deciphering the Role of ER Stress in ALS Pathogenesis.

G. Joshi, M. D. Tatman, M. J. Monteiro; University of Maryland-Baltimore, Baltimore, MD.

There is considerable evidence showing chronic induction of ER stress is associated with many neurodegenerative diseases, including amyotrophic lateral sclerosis (ALS). However, direct evidence that ER stress is responsible for causing disease is more difficult to ascertain. This is because of the difficulty in separating the effects of ER stress from the gain or loss-of-function of the instigating molecule responsible for triggering the ER stress. For example, retention and build-up of a misfolded protein in the ER by the protein quality control systems could trigger ER stress but could also produce loss-of-function effects from retention of the molecule. To overcome this problem, we generated transgenic mice (Tg) expressing CD3δ tagged with Dendra2 in neurons. CD3δ is one of several subunits that forms the T-cell antigen receptor complex. It is an ideal substrate for studying ER-associated degradation (ERAD) because expression of the subunit without its cognate partners is recognized by the ER quality control systems as being an orphan protein and is therefore targeted by ERAD. Thus, ectopic expression of CD3δ-Dendra2 in non-T cells, such as in neurons, should result in elimination of the protein by ERAD. However, we predicted that the prolonged expression of CD3δ-Dendra2 in neurons would trigger ER stress from a build-up of the protein as the quality control systems in organisms wane during aging. A transgenic mouse line expressing CD3δ-Dendra2 was generated and characterized. The line was also crossed with a P497S UBQLN2 mouse model of ALS, which we previously showed recapitulated central features of the human disease. We predicted that double transgenic mice from this cross would not only develop disease earlier, but disease would be exacerbated because of strong induction of ER stress seen in affected P497S animals. The strong induction of ER stress is P497S animals is consistent with our previous studies showing UBQLN proteins function in ERAD. Quantification of the number of motor neurons (MN) in spinal cord sections of single transgenic CD3δ-Dendra2 expressing mice revealed an age-dependent decline, which correlated with induction of ER stress markers. Furthermore, mice double transgenic for the reporter and the P497S UBQLN2 transgene displayed increased MN loss compared to

age-matched single Tg mice carrying each of the transgenes. Our results suggest that chronic induction of ER stress may be sufficient to trigger motor neuron disease. The CD3δ-Dendra2 transgenic mouse line appears to be a useful tool for interrogating the effects of ER stress in neuron function and neurodegeneration.

Conformational Heterogeneity in the α-Synuclein Aggregation Leads to the Formation of Diverse Strains with Distinct Prion-like Behavior.

S. Mehra[1], S. Ahlawat[2], H. Kumar[3], N. Singh[1], A. Navalkar[1], K. Patel[1], R. Kumar[1], N. N. Jha[1], J. Udgaonkar[3], V. Aggarwal[2], S. K. Maji[1]; [1]Indian Institute of Technology Bombay, India, Mumbai, INDIA, [2]Tata Institute of fundamental research, Hyderabad, INDIA, [3]Indian Institute of Science Education and Research, Pune, INDIA.

α-Synuclein (α-Syn), a neuronal protein, is misfolded and aggregated in several neurodegenerative diseases, termed as α-Synucleinopathies. While sharing the same pathological protein, synucleinopathies demonstrate distinct clinical and pathological phenotypes. The coalition of protein aggregates made up of the same precursor protein but with multiple pathological phenotypes occurring due to the presence of different conformational strains has been demonstrated for prion diseases. However, the factors that are responsible for the formation of prion-like strains in synucleinopathies is still obscure. α-Syn forms heterogeneous high-molecular-weight assemblies through a series of conformational changes as well as intermolecular interactions. Variation in incubation conditions and/or in the presence of modulator/cellular factors, α-Syn may populate into numerous conformational states to form partially folded intermediates and protofibrils. Owing to the heterogeneity in the protein aggregation and cellular systems, individual species involved in the aggregation pathway may deviate and populate into different types of structural assemblies, in *vivo*. Here, we strategize to isolate the intermediate species formed during the α-Syn aggregation pathway and study their ability to form different fibrillar strains. Using interdisciplinary tools, we comprehensively characterized two α-Syn variants (named as PMF and HMF) formed in the process of aggregation. These variants displayed structural differences as probed by solid-state NMR and Hydrogen-deuterium exchange mass spectrometry as well as exhibited significant functional differences in terms of cytotoxicity and prion-like transmission behavior. We demonstrated that HMF are more resistant to protease digestion, and these fibrils are also protected against Hydrogen-deuterium exchange (HDX). Whereas, PMF are readily digested with proteinase-K and get labeled upon HDX displaying it to be a less protected fibril type. In the cellular context, these strains exhibited distinct internalization and transmission ability. Although PMF strain showed comparatively less internalization and cell-to-cell transmission compared to the HMF, it presented relatively high seeding ability both in *vitro* and in *cells*. Therefore, studying these different structural assemblies will be a step closer to simulate the in *vivo* conditions delineating the differences in the pathologies and designing conformation-based inhibitors of α-Syn.

Analyzing Premature Substrate Release from ClpXP with Single Molecule Microscopy.

X. Wang, P. Coffino, S. Simon; the Rockefeller University, New York, NY.

AAA+ proteases, such as proteasomes, include a subcomplex that engages, translocates and (if required) unfolds tagged substrates, before delivering them to an associated protease particle. Occasionally, substrates can be prematurely released, resulting in partially degraded products that may have various physiological impacts. A potential cause of partial degradation is the presence of domains that reduce

the grip that the AAA+ proteases has on the substrate. This is manifested in the low rate of degradation for proteins with glycine-alanine (GA) repeats found in Epstein-Barr viruses, indicating that the lack of bulky side-chains in the amino acid sequence makes the substrate more slippery. However, it is not resolved whether this effect of GA repeats results from an increase in the likelihood of substrate dissociation, or a prolongation of the time needed to unfold engaged substrates, or a combination of both possibilities. In this study, we dissected the problem by monitoring the dissociation of protein substrates from the AAA+ protease ClpXP at single molecule resolution using Total-Internal-Reflection Fluorescence (TIRF) microscopy under a quasi-steady-state condition. We designed a protein substrate containing a domain encoding the *E. coli* dihydrofolate reductase (ecDFHR), which is a hard-to-unfold protein that becomes fully resistant to unfolding upon binding methotrexate (MTX). By placing a GA repeat at the C-terminal non-structured region of the ecDHFR substrate, we forced ClpXP to stall at or near the GA repeat. Comparing the degradation rates of the ecDHFR substrates with, or without, the GA repeats in an ensemble assay in a defined solution, we confirmed the observation that the presence of GA repeats leads to a lower rate of degradation by ClpXP. After examining dwell-time of MTX-bound substrate with TIRF microscopy, we found that GA repeats had little effect on the rate of substrate dissociation. We also studied the interaction between ClpXP and ecDHFR substrates with Surface Plasmon Resonance (SPR) to probe the equilibrium of substrate binding and dissociation. Together, the results suggest that GA repeats impede protein degradation without making the substrates more likely to dissociate from the AAA+ proteases, implying that there is a difference in the mechanisms of interaction by which ClpXP unfolds and retains the substrate.

P1601/B737

Functional Cooperativity between the Trigger Factor Chaperone and the ClpXP Proteolytic Complex.

W. A. Houry; University of Toronto, Toronto, ON, CANADA.

A functional association was uncovered between the ribosome-associated trigger factor (TF) chaperone and the ClpXP degradation complex in bacteria. Bioinformatic analyses demonstrated conservation of the close proximity of *tig*, gene coding for TF, and genes coding for ClpXP suggesting a functional association. Effect of TF on ClpXP-dependent degradation varied based on the nature of substrate. While degradation of some substrates was slowed down or unaffected by TF, surprisingly, TF increased the degradation rate for a third class of substrates. These include λ phage replication protein λO, master regulator of stationary phase RpoS, and SsrA-tagged proteins. Globally, TF enhances the degradation of about 2% of newly synthesized proteins. TF was found to interact through multiple sites with ClpX in a highly dynamic fashion to promote protein degradation. This chaperone-protease cooperation constitutes a unique and likely ancestral aspect of cellular protein homeostasis in which TF acts as an adaptor for ClpXP.

Phosphorylation-dependent Proteolysis Perturbs GFAP Proteostasis, Implicating Caspase-6 in Early Onset Alexander Disease.

R. A. Battaglia[1], A. S. Beltran[1], R. Dumitru[1], J. Robinson[1], S. Delic[1], L. Herring[1], V. Madden[1], N. Ravinder[2], E. Willems[2], R. Newman[2], J. Goldman[3], M. Perng[4], M. Inagaki[5], N. Snider[1]; [1]UNC, Chapel Hill, NC, [2]Thermo Fisher Scientific, Carlsbad, CA, [3]Columbia University, New York, NY, [4]National Tsing Hua University, Hsinchu, TAIWAN, [5]Mie University Graduate School of Medicine, Tsu, JAPAN.

Glial fibrillary acidic protein (GFAP) is the major component of the intermediate filament cytoskeleton in mature astrocytes. *GFAP* mutations cause the rare and fatal leukodystrophy Alexander Disease (AxD), via a toxic gain-of-function mechanism involving pathologic aggregation of mutant GFAP within Rosenthal Fibers (RFs). Our major objective is to understand the causes and consequences of GFAP aggregation and RF formation in AxD. Although there are over 70 different GFAP missense mutations known to cause AxD, the underlying mechanism linking different mutations to disease-relevant phenotypes remains unknown. We used AxD patient brain tissue and induced pluripotent stem cell (iPSC)-derived astrocytes to investigate the hypothesis that AxD-causing mutations perturb key post-translational modifications on GFAP. Phospho-proteomic analysis was performed on GFAP extracted from post-mortem tissues from AxD patients (representing 10 different mutations) and control unaffected subjects. The proteomic results were confirmed by immunoblot with phospho-specific antibodies. Mechanistic studies were undertaken in human AxD iPSC-astrocytes and corresponding isogenic controls that were generated via CRISPR/Cas9 gene editing. Our results reveal abundant, selective phosphorylation of GFAP on Ser13 in patients who died very young (N=8; median age at death=1.7 years; range 0.5-14 years), independently of the mutation they carried. We did not observe significant pSer13-GFAP in control subjects or in AxD patients who survived longer (N=5; median age at death=38 years; range 27-50 years). Human AxD iPSC-astrocytes accumulated pSer13-GFAP in cytoplasmic aggregates within deep nuclear invaginations, resembling the hallmark RFs observed in *vivo*. In contrast, isogenic control iPSC-astrocytes lacked pSer13-containing GFAP aggregates. While WT and non-phosphorylatable S13A GFAP variants were capable of assembling into filaments, the phospho-mimic S13D GFAP variant formed large perinuclear aggregates. Furthermore, Ser13 phosphorylation facilitated GFAP cleavage by caspase-6, which was only expressed in the brain tissue from young AxD patients. Consequently, in brain tissue from young AxD patients there was abundance of cleaved GFAP, which was not seen in old AxD patients or in normal subjects (young and old). In conclusion, our study reveals how missense mutations, affecting discrete domains on the GFAP molecule, converge upon a common mechanism to compromise GFAP proteostasis in AxD. Our findings provide a basis for exploring potential PTM-based diagnostic and therapeutic strategies in AxD and potentially other diseases characterized by defective intermediate filament proteostasis.

P1603/B739

Giv Interacts with and Promotes Cell Surface Localization of Grp78 during ER Stress.

C. Limso[1], J. Ngo[1], P. Nguyen[1], S. Leal[1], D. Sahoo[2], P. Ghosh[2], **D. Bhandari**[1]; [1]California State University Long Beach, Long Beach, CA, [2]University of California, San Diego, CA.

Cancer cells are known to evade endoplasmic reticulum (ER) stress induced death and one of the key factors that helps in survival is cell surface localization of the chaperone, glucose regulated protein 78 kDa (GRP78), from where it aids in promotion of cytoprotective signaling. However, the mechanism by which GRP78 localizes to the plasma membrane remains poorly understood. Here, we identify Gα-Interacting Vesicle Associated Protein (GIV) - an enhancer of the pro-survival signaling during ER stress - as a binding partner of GRP78. We show that GIV and GRP78 interact in an ER-stress dependent manner. This direct interaction occurs through binding between the substrate-binding domain of GRP78 and the carboxyl-terminal region of GIV. GIV promotes the ER stress dependent localization of GRP78 to the plasma membrane as determined by cell surface biotinylation experiments. Finally, Kaplan-Meier analysis of disease-free survival in breast cancer patients shows poor prognosis for patients with high expression of both GIV and GRP78. Taken together, our work suggests a crucial role for GIV in facilitating

localization of GRP78 to the plasma membrane, from where these two proteins can promote cell survival signaling.

P1604/B740

Cellular Secretion and Cytotoxicity of Transthyretin Mutant Proteins Underlie Late Onset Amyloidosis and Neurodegeneration.

R. B. Ibrahim[1,2], S. Yeh[2], K. Lin[3], F. Ricardo[4], T. Yu[4], C. Chan[5], Y. Liu[3], J. Tsai[2]; [1]Taiwan International Graduate Program in Interdisciplinary Neuroscience, National Yang-Ming University and Academia Sinica, Taipei, TAIWAN, [2]National Yang-Ming University, Taipei, TAIWAN, [3]Taipei Veterans General Hospital, Taipei, TAIWAN, [4]Academia Sinica, Taipei, TAIWAN, [5]National Taiwan University, Taipei, TAIWAN.

Transthyretin amyloidosis (ATTR) is a progressive life-threatening disease characterized by the deposition of transthyretin (TTR) amyloid fibrils in the body's organs and tissues, causing familial amyloid polyneuropathy (ATTR-FAP), cardiomyopathy (ATTR-FAC), or oculoleptomeningeal amyloidosis (OLMA). Several pathogenic variants have been shown to destabilize TTR tetramers, leading to aggregation of misfolded TTR fibrils. However, factors that underlie the differential age of disease onset amongst amyloidogenic TTR variants remain elusive. To understand these phenotypic differences, we generated TTR mutants with different disease onsets and study their amyloidogenic properties in cultured cells and Drosophila melanogaster. We found similar cellular secretory pattern in both HEK and HepG2 cells for wild-type (WT) TTR to those of the late-onset mutant (Ala97Ser), stable mutant (Thr119Met), early-onset mutant (Val30Met), but not unstable mutant (Asp18Gly). Cytotoxicity assays revealed their toxicities in the order of Val30Met>Ala97Ser>WT>Thr119Met in IMR-32 neuroblastoma cells. Surprisingly, while early onset amyloidogenic TTR monomers are retained by the endoplasmic reticulum quality control (ERQC), late-onset amyloidogenic TTR monomers can be secreted extracellularly. Interestingly, Ala97Ser TTR overexpression in *Drosophila* causes late-onset neurodegeneration but aggressively shortened lifespan, recapitulating human disease progression. Our study demonstrates that escape of TTR monomers from the ERQC may underlie late-onset amyloidogenesis in patients and suggests potential treatment strategies targeting ERQC for mitigating late-onset ATTR.

P1605/B741

Unexpected Control of Nucleation by Protein Translation Rate.

S. Venkatesan, 64110; Stowers Institute for Medical Research, Kansas City, MO.

Protein translation is the most energy-consuming process in the cell. Thus, translation and protein quality control must be tightly linked. Proteins are believed to be most susceptible to aggregation during or shortly after translation, before they have reached the fully folded native state. We put that notion to test by evaluating nucleation-limited, or "prion-like" aggregation under different rates of translation in the cell. We included prions of diverse structure, ranging from intrinsically disordered amyloid-forming proteins (IDPs), to well-folded death domains that polymerize in the native state. Remarkably, death domains retain their native fold even in the prion form, so any misfolding may only perturb their attaining the prion form. The expectation is therefore that translation rate will hamper death domain nucleation. To probe this, we deployed a quantitative reporter of nucleation-limited protein self-assembly in living cells (termed Distributed Amphifluoric FRET or DAmFRET). To determine if these

effects occur directly at the level of the translating prion protein-encoding transcript itself, we inserted an out-of-frame start codon immediately upstream of the ORF to decelerate translation initiation specifically of our prion protein of interest. Strikingly, this manipulation dramatically reduced nucleation for all proteins tested, regardless of their structure, and independently of changes in their concentration. Further experimentation revealed that the proteins remained fully competent for polymerization when provided with a pre-existing template. Hence, translation rate specifically influences the kinetic barrier to nucleation. Overall, our observations are true in both yeast and mammalian cells alike. We are exploring microscopy-based tools to visualize how translation governs the physical basis of protein phase behavior. Given the generality of the effect of translation on the nucleation of a wide range of proteins, the mechanism quite likely involves the increased local concentration of newly translated polypeptides occurring at the polysome.

P1606/B742

Overexpression of UBQLN1 Alleviates Motor Neuron Loss and Neuropathology in the P497S UBQLN2 Mouse Model of ALS/FTD.

S. Wang, M. Tatman, **M. J. Monteiro**; University of Maryland-Baltimore, Baltimore, MD.

Amyotrophic lateral sclerosis (ALS) is a devastating neurodegenerative disease characterized by progressive loss of upper and lower motor neurons of the central nervous system. Median survival after diagnosis is typically 3 to 5 years, and there is no effective treatment to prevent or halt the disease. Major insight into ALS has emerged through discovery that mutation in more than 30 different genes cause ALS. Interestingly, mutations in genes involved in protein quality control are linked to ALS more than any other functional group. Mutations in one such factor, UBQLN2, have been identified as a genetic cause of ALS and frontotemporal dementia (FTD). UBQLN2 belongs to a family of four homologous proteins found in humans that function in protein quality control. The proteins share the same structural organization composed of N- and C-terminal ubiquitin-like (UBL) and ubiquitin-associated (UBA) domains and a central domain containing multiple STI1 domains, that bind to poly-ubiquitin chains and the proteasome respectively. These structural features are consistent with the diverse functional properties played by the proteins as shuttle factors in proteasomal degradation, facilitators of autophagy and in assisting in protein refolding. Most UBQLN2 mutations map to a PXXP domain that is only present in UBQLN2 and not in the other UBQLN family members. We previously showed that overexpression of UBQLN1, which shares high homology to UBQLN2, can rescue toxicity in cell and animal models of Huntington's disease. Accordingly, we speculated that overexpression of UBQLN1 may counteract and alleviate the pathogenic effects of UBQLN2 ALS/FTD mutations. To test this idea, we crossed transgenic (Tg) mouse lines expressing human UBQLN1 with the P497S UBQLN2 mouse model of ALS/FTD. The P497S mouse model displays age-dependent motor neuron disease, cognitive deficits and neuropathologic alterations (build-up of ubiquitin and p62-positive inclusions and TDP-43 proteinopathy), recapitulating central feature of the human disease. All four genotypes from the resulting cross were characterized pathologically. The characterizations revealed that UBQLN1:P497S double-Tg mice had dramatic reduction of UBQLN2 inclusions in the brain and spinal cord, diminished loss of neurons in the brain and of motor neurons in the spinal cord, as well as alleviation of ER stress and of TDP-43 mislocalization. Taken together these results demonstrate that overexpression of UBQLN1 in P497S mice alleviates most of the pathologic signs of disease caused by the UBQLN2 mutation. Therefore, strategies to increase UBQLN1 expression may provide an attractive therapeutic opportunity to treat ALS/FTD caused by UBQLN2 mutations.

P1607/B743

The Lon Protease Autodegrades in *Caulobacter Crescentus*.

B. B. Barros[1], R. Zeinert[2], P. Chien[1]; [1]University of Massachusetts Amherst, Amerst, MA, [2]University of Massachusetts Amherst, Amherst, MA.

Lon is a highly conserved AAA+ protease found in prokaryotic and eukaryotic organisms; it relies on the hydrolysis of ATP in order to remove damaged or misfolded proteins from the cell as a part of the cells natural stress response. In *Caulobacter crescentus*, Lon is also capable of regulating the concentrations of key regulatory proteins responsible for a variety of cell functions like growth and motility, regulated proteolysis is a vital function of healthy bacterial growth. So, when this carefully balanced system is disrupted it often results in reduced viability. Because protein turnover is irreversible and costly, cells must carefully regulate their protease activity, Lon is controlled by transcriptionally upregulating the *lon* gene in the presence of high stress or at decisive cell cycle checkpoints. The question remains however, after the cell has responded to the stress and survives, what happens to the surplus of Lon protease in the cell. Here we show that Lon itself is degraded and that it plays an important role in its own post-transcriptional regulation. Using mutants deficient only in catalytic activity, we find that Lon targets itself for degradation. In preliminary work, we find that stabilizing catalytically active Lon appears to be toxic for *Caulobacter*, suggesting that the turnover of Lon is needed during normal growth. By studying how Lon is under its own proteolytic control, we hope to further our understanding in Lon's capability to respond to stress conditions and achieve cell homeostasis.

P1608/B744

Interaction of the Yeast Smyd Methyltransferase Set6 with the Gim Complex/prefoldin Links Its Function to the Regulation of Proteostasis.

D. Jaiswal[1], J. Lum[1], J. Moresco[2], J. Yates III[2], E. Green[1]; [1]University of Maryland Baltimore County, Baltimore, MD, [2]Scripps Research Institute, La Jolla, CA.

The SMYD family of lysine methyltransferases are key developmental regulators, particularly implicated in muscle differentiation, and known to promote pathogenesis when deregulated, including being overexpressed in numerous types of cancer. The enzymes contain a split SET (Su(var)3-9, Enhancer of zeste, Trithorax) domain that catalyzes methylation on target substrates, and a MYND (Myeloid translocation protein, Nervy, Deaf) domain, which is a zinc finger motif that promotes both protein-protein and protein-nucleic acid interactions. In mammalian systems, SMYD enzymes are known to catalyze both histone and non-histone protein methylation, although the extent of their methylation of the proteome and the signaling pathways to which they respond are not clear in many cases. In genetic model systems, the SMYD family of enzymes are highly-conserved but their characterization is very limited. Here, we sought to define the biological function of the budding yeast enzyme Set6, a SMYD family member without defined function or known substrates. We identified a physical and genetic link between Set6 and the GimC/prefoldin complex, a protein chaperone that receives nascent chains at the ribosome and transfers them to the chaperonin CCT/TRiC. The loss of Set6 suppresses many of the defects associated with loss of members of the GimC/prefoldin complex, suggesting that they function in the same pathway. Additional genetic data links Set6 to translational control, indicating that Set6 may play a regulatory role in translation that antagonizes GimC/prefoldin function. Further, biochemical studies show that Set6 is an active methyltransferase that targets multiple substrates within the cell.

Overall, our data suggest that Set6 acts together with GimC/prefoldin to regulate protein abundance and quality control, implicating the SMYD lysine methyltransferase family in the maintenance of proteostasis and defining a new biological function for this previously-uncharacterized enzyme.

P1609/B745

Cytoplasmic Phosphorylation of FUS's Prion-like Domain as a Mechanism to Regulate Liquid-liquid Phase Separation.

I. Owen, S. Rhoads, D. Yee, H. Wyne, G. Gonzales, F. Shewmaker; Uniformed Services University, Bethesda, MD.

Fused in Sarcoma (FUS) is a ubiquitously expressed predominantly nuclear protein with many RNA/DNA metabolism-related functions. FUS contains a prion-like domain that facilitates its liquid-liquid phase separation into functional granule structures. Chronic cytoplasmic persistence of this phase-separated state is implicated in diseases such as amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). In cell models a sub-population of FUS is localized within cytoplasmic stress granules following osmotic and oxidative stress. Likewise, disease-associated mutant protein, FUS(R495X), forms liquid-state cytoplasmic inclusions. We previously showed following DNA damage, PIKK kinases phosphorylate consensus sites within FUS's prion-like domain altering liquid-phase transitions. Here, we show that transient phosphorylation of non-PIKK consensus sites occurs following non-DNA damaging stress. Within cytoplasmic inclusions we observe FUS's prion-like domain to be phosphorylated at PIKK and non-PIKK sites. These phosphorylation events are not PIKK-kinase dependent, indicating additional kinases are modifying FUS's prion-like domain. Phosphomimetic substitution within the prion-like domain of mutant FUS changes the persistence of cytoplasmic liquid-state granules. Our findings suggest prion-like domain phosphorylation is a mechanism to regulate FUS's liquid-liquid phase separation. Modulation of prion-like domain phosphorylation may offer therapeutic strategies for ALS and FTD.

P1610/B746

Selective, Stress-enhanced ER-export of Misfolded Transmembrane Proteins.

B. S. Park, P. Satpute-Krishnan, 20814; Uniformed Services University, Bethesda, MD.

To avoid accumulation and aggregation of misfolded secretory pathway proteins, cells utilize protein quality control (PQC) pathways to recognize and refold or destroy misfolded secretory pathway proteins. The best characterized clearance pathways for misfolded secretory pathway proteins are ER associated degradation (ERAD) or autophagy, both of which involve the retention of misfolded proteins in the ER prior to degradation. While probing PQC systems that handle diverse, disease-associated misfolded GPI-anchored proteins (GPI-APs), including mutants of prion protein, we discovered an ER-stress enhanced PQC pathway that we named RESET. RESET is the major pathway used by cells to clear misfolded GPI-APs out of the ER for constitutive or ER stress-enhanced turnover. Instead of being retained in the ER for degradation, during RESET, misfolded proteins are released by the ER-resident chaperone calnexin and bound by the p24-family member Tmp21 for export to the Golgi. Tmp21 is required for ER-export to the Golgi. The misfolded proteins subsequently transit the cell surface en route to lysosomes where they are degraded. We now find that a sub-population of select misfolded transmembrane proteins, including hypercholesterolemia mutants of LDL receptor (LDLR) C184Y and C358Y and cysteine mutants of amyloid precursor protein (APP), are also released by calnexin for the Tmp21-mediated RESET pathway. siRNA knockdown of Tmp21 studies demonstrate that Tmp21 is

required for ER-export of LDLR C184Y. In contrast, the well-characterized transmembrane ERAD substrate, CD3δ, appears to be exclusively handled by ERAD and does not appear to associate with Tmp21. As with GPI-APs, after undergoing RESET, the APP and LDLR mutants continue through the Golgi to the cell surface where they are rapidly internalized to lysosomes. Next we tested for the consequence of the transient cell-surface exposure of these RESET substrates. We discovered that the fraction of LDLR mutants that undergoes RESET are capable of LDL uptake. Imaging studies revealed that LDLR C184Y binds fluorescently labeled LDL ligands at the cell surface and internalizes the ligands into lysosomes. In the case of APP mutants, triggering RESET with ER-stress spikes the release of amyloid beta from cells as determined by ELISA. Thus, the fraction of misfolded transmembrane proteins that undergoes RESET for secretion to the cell surface may have potentially beneficial or detrimental physiological consequences, depending on the function of the RESET substrate. Additionally, our discovery that a fraction of APP mutants associate with Tmp21 for RESET may provide a new lead to determine the mechanistic basis for the genetic link between Tmp21 and Alzheimer's disease that was identified by other labs.

Systems and Synthetic Cell Biology

P1611/B748

Phase Separation of a Structured Protein Domain.

S. Saha[1], J. Bindics[1], S. Jelenic[1], A. S. Holehouse[2], M. Ruer[3], R. V. Pappu[2], A. A. Hyman[3]; [1]Institute of Molecular Biotechnology (IMBA), Vienna, AUSTRIA, [2]Washington University, St. Louis, MO, [3]Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, GERMANY.

Liquid-liquid phase separation has been proposed to drive assembly of many functionally distinct cellular compartments not enclosed within lipid membranes. It is likely that material properties of these compartments regulate their functional output. Research from many labs have shown how both compartment assembly and material properties depend on scaffold proteins that are intrinsically disordered. However, the contribution of structured protein domains in this process remain unclear. To address this, we investigated the phase separation properties of PGL-3, one of the scaffold proteins that drive assembly of the canonical liquid-like 'P granule' compartment in *C. elegans*. We found that in the case of PGL-3, both compartment assembly and material properties depend predominantly on a structured protein domain in contrast to intrinsically disordered regions. The N-terminal region accounting for 65% of the PGL-3 protein (PGL-3_N) is alpha-helical. On the other hand, the C-terminus (PGL-3_C) accounting for the other 35% of the protein is unstructured. While the N-terminal fragment PGL-3_N phase separates identical to full-length PGL-3 in vitro, the C-terminal fragment PGL-3_C is neither necessary nor sufficient for phase separation. We explored the molecular mechanism of how the N-terminal fragment PGL-3_N regulates material properties in PGL-3 condensates. Interestingly, we identified a 25 amino acid region within PGL-3_N (PGL-3_liq), accounting for just 4% of the protein, that maintains 'liquidity' in PGL-3 condensates. PGL-3 constructs lacking the PGL-3_liq sequence phase separate into condensates that harden over time from a liquid-like state to a solid-like state. We found that the activity of PGL-3_liq in maintaining liquidity is sequence-specific, since a polypeptide of identical length and amino acid composition but with the sequence of amino acid residues scrambled could not substitute for the role of PGL-3_liq. I will discuss in detail our findings on how PGL-3_liq regulates material properties in PGL-3 condensates. Our work demonstrates the importance of structured protein domains in liquid-liquid phase separation and sets the stage for investigations into how structured

protein domains cooperate with intrinsically disordered protein regions to assemble cellular liquid-like compartments.

P1612/B749

Critical Role of Rhythmic Poly(a) Tail Regulation in Circadian Gene Expression.

X. Yao, S. Kojima, J. Chen; Department of Biological Sciences, Virginia Polytechnic Institute and State University, BLACKSBURG, VA.

Circadian gene expression has been well understood at the transcriptional level for decades. Core clock genes with their protein products form negative feedback loops essential for temporal oscillation. However, recent genome-wide studies highlighted the role of post-transcriptional regulation in circadian gene expression. Particularly, rhythmicity of poly(A) tail lengths are found to strongly correlate with the rhythmicity in protein expression in mouse liver. Poly(A) tail is generally thought to control mRNA decay and translation activity. To understand the specific role of rhythmic poly(A) tail regulation in circadian gene expression, we constructed a simplistic model that depicts rhythmic control imposed upon basic mRNA expression processes, including transcription, deadenylation, polyadenylation and degradation. Our results revealed rhythmicity in deadenylation as the strongest contributor to the rhythmicity in poly(A) tail length, and the abundance of long-tailed mRNA. Our model further demonstrated that the rhythmic patterns in the expression of several deadenylase subunits could cluster the peak phases of poly(A) tail length and long-tailed mRNA abundance, respectively, into three distinct time windows around the clock, regardless of the rhythmic features in transcription, polyadenylation and degradation. This behavior could allow rhythmicity in deadenylase expression to be a strong organizer for circadian gene expression across the genome. Last, our model suggested factors that could contribute to the experimentally observed rhythmicity in poly(A) tail length and total mRNA abundance.

P1613/B750

Identification of Gene Regulatory Networks for Robust Tissue-scale Spatial Pattern Formation during Morphogenesis.

S. Modi, I. Carulli, R. Zurakowski, J. P. Gleghorn; University of Delaware, Newark, DE.

Proper tissue and organ function are dictated, in part, by the correct spatial organization and interaction of multiple cell populations. During embryonic development, this coordinated spatial and temporal organization is frequently achieved by having sender-receiver type signaling systems between different cell populations. In these systems, specific morphogens are secreted by sender cells and receiver cells then sense the morphogen gradient using a network of transcriptional activators/repressors called the intracellular gene regulatory network (GRN) to determine their function. This sensing is influenced by stochastic noise appearing at the cellular and multi-cellular tissue scale. Cellular noise arises from gene expression noise and diffusion, degradation, and secretion of morphogens whereas spatio-temporal fluctuations in growth factors, cell movement, cell proliferation and cell death drive noise at the tissue scale. We developed a computational tool to infer the minimal structure and parameters of GRN and intercellular interactions within interacting cell types to explain experimentally observed spatial gene expression patterns. To validate the computational tool, a bacterial system is used with a sender cell population that secretes a morphogen that diffuses through the medium into a receiver cell population to activate receiver gene expression. Reporter genes are used to image and quantify gene expression intensities in both cell populations. Stochasticity can be disadvantageous to receiver cell fate patterning

as the cells must transduce the morphogen gradient and reliably lock into a particular cell fate and prevent random switching. This feature is encoded in the interplay of the GRN and the intercellular morphogen exchange. Hence, we develop and simulate a stochastic reaction-diffusion model in silico and rank order the inferred networks based on the robustness of their generated patterns against stochastic gene expression and random spatial distribution of cell-types. This tool provides insights into optimizing the inter- and intracellular networks for reducing the effect of stochasticity on pattern formation at the tissue-scale needed for proper morphogenesis.

Ph-triggered Coacervate Formation Activates Enzyme Reactions.

C. Love[1], J. Steinkühler[2], R. Dimova[2], D. Tang[1]; [1]Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, GERMANY, [2]Max Plank Institute of Colloids and Interfaces, Potsdam, GERMANY.

The field of liquid-liquid phase separation (LLPS) in biology has attracted much attention over the last decade and bimolecular condensates have now been identified in a wide range of eukaryotic organisms. Despite this, the precise function of membrane-free compartments within biological systems has not been entirely elucidated. As biology is innately complex, it is often challenging to determine the function of condensates within the myriad of biochemical processes. On the other hand, in *vitro* assays provide a simplified bottom-up approach that allow for the controllable testing of condensate function. We have therefore developed a method for the *in-situ* formation of coacervates (a form of condensates) within giant unilamellar vesicles (GUVs) to enable the controllable testing of the role of phase separation in regulating biochemical reactions. Coacervation, a specific type of LLPS driven by the electrostatic attraction of oppositely charged polymers, has been implicated as one of the driving forces for condensate formation. Here, we exploit the intrinsic pKa of coacervate-forming polymers polylysine and either ATP or carboxymethyl dextran to reversibly drive coacervate formation within lipid vesicles with pH changes. We show that the *in-situ* coacervate formation activates dormant reactions in solution, by the up-concentration of the reactants. Our results, demonstrate a clear functional role of condensates and show that minimal and dynamic in *vitro* models can offer fundamental insights into our understanding of membrane-free condensates in biology.

Differentiated Embryonic Chondrocyte Gene 1 (*Dec1)* Deficiency Inhibits Tac-induced Fibrosis in Cardiac Hypertrophy.

U. K. Bhawal[1], H. T. Le[2], F. Sato[2]; [1]Nihon University School of Dentistry at Matsudo, Matsudo, JAPAN, [2]Wakayama Medical University, Wakayama, JAPAN.

Basic helix- loop-helix (BHLH) transcription factor *Dec1* (differentiated embryonic chondrocyte gene 1) is associated with tumor progression, inflammation and metabolism. However, the effect of *Dec1* on cardiac function and cardiac fibrosis is still not known. We performed TAC (transverse aortic constriction) in both of wild type (WT) and *Dec1* knock out (KO) mice. After TAC operation, all mice were assessed cardiac function by echocardiography as well as heart tissues were collected to analysis fibrosis and inflammation by immunohistochemistry and real time PCR. We found that fractional shortening (FS%) did not attenuate and *BNP* expression was lower in TAC-operated *Dec1* KO mice whereas TAC induced more cardiac hypertrophy in *Dec1* KO mice than WT mice, exhibiting an increase in heart weight/body weight ratio and thickness of left ventricle post wall. In addition, TAC-induced cardiac

fibrosis was decreased in *Dec1* KO mice, involving αSMA, TGFβ1 and TNFα expression. These results indicate that *Dec1* deficiency prevents cardiac dysfunction and inhibits cardiac fibrosis, suggesting an important role of *Dec1* in cardiac fibrosis.

Application of RNA Interference for Development of Capric Acid-rich *Camelina Sativa* Germplasm.

Y. B. Blume[1], R. Y. Blume[1], H. J. Kim[2], T. J. Nazarenus[2], L. O. Sakhno[1], A. I. Yemets[1], E. B. Cahoon[1]; [1]Inst Food Biotechnology & Genomics, Kyiv, UKRAINE, [2]University of Nebraska-Lincoln, Lincoln, NE.

Camelina sativa has been shown to be a viable feedstock for biodiesel and bio-based jet fuel. Such jet-fuel generates up to 75% lower greenhouse gas emissions relative to petroleum-derived jet fuel during production and use as a commercial aviation fuel. Therefore we decided to enhance the value of camelina seed oil for bio-jet fuel by increasing its content of medium-chain fatty acids (C10:0, C12:0, C14:0) through application of RNA interference. The obtained results demonstrated the feasibility of engineering *C. sativa*, including a Ukraine-adapted variety with high yield level, for the production of oils with up to 30% of medium-chain fatty acids. Such oils are more readily convertible to bio-jet fuel than conventional camelina oil that is rich in C16-C22 fatty acids. Levels of medium chain fatty acids were further increased in camelina seed oil by silencing expression of genes (AAE15/16) for enzymes that limit accumulation of these fatty acids. Obtained results on two successfully breeded T_3 lines of engineered camelina germplasm showed increase of C10:0 content in seed oil up to 13% and 14%. The *C. sativa* varieties generated by this research will promote enhanced profitability for dryland farmers and an optimized, low carbon emission feedstock for the aviation fuel industry.

Major Royal Jelly Protein 1 Increases Cell Number and Recombinant Protein Production in Cho Cells.

A. Robles Zamora, 64460; ITESM, Monterrey, MEXICO.

Major Royal Jelly Protein 1 increases cell number and recombinant protein production in CHO cells A. Robles-Zamora[1], M. A. Torres-Acosta[1,2], J.M. Aguilar-Yáñez[1], M.E.G. Brunck[1] [1]Centro de Biotecnología FEMSA, Tecnológico de Monterrey, Monterrey, Mexico [2] Advanced Centre for Biochemical Engineering, University College London, London, UK CHO cells are commonly used to produce industry-relevant recombinant proteins that require post-translational modifications. A common research goal is to find new strategies to increase production yield, which augments product availability while reducing cost of production. Major Royal Jelly Protein 1 (MRJP1) is the main protein component of Royal Jelly, the only source of nutrition in the beehive for queen bees. Royal Jelly consumption leads to increased lifespan and body size amongst other features in queen bees. Here we report the supplementation of culture media with recombinant MRJP1 protein in wild-type cells (CHO-S) and a CHO system engineered to produce galsulfase (Gal-CHO), a drug used in the management of Fabry disease. MRJP1-supplemented medium yields significantly more CHO-S and Gal-CHO cells, 39.61% (SD±11.52%) and 36.21% (SD±11%), respectively, than vehicle-supplemented medium after 4 days in culture. In addition, specific galsulfase production was significantly increased in Gal-CHO cell in MRJP1-supplemented cultures at day 4 (54.92% SD± 20.52%, t-student test, $p<0.001$). We are currently investigating the molecular mechanisms involved in the observed phenotype. We suggest MRJP1 supplementation may be a commercially suitable alternative to expensive growth factors or complex boosts mixtures to increase industry-relevant recombinant protein production in CHO recombinant systems.

Honey Proteomics: Environmental Biomonitor of the Ecosystem Health and Potential Diagnostic Biomarkers for Honeybee Disease.

R. S. Cornero, L. A. Liotta, A. Luchini; George Mason University, Manassas, VA.

Honeybees play an important environmental role as pollinators and biodiversity promoters in both farm-growth and non-farm-growth plants. Every year, 15% of the total colonies in the USA are lost due to a combination of environmental factors including pathogens, exposure to pesticides, and climate change. In order to reduce honeybee mortality, it is important to identify the precise biological factors such as bacteria, viruses, fungi, and pathogens which cause increased mortality among honeybee populations. In this work, we focused on identifying honey proteins and peptides to use them as an environmental biomonitor and a tool for the diagnosis of honeybee disease. Because of the low concentration of protein in honey (0.1-0.5%) and the high concentration of sugars, identifying low abundance peptides and proteins causes unresolved challenges. To overcome this problem, we used multifunctional core-shell nanoparticles, which are a concentration method based on an affinity bait covalently bound to a polymer nanoparticle. When applied to a protein solution, the nanoparticles rapidly capture, concentrate and preserve solution-phase analytes, which can be then measured with standard analytical methods. In this study, we analyzed 15 honey samples collected in Virginia, Maryland, and Argentina with tandem mass spectrometry using a Thermo Fusion Orbitrap mass spectrometer and proteomic databases including Apis mellifera, geographically consistent plant, bee pathogens such as deformed wing virus, Varroa destructor, and Nosema ceranae, and plant pathogens. In order to ensure the specificity of the identified peptides, we applied a bioinformatics pipeline to compare peptide sequences to the entire RefSeq non-redundant database. We identified, for the first time, thousands of low-abundance peptides of diverse origin an example being Apis mellifera heat shock proteins, which are promising general stress biomarker, honeybee microbiome (Lactobacillus kunkeei, Gilleamella apicola) and pathogens (deformed wing virus, Varroa destructor, and Nosema ceranae), pollen (Profilin from Helianthus annuus), nectar, and plant pathogens (Sphingomonas sp).The present study showed that honey can be used as a tool for honeybee diagnostic disease and environmental biomonitoring. Through the use of functionalized affinity particles, we overcame the sensitivity problem that affected proteomics measurements in the honey and identified thousands of new honey peptides. In the future, we plan on expanding the number of samples to more diverse geographical areas and to follow hives longitudinally in order to correlate honey proteomics to disease status and response to treatment.

Incorporation of Engineered Quorum Signaling to Control Biomaterials Based Upon Bacterial Biofilms.

A. Oliver, J. Urban, X. Fang, E. Nafziger, B. Abu-Ageel, S. Challa, A. Isler, H. Peng, V. Zhu, M. Saha; the College of William and Mary, Williamsburg, VA.

Prokaryotic biofilms rather than planktonic cells constitute the predominant form of prokaryotic life in nature. Despite the ubiquity of biofilms and their immense potential for bioengineering applications, ranging from bioremediation and nanomaterials manufacturing to their use as living materials, they have not been the focus of applications within the field of synthetic biology. To render biofilm utilization more feasible within synthetic biology, there is a need for a versatile and holistic toolkit to position and control biofilms precisely. To address this need, we have expanded upon the technique of biofilm

lithography pioneered by Jin and Reidel-Kruse (PNAS, 2018) through the incorporation of engineered quorum signaling within the biofilm. We will demonstrate additional functionality by tying biofilm maintenance, and propagation to the reception of these quorum signaling molecules. This approach can be used to limit the propagation of a biofilm, as the biofilm will only be maintained and propagated in regions where the local concentration of HSL reaches a certain threshold. With our toolbox, we have demonstrated that we are able to adhere to an inner layer of bacterial "sender" cells, which produce a quorum sensing signal that is able to be detected by an outer layer of bacterial "receiver" cells. Upon detection of the quorum signaling molecules, the receiver cells are able to express varied gene(s) of interest. As the sender and receiver circuits are constructed via 3G assembly, they are incredibly modular, and rapidly constructed. Currently we have demonstrated functionality of our toolbox through the assembly of a LuxI-based sender circuit, and a PLux/LuxR based receiver circuit with MScarlet-I as an output.

P1620/B757

Metabolic Stress Augments the Production of Advanced Glycation End Products Posttranslational Modifications on Proteins from Cellular Pathways Involved in Antigen Processing and Epitope Selection in Mouse Dendritic Cells.

C. C. Clement, L. Santambrogio; Weill Cornell Medicine, New York, NY.

Increased oxidized ribose, glucose, glyoxal and methylglyoxal concentrations are observed in several metabolic diseases including diabetes and metabolic syndrome, mediating the non-enzymatic protein glycation and carbonylation followed by protein unfolding, cross-linking, and aggregation. In this presented research, we hypothesized that the protein posttranslational modifications induced by glycation and glycoxidation, i.e., the advanced glycation end products (AGE), will damage the immunological mediated pathways in mice models of T2DM metabolic syndrome. To test our hypothesis, we analyzed the AGE-modified proteomes and the immunopeptidomes eluted from MHC-II receptors using the CD11c+ purified primary dendritic cells from healthy controls C57BL/6, and *Ob/Ob* obese mice, models of T2DM. In addition, we validated the AGE-modified proteins in mouse JAWS dendritic cells treated with glucose concentrations (15-20 mM) found in the sera of diabetics. The peptides bearing AGE-amide adducts were sequenced by bottom-up label-free MS/MS that employed a QExactive HF quadrupole mass spectrometer. The immunopeptidomes were sequenced using the top-down MS/MS and an Orbitrap Fusion Tribid mass spectrometer using a combination of data-dependent (DDA) and data independent acquisition (DIA) methodologies. Bioinformatics and label free quantitative (LFQ) analyses highlighted the significant differences in the quantitative proteomic and peptidomic expression profiles among several cellular pathways affected by AGE, including endosomal maturation, antigen presentation, and processing machinery. An alysis of the type of AGE-PTM accumulated in the proteomes from Ob/Ob and JAWS dendritic cells treated with 20 mM glucose ranked the site-specific carboxymethylation of lysine (CML) as the most abundant AGE followed by formylation of lysine and carboxymethylation of arginine (CMA). Further mapping of PTM on the in *vitro* glycated human MHC II allowed the identification of key AGE-modified amino acids residues involved in peptide epitope binding. Overall, these results highlight the potential role for AGE-PTM accumulation in the pathophysiology of immune responses.

The Reactome Pathway Knowledgebase: Curation and Visualization of Variants, Drugs, and Understudied Human Proteins.

R. Haw[1], *. Reactome Consortium[1], H. Hermjakob[2], P. D'Eustachio[3], G. Wu[4], L. Stein[5]; [1]Ontario Institute for Cancer Research, Toronto, ON, CANADA, [2]EMBL-EBI, Hinxton, UNITED KINGDOM, [3]NYULMC, New York, NY, [4]OHSU, Portland,, OR, [5]Ontario Inst Cancer Res, Toronto, ON, CANADA.

Pathway databases are a powerful bioinformatics tool for organizing and analyzing very large data sets, linking knowledge at a molecular level to more precise and effective diagnoses and treatments of human diseases. Reactome (https://reactome.org/) is an open-source, manually-curated and peer-reviewed knowledgebase of human reactions, pathways and biological processes. Our knowledgebase now comprises 12,608 human reactions organized into 2,287 pathways involving 11,040 proteins encoded by 10,860 different human genes, 2,078 small molecules (of which 222 are drugs), and 12,335 complexes. These annotations are supported by 30,398 literature references. We have curated a broad range of major disease processes that arise from somatic or germ-line mutations. To date, over 2000 unique variant annotations (for 305 proteins) have been associated with disease-variant forms of 968 reactions and other reactions that capture the effects of small molecule and drugs on these disease processes. Variants are chosen for annotation based on guidelines and data from ClinGen and COSMIC, and annotated with Disease Ontology terms. The annotation of small molecules, chemicals, protein or RNA drugs, are now cross-referenced to IUPHAR, PubChem or ChEBI allowing us to model the effects of therapeutic intervention on disease and normal pathways. As part of the Illuminating the Druggable (IDG) program, we have undertaken the role to project understudied proteins in the context of biological pathways to infer potential functions of these proteins. Reactome thus provides powerful, intuitive and reusable tools for visualization, interpretation and analysis of pathways to support basic and clinical research, genome analysis, modelling, systems biology and education.

P1622/B759

Screening of Tyrosine Motifs Which Can Induce Efficient Cell Proliferation and Its Development.

K. Umene, M. Kawahara; Department of Chemistry and Biotechnology, Graduate School of Engineering, the University of Tokyo, Bunkyo-ku, JAPAN.

Regulating induction of cell fate such as proliferation, differentiation and cell death is important technology for any cell-regulating technology such as regenerative medicine. Cell fate is induced and regulated by many mechanisms within a cell and one of the most significant one is signal transduction. In many cases cell fate has been controlled by adding sophisticated combinations of cytokines and chemicals. But these approaches depend on receptors which are endogenously expressed within a cell. To overcome this limitation, we have developed a technology of constructing artificial receptors which can regulate cell fate such as proliferation and differentiation. One of our approaches is to engineer a tyrosine motif, which is a part of the intracellular domain of receptors and acts as a binding region with intracellular endogenous signaling molecules. Here we show a new method for selecting artificial receptors which can induce cell proliferation in an efficient way by introducing random mutations to residues surrounding a tyrosine motif. Since this surrounding sequence is known to be important for their binding affinity against signaling molecules, in this way we can develop a *de novo* receptor library. In this study, we made such a receptor library using a signal transducer and activator of transcription 1 (STAT1) binding motif by randomizing 3 residues surrounding the central tyrosine residue. We

introduced this library into a cell line and after screening, several clones were obtained, all of which was shown to induce ligand-dependent cell proliferation. A signaling analysis revealed that different patterns of the activation of signaling molecules were successfully induced by this library. Interestingly, a key residue was found to be important for induction of efficient cell proliferation. As a conclusion, we succeeded in development of phenotypic screening of tyrosine motifs which can induce efficient cell proliferation.

Recording Calcium in *Vivo*: Using a DNA-based Memory Device to Record Ca^{2+} Signaling in Mammalian Cells.

E. S. Li, S. Paudel, R. Nalamalapu, M. S. Saha; William & Mary, Williamsburg, VA.

Calcium (Ca^{2+}) ions are essential in nearly every aspect of cell biology, from early development to wound healing. As a ubiquitous messenger in cell signaling, control of intracellular calcium levels is tightly regulated within the cell, and complex spatial and temporal dynamics of calcium ion levels in the cell have far reaching effects on gene activation. This has driven efforts to track Ca^{2+} dynamics in cells; however, methods to do so in the past decades have relied on using Ca^{2+}-sensitive probes and live-fluorescent imaging, which may potentially disrupt Ca^{2+} dynamics and consequent gene expression. We have employed several approaches to tracking Ca^{2+} activity in *vivo*. First, we have used fluo-4 in primary neuronal cell cultures. We have also utilized GCaMP to measure intracellular Ca^{2+} levels in whole *Xenopus* embryos. Limitations to both of these approaches include photobleaching effects and fluorescence microscopy of live cells. In order to obviate the need for a fluorescent-based readout, we have aimed to construct a DNA-based memory device in order to record intracellular Ca^{2+} levels in mammalian cells by relying on sequencing output of a targeted gene locus. This transcriptionally activated recording can be multiplexed with other cellular events in order to investigate the relationship between intracellular calcium dynamics and its consequent effects on key gene regulatory pathways. Utilizing a CRISPR-mediated analog multi-event recording apparatus (CAMERA), an engineered Ca^{2+}-responsive promoter with nuclear factor of activated T-cells (NFAT) response elements is placed upstream of an engineered base editor, which will generate C•G to T•A mutations at a designated locus on the CCR5 gene in the HEK293T genome. Following induction of intracellular calcium levels, DNA-based recording of dynamic Ca^{2+} levels is detected with high-throughput sequencing of the target genomic locus. Results with traditional calcium indicators display clear differences in the calcium activity of neuronal precursors (high frequency, low amplitude activity) compared to neuronal cells committed to differentiation (low frequency, high amplitude); these results are being compared with those obtained from the memory-based recording system.

Exploring the Hedgehog Signaling Pathway Using Unnatural Amino Acid Mutagenesis.

E. Ivorra-Molla[1], S. Palani[1], A. Rudolf[2], B. Bishop[2], P. Ingham[3], C. Siebold[2], M. Balasubramanian[1]; [1]University of Warwick, Coventry, UNITED KINGDOM, [2]University of Oxford, Oxford, UNITED KINGDOM, [3]Nanyang Technological University, Singapore, SINGAPORE.

Hedgehog (Hh) is a secreted signaling protein involved in tissue patterning during embryogenesis and stem cell regulation in adults. Misregulation of the Hedgehog pathway leads to developmental defects and can be a driver for cancer. The extracellular Hh ligand can directly bind to a number of cell surface

receptors, including its canonical receptor Patched (Ptc), and co-receptors Boc, Cdon, Hhip, and Gas1. However, how Hh interacts with these proteins is not fully understood. Unnatural amino acid mutagenesis is a powerful approach through which non-natural amino acids are introduced within proteins in a site specific manner through the use of a repurposed sense codon (UAG) in the mRNA of interest and an orthogonal $tRNA_{UAG}$ and a tRNA aminoacyl tRNA synthetase that recognises $tRNA_{UAG}$ in the mRNA. The use of cross-linking amino acids, such as Benzoyl phenylalanine, into proteins allows the identification of direct binding partners and allows mapping of the interaction site distances with sub-nanometer precision. We have applied this powerful methodology to first validate the known interaction sites of the Hh ligand with its receptors Ptc and Hhip, respectively, and find that the cross-linking studies are largely consistent with the published X-ray and cryo-EM data on Hh-Ptc and Hh-Hhip interactions, while also identifying new interaction sites. We are now using this approach to precisely understand the different domains on Hh that interact with other Hh receptors such as Boc, Cdon, Gpc3, and Gas1.

P1625/B762

Engineered Adhesin Library for Construction of Bacterial Biofilm-based Biomaterials.

J. Urban, B. Abuageel, S. Challa, X. Fang, A. Isler, E. Nafziger, A. Oliver, H. Peng, H. Zhu, M. Saha, E. Bradley, M. Patel; William & Mary, Williamsburg, VA.

The majority of prokaryotic cells live in multicellular consortia known as biofilms. Biofilms are typically associated with increased pathogenicity and environmental effects such as biofouling. However, due to their ubiquity and outstanding bioengineering potential, bacterial biofilms may be repurposed as living biomaterials to perform useful functions ranging from bioremediation to clinically-relevant sensors. Design and production of such synthetic biology applications is hindered by a lack of well-characterized parts for biofilm engineering and control. To ensure robustness and control of biofilm-based biomaterials, we have constructed a library of biofilm-forming and strengthening adhesins for use in E. coli biofilms. This library builds upon pDawn-AG43, a plasmid designed by Stanford bioengineers (Jin and Riedel-Kruse, PNAS, 2018) for blue-light induced biofilm formation. The adhesin utilized in pDawn-AG43, E. coli outer membrane protein antigen 43, forms spatially-controlled but relatively weak biofilms when induced. Using both genomic PCR and DNA synthesis, we obtained three amyloid fibers to complement and even replace AG43. These include: curli fibers (the main proteinaceous component of native E. coli biofilms), SaSuhB (a macroscopic fiber produced by S. Aureus), and Functional Amyloid in Pseudomonas, or FAP (an amyloid fiber that contributes to biofilm formation in P. Aeruginosa). Such fibers were placed in 3G Assembly-compatible format for the construction of chemical and light-induced circuits, and fiber expression was quantified via Congo Red staining. For both SaSuhB and FAP, fiber expression was further visualized via microscopy. An alysis of all three adhesins has shown robust, controllable adhesion and biofilm formation, which expands upon the available tools for biofilm formation and control.

P1626/B763

Stem Cell Manufacturing Using Sustained-release Nano-micro Carrier in Single-use Bioreactor Systems.

J. Kim, J. Hwang, S. Yu, S. Hong, Y. Choi; CHA University, Seongnam-si, KOREA, REPUBLIC OF.

In the last decade, micro-carriers and bioreactor system has been developed for clinical trials in many companies because stem cell-based therapy demand a large number of cells. However, micro-carriers

were very high cost due to surface modification for cell attachment. Here we have developed a nano-microcarrier and single-use bioreactor system for effective expansion of adult stem cells. The nano-microcarrier includes open porous silica nanoparticles (OSNs)-conjugated polystyrene microbeads (PS-OSN), which is able to load the growth factors or cell attachment factors efficiently and to control the sustained release. As a result, we have established an optimal condition for adult stem cell cultivation using PS-OSN carriers in single-use bioreactor system. Also, a stable and effective expansion yield of the stem cells was achieved compared to commercialized micro-carriers. In addition, we confirmed the pluripotency and proliferative capacity of stem cells compared to conventional monolayer cultivation. Our results will apply to the cost-effective tool in downstream for stem cell-based therapy.

Engineering Tissues and Organs

Recapitulating Biological Signaling Scenarios with Spatiotemporal Control Using a Multiplexed, DNA-Patterning Approach.

O. J. Scheideler, D. V. Schaffer, L. L. Sohn; University of California, Berkeley, Berkeley, CA.

Dissecting the complex action of the biological signals that orchestrate single-cell fate decisions as well as tissue function/dysfunction is challenging due to the spatiotemporal parameters modulating their actions. This complexity is further compounded by the fact that these signals—soluble ligands, extracellular matrix-sequestered cues, and cell surface-presented cues—comprise a larger network in which multiple signals are coordinating with each other across time and space. In order to model and investigate such dynamic signaling scenarios in *vitro*, we have engineered a DNA-based patterning platform that imparts unprecedented spatial and temporal control over individual and multivariable signaling scenarios. Specifically, we utilize photolithography to generate a patterned photoresist (PR) template that guides the conjugation of DNA oligonucleotides onto a surface. The PR-template can be stripped and a new one patterned without damaging the initial DNA layer. As we demonstrate, we can subsequently register and layer up to 10 orthogonal DNA strands, remarkably without sacrificing lithographic resolution. The resulting, multiplexed DNA patterns are highly functional and can hybridize to complementary DNA sequences that have been tagged to cells and/or solid-phase signaling ligands. The precision of the DNA patterns is thus transferred to the assembled in *vitro* model, imparting micron-scale control in recapitulating single-cell to bulk-tissue signaling environments. To demonstrate our platform's utility in de-coupling the spatial dependencies of biological signals, we investigated how two competing niche signals, fibroblast growth factor-2 (FGF-2) and ephrin-B2, coordinate spatially to instruct adult neural stem cell fate decisions at the single-cell level. By modulating their spatial presentation, we observe a strong spatial bias toward FGF-2 that, in some unexpected cases, did not translate to the predicted phenotype of high proliferation and maintenance of stem cell identity but rather high neuronal differentiation. To achieve temporal control within our platform, we demonstrate various nuclease-based strategies to modulate the action of DNA-hybridized signals. With these spatiotemporal capabilities in-hand, our DNA-directed approach provides opportunities to investigate the underlying signaling mechanisms of key processes across a wide range of biological disciplines.

P1628/B765

Electrophysiological Property Evaluation of Reconstructed Cardiac Tissue-like Cell Community.

K. Fujii, T. Kaneko; Hosei University, Koganei, JAPAN.

Cardiac tissue in vivo has a structure that cardiomyocytes (CMs) and fibroblasts (Fibs) are regularly oriented. While, cardiac cell sheet obtained by dispersed culture has multi-directional sarcomere structure and random contacts of CMs and Fibs. We previously reported that dispersed culture of cell obtained from cardiac tissue had made conduction velocity slower. Therefore, there is an issue that they show the different functions such as contractile force and electrophysiological property. It is said that cardiac cell sheet transplantation is adopted as a therapeutic discipline; however the minute and detailed effect is still incompletely understood. In this study, we obtained cardiac tissue-like structure on a substrate with agarose microchamber, where Fib network is localized between two Linear-CM communities and mediates their signal conduction. The CM-Fib-CM network resembling cardiac tissue in vivo was reconstructed using micro patterning of agarose gel and conducted membrane potential measurement using multi electrode array system. The condition of cell community was divided into 3 stages based on Fib proliferation: network consisting of CM only, network which CMs and Fibs localized in designated spots, and cardiac tissue-like cell community. Then we demonstrated the function of cell community and compared between 3 stages. Firstly, we found that there was no significant difference between 3 stages in Inter-spike interval (ISI) which is the time between subsequent action potentials of Na^+ Infflux. It means these 3 types of cell community had almost the same spontaneous rate and pacing speed. Secondly, we focused on Coefficient Variation (CV) in order to evaluate stability of cell community. As a result, cardiac tissue-like cell community showed the lowest CV value and the most stable beating. It is thought that almost the same ISI between groups resulted from cell orientation/structure and proportion of CM and Fib. Cell communities demonstrated in this study are reconstructed using AMC, therefore cell orientation was unidirectional and CM networks and Fib ones are located in designated spots. Moreover we assumed that Fibs had an effect on cardiac stable beating. Further studies are required in order to reveal the role of Fibs in cardiac tissue and we have been analyzing also in terms of conduction velocity of each cell community.

P1629/B766

Scaffold-based Biosensors - New Tools for Studies of Three-Dimensional Tissue Culture Models.

R. Dmitriev, I. Okkelman; University College Cork, Cork, IRELAND.

Cells heavily depend on presence of the extracellular matrix, which is frequently used in re-creating in *vivo* conditions in 2D/ 3D tissue culture, tissue engineering and transplantation applications. In turn, analysis of extra- and pericellular metabolites, dissolved oxygen and other biomolecules can inform on cell physiology, viability, mitochondrial function and bioenergetics, without the need of the intracellular measurements. A broad selection of various scaffolds and matrices employed in tissue engineering prompts design of multi-functional 'hybrid' matrices, which not only support the cell function but also provide additional functionality. Here, we present an approach enabling design of biosensor matrix materials, based on use of luminescent dyes, nanosensors and bioengineered fluorescent proteins. First, organic polymer-based scaffolds such as polystyrene or PCL can be modified via impregnation of Pt(II)-porphyrin hydrophobic dye and become O_2-sensitive. Alternatively, various collagen-based matrices display aggregation and retention of water-soluble O_2-sensitive nanosensors; this feature can be exploited for producing biosensing xenotransplants or modifying Matrigel for organoid and related

structures. Third approach is based on the use of inventory of protein-binding domains and pH, $Ca^{2+}$and other biosensor proteins. Here, we present new data on production of cellulose and collagen-based biosensor matrices compatible with measurement of extracellular pH in 3D cultures of colon cancer cells and mouse intestinal organoids. Such biosensor matrices are compatible with conventional fluorescence microscopy and enable quantitative measurements based on the intensity or fluorescence lifetime (FLIM, 1.5-2.2 ns) or phosphorescence lifetime (PLIM, 10-50 ʋs range) imaging readouts. In a proof-of-concept study, we produced pH-sensing cellulose scaffold based on cyan fluorescent protein and used it for monitoring pH changes associated with action of mitochondrial uncoupler on the mouse intestinal organoids. We found that recorded changes in pH were concomitant with the effect on cell oxygenation due to action on the mitochondria. We also demonstrate how the Matrigel matrix can be modified with O_2-sensitive nanoparticles in order to monitor oxygenation in vicinity of live intestinal organoids. Collectively, presented approach provides means for label-free quantitative analysis of metabolism in the tissue-engineered constructs.This work was supported by the Science Foundation Ireland (SFI) grants 13/SIRG/2144 and 18/IF/6238.

A Validated Test for Assessing Cell Viability in Scaffolds: Measuring Atp/dna for Cells in Hydrogel Scaffolds.

D. ARORA, 20877, A. L. Horenberg, D. Bienek, C. G. Simon, Jr.; National Institute of Standrds and Technology, Gaithersburg, MD., gaithersburg, MD.

Abstract: Tissue engineered medical products are often comprised of cells suspended in a 3D scaffold. The mechanism of action may require that the cells are viable to regenerate tissue or to secrete bioactive factors that induce tissue repair. There is a need to be able to reliably measure cell viability in scaffolds as a quality attribute of the product. Traditional biochemical cell viability assays assess membrane leakiness, metabolic activity or the presence of cellular components that are indicative of cell viability (such as ATP). The scaffold may interfere with these assays in unknown ways, such as by impeding the diffusion of assay components or by altering reaction kinetics, making it difficult to interpret results. We have developed a model scaffold-cell-assay system for assessing cellular viability. For this assay, moles of ATP per gram of DNA was measured using a luminescence ATP assay and a fluorescence DNA assay. A glucose-based, polysaccharide, shear-thinning hydrogel was used for the scaffold which was seeded with human Jurkat cells. Control experiments were conducted with gels spiked with ATP and DNA to make sure that, 1) at the hydrogels do not interfere with the assay, 2) the gel components do not contain ATPases and 3) the assay reactants could adequately diffuse into and out of the hydrogels to obtain reliable results. In order to validate results, in situ results for gels were compared to results from gels that were disassembled by shear-thinning pipetting action to release the contents. Results from these studies are guiding an interlaboratory study to support an ASTM Standard Test Method for Measuring Cell Viability in Scaffolds. The model scaffold-cell-assay system may also be used as a test bed to assess advanced measurements of cell viability in scaffolds, especially less invasive or 3D imaging techniques such as electron paramagnetic resonance imaging of oxygen consumption or photoacoustic imaging of live cell distribution within 3D scaffolds.

Synchronization of Beating between Dispersed Cardiomyocytes and Cardiac Tissue Piece.

T. Nakamura; Hosei University,, Tokyo, JAPAN.

Myocardial infarction is a famous disease in the heart. Transplanting cardiomyocytes sheet onto infarcted area is expected as a new treatment for heart disease. A new method using cardiomyocytes sheet has been developed for the treatment of the ischemic heart disease. However, the mechanism of beating synchronization at transplantation between cardiomyocytes sheet and heart is still unclear. As post-transplant electrophysiological signals couldn't be measured continuously in *vivo* heart, in *vitro* model of transplantation between cardiomyocytes sheet and heart were reproduced on Multi Electrode Array (MEA) by using dispersed cardiomyocytes and cardiac tissue piece. Recently, MEA system measure of extracellular potential and expected to evaluate the beating synchronization process. To reveal the synchronization process between autonomous beating dispersed-cardiomyocytes and cardiac tissue piece with the oriented impulse conducting system, we measured and analyzed the extracellular potential of these cardiomyocytes for beating interval. For analysis, the sodium peaks' time at each sample was of tainted. Then, Inter spike interval (ISI), the beating interval, can be captured. Also, the beating time difference between dispersed cardiomyocytes and cardiac tissue piece were calculated. As a result, we obtained two kinds of data. Dispersed cardiomyocytes having long and stable ISI became pacemaker-region, and on the other hand, a dispersed cardiomyocytes or cardiac tissue piece having short and stable ISI became pacemaker-region. Therefore, we clarified that the stable beating rate was dominant for was pacemaking regardless of beating speed and whether dispersed cardiomyocytes or cardiac tissue piece. In conclusion, stable beating function was a more important factor than oriented structure in beating synchronization. When the cardiomyocytes sheet is to be used as a treatment method, cardiomyocytes sheet will be pacemaking after transplantation if the beats of cardiomyocytes sheet is more stable than it of heart. Moreover, it was suggested that to transplant cardiomyocytes sheet having stable beating might be induced the arrhythmia of heart.

Thick, Functional, 3D Liver Tissue Microenvironment Model.

S. M. Moss, H. Strobel, J. Hoying; Advanced Solutions Life Sciences, Manchester, NH.

It is estimated that 90% of pharmaceuticals fail during clinical trials, despite success in animal studies. In order to alleviate this bottleneck two main strategies are needed. 1. Tissue throughput, repeatability, and automation needs to be addressed to enable clinical level production. 2. To reduce these failures, there is a strong need for in vitro models that can recapitulate the 3D in vivo environment using humantissues.In this study we have developed a robust 3D liver model leveraging 3D printing and sacrificial moulding techniques to create a thick (≤ 1mm), high-cell density hepatic tissue. To accomplish this, vertical pillars of a sacrificial hydrogel were printed within individual wells of a 96-well plate to ultimately form channels for media exchange. 10-20 million primary human or rat hepatocytes/ml, mixed with varying numbers of non-parenchymal cells (NPCs), with or without isolated, adipose, microvessels were suspended in proportionally small amounts of type 1 collagen. The hepatocyte/NPC/microvessel collagen slurry was dispensed around the sacrificial pillars, which were then washed out after the tissue sets.Culture supernatants were analysed for the production of urea and the absence of lactate dehydrogenase (LDH). Urea secretion levels were 2.8 times higher at day 7 than day 2, demonstrating that hepatocytes maintained their functionality during longer term culture in

a thick 3D tissue format. LDH values were over 100 times lower at day 7 than day 2. This indicates that despite some expected cell death following hepatocyte thawing and seeding, the construct quickly stabilized and maintained viability through day 7. Histological analysis confirmed a high cell density at day 7 and negligible necrosis. Imaging of the hepatic tissue constructs with the GE INCell 6500 high content cell imaging system showed preservation of the original tissue and wall structure of the exchange channels as well as cell heterogeneity within the thick tissue construct.In addition to developing a fabricated tissue construct that creates an hepatic-like tissue environment in a throughput format, we are using this liver construct to develop automated tissue fabrication, integrating our BioAssembly® platform with the GE in Cell scanner to enable commercial-level production of sophisticated 3D tissue models with the potential to decrease drug discovery timelines and improve bench to bedside care.

Modulation of Cartilaginous Matrix Characteristics by Mechanical Dose - Optimization of in Vitro Fibrocartilage Reconstruction.

E. Lee, S. Jang, J. Lee, J. Kwon, B. Koo, J. Park, T. Oh; Kyung Hee Univ, Seoul, KOREA, REPUBLIC OF.

For reconstruction of fibrocartilage tissue, induction of tissue alignment and cartilaginous matrix production is essentially needed. Although tensile stimulation is the most effective approach to induce tissue alignment, recent studies showed that mechano-transduction interferes with the signaling pathway which is upstream to chondrogenesis. In our study, sheet-cultured meniscal chondrocytes (MCs) were rolled-up to form cable-shape tissue construct. When the roll-up cultured MCs were subjected to static tension (10%), they resulted in severely attenuated glycosaminoglycans (GAGs) production even in the presence of TGF-β3, a chondrogenic growth factor. To minimize the inhibitory effect of mechano-transduction on cartilaginous matrix production, the dose of tensile stimulation was modulated by tension-release after the induction of tissue alignment by static tension. The mechanical dose of 10% tensile stimulus for more than 7 days subjected to MCs resulted in maintenance of highly aligned tissue upto 5 days after tension release. When the roll-up cultured MCs were subjected to dose-modulated tensile stimulus during 3 weeks of chondrogenesis, matrix production was potentiated in contrast to the cells kept in static tension state for 3 weeks. Examination of nuclei angle showed that application of 7 days of static tension resulted in maintaining the tissue alignment in majority of the cells even after the tension release. The proportion of cells showing nuclear translocation of YAP increased in mechanical dose-dependent manner. The mechanical dose-modulated tissues subjected to chondrogenesis not only maintained tissue alignment but also produced cartilaginous matrix composed of type I collagen and GAGs matrix, which was evidenced by immunohistochemical staining and histological analysis. In conclusion, these finding suggest that the optimization of tensile stimulus can modulate the characteristics of cartilaginous matrix production, which can lead to the successful reconstruction of fibrocartilage.

Application of Recombinant Collagenase to Tissue Dissociation and Cell Recovery.

J. Lim[1,2], D. Choi[2], J. Park[1], C. Choi[1,3], W. Lee[1,3]; [1]Korea Institute of Industrial Technology, Yeongcheon, KOREA, REPUBLIC OF, [2]Yeungnam University, Gyeongsan, KOREA, REPUBLIC OF, [3]Connext Co., Ltd, Yeongcheon, KOREA, REPUBLIC OF.

Purpose: Collecting pure and qualified cells from human donor is a critical but challenging process that hinders successful tissue-engineering and cell biology researches. Mostly, collagenase, derived from *Clostridium histolyticum,* is utilized to isolate cells from tissue. However, crude collagenase contains various neutral proteases which can cause cellular damage during tissue dissociation. Therefore, we produced recombinant collagenase from *Escherichia coli* through bioprocessing technology. **Materials and methods:** Collagenase potency assay of recombinant collagenase was performed using FALGPA peptide as a substrate (synthetic short polypeptide specifically recognized by collagenase). Based on potency assay, proper unit of recombinant collagenase was treated to lung, kidney and spleen tissue from mice to recover immune cells and bovine cartilage to obtain chondrocytes. Three commercialized enzymes were used as a control representing crude collagenase. To compare cell quality, genetic and CD markers were measured by real time PCR and flow cytometry. **Results:** Comparing to control collagenases, immune cells recovered by recombinant collagenase showed fewer numbers, while population of T cell, B cell, NK cell, NKT cell, myeloid and mononuclear phagocyte was similar in both collagenases. However, population of immune cells from spleen obtained by recombinant collagenase showed more even distribution compare to crude collagenase derived ones. Chondrocytes, on the other hand, showed similar recover rate with both cases but ones gained by recombinant collagenase exhibited healthy chondrocyte-like characteristics in regard of genes (*Aggrecan*, *Col1a1*) and surface CD markers (CD14, CD44). **Conclusions:** Although tissue dissociation capacity of crude collagenase in lung, kidney and spleen was confirmed to be superior to the recombinant one, distribution of recovered immune cells was mostly similar in both cases. In particular, unlike other two tissues, spleen-originated immune cells with recombinant collagenase showed more even distribution. Since splenic immune cells are used as a reference for immune cells extracted from organs, it is advantageous to present a clear standard using recombinant collagenase. In addition, chondrocytes recovered by using our recombinant collagenase were determined to maintain their original characteristics better than crude collagenase-isolated ones.

Connectivity of the Glomerular Capillary Network.

M. Terasaki, J. Brunson, J. Sardi; University of Connecticut Hlth Ctr, Farmington, CT.

The capillary network of the kidney glomerulus performs the initial filtration of blood in the nephron. It begins as a single capillary loop, but it is not known how the network forms or how short cuts between afferent (input) and efferent (output) capillaries are prevented. The ATUM tape collector method was used to image 500 nm thick serial sections of mouse glomeruli at 50 nm per pixel. 12 glomeruli were reconstructed. Afferent capillaries were thicker in cross section than efferent capillaries indicating that capillary diameter adapts to flow volume. A no cross zone bisecting the glomerulus between the afferent and efferent capillaries demonstrates the lack of short cuts. The connectivity was determined by a virtual reality system, and was analyzed by network theory, a well established mathematical tool. The glomerulus is not a "planar graph" which shows that it does not form from longitudinal splitting of capillaries. Even though the 12 glomeruli vary five fold in branch number, the number of branches in the shortest path is approximately the same for all of the glomeruli. This may indicate that later branches are added on the side of the glomerulus opposite from the input and output capillaries.

P1636/B774

Loss of Hhex Causes Absence of Hepatopancreatic Ducts but Formation of an Intrahepatic Intestinal Tube Due to Expansion of the *Cdx1b* and *Pdx1* Expression.

C. Gao, W. Huang, **Y. Gao**; Zhejiang University, hangzhou, CHINA.

The hepatopancreatic duct (HPD) system links the liver and pancreas to the intestinal tube and is composed of the extrahepatic biliary duct, gallbladder and pancreatic duct. Haematopoietically-expressed-homeobox (Hhex) protein plays an essential role in the establishment of HPD, however, the molecular mechanism remains elusive. Here we show that zebrafish *hhex*-null mutants fail to develop the HPD system characterized by lacking the biliary marker an nexin A4 and the HPD marker *sox9b*. The hepatobiliary duct part of the mutant HPD system is replaced by an intrahepatic intestinal tube characterized by expressing the intestinal marker fatty-acid-binding-protein 2a (*fabp2a*). Cell lineage analysis showed that this intrahepatic intestinal tube is not originated from hepatocytes or cholangiocytes. Further analysis revealed that *cdx1b* and *pdx1* were expressed ectopically in the intrahepatic intestinal tube and knockdown of *cdx1b* and *pdx1* restored the expression of *sox9b* in the mutant. Chromatin-immunoprecipitation analysis shows that Hhex binds to the promoters of *pdx1* and *cdx1b* genes to repress their expression. We therefore propose that Hhex, Cdx1b, Pdx1 and Sox9b form a genetic network governing the patterning and morphogenesis of the HPD and digestive tract systems in zebrafish.

Lysosome Rich Enterocytes (LREs) Mediate Protein Absorption in the Vertebrate Gut.

J. Park[1], D. S. Levic[1], K. D. Sumigray[1], J. Bagwell[1], O. Eroglu[1], C. Block[1], C. Eroglu[1], R. Barry[2], C. R. Lickwar[1], J. F. Rawls[1], S. A. Watts[2], T. Lechler[1], M. Bagnat[1]; [1]Duke University, Durham, NC, [2]University of Alabama at Birmingham, Birmingham, AL.

The guts of neonatal mammals and stomachless fish have a limited capacity for luminal protein digestion, which allows oral acquisition of antibodies and antigens. However, how dietary protein is absorbed during critical developmental stages when the gut is still immature is unknown. Here, we show that specialized intestinal cells, which we call lysosome-rich enterocytes (LREs), internalize dietary protein via receptor-mediated and fluid-phase endocytosis for intracellular digestion and trans-cellular transport. We identify a conserved endocytic machinery in LREs, composed of the scavenger receptor complex Cubilin/Amnionless and Dab2, that is required for protein uptake by LREs and for growth and survival of larval zebrafish. Moreover, impairing LRE function in suckling mice, via conditional deletion of Dab2, leads to stunted growth and severe protein malnutrition reminiscent of kwashiorkor, a devastating human malnutrition syndrome. These findings identify digestive functions and conserved molecular mechanisms in LREs that are crucial for vertebrate growth and survival.

Nitric Oxide Signaling in Regulation of Normal Heart Loop Morphology.

A. Pereira, W. Denetclaw, PhD.; San Francisco State University, San Francisco, CA.

Asymmetric elevation Ca2+ signaling at the left side of the Hensen’s node in early embryo development is essential for normal right side heart looping and consequently normal heart development. As in all vertebrates, the first organ to develop is the heart and an early indicator of a properly forming heart is a

dextral C-shaped heart loop. In the chicken embryo cardiogenesis begins in bilateral heart fields within the splanchnic mesoderm closely associated with the endoderm. Both are created by the migration of cardiac progenitors from the anterior third region of the primitive streak at gastrulation (HH3-4 stage embryos).The progenitors migrate lateral and anterior in the cranial mesoderm to be in parallel with the embryo midline and slightly anterior to Hensen's node.There an oblong region of cardiac progenitors is formed creating the bilateral heart fields which consist of the first heart fields(FHF) and secondary heart fields (SHF). Endocardial tubes then form showing cellular cardiac differentiation and progression of the nascent heart that forms in an anterior-posterior axis in the embryo as a heart tube at HH10 stage embryo and loops at HH13-15. When calcium levels are elevated on the right side or blocked on the left side of Hensen's Node, both result in 30% of embryos with situs inversus (reversal of the heart loop). Nitric oxide (NO) formation also depends on elevation of calcium and can promote cardiomyocyte proliferation. However the role of Nitric Oxide (NO) in regulation of heart looping is unknown. Our objective for this study was to investigate NO signaling effects on early heart tube looping as a regulated process of morphogenesis in the chicken embryo. We hypothesized NO involvement in cardiac looping may be by its ability to regulate cardiomyocyte proliferation and under absence of NO may cause a looping defect due to absence of sufficient cardiogenic cells. To investigate, an acrylic bead soaked in L-NAME, a competitive inhibitor of nitric oxide synthase(NOS), or DETA-NONATE, an NO donor, was placed to the right side of Hensen's Node to block or elevate NO signaling. Our findings show 80% abnormal heart tube formation with situs ambiguous, a range of morphological heart looping defects, when NO signaling is disrupted. These results suggests that the calcium elevation on the right side functions in the activation of NOS for NO production and signaling, possibly by its canonical pathway, to regulate in the normal heart loop. NO signaling in early embryo development is not well understood and it's role in cardiomyocyte proliferation may also need to be studied to fully understand cardiogenesis. NSF DBI-1548297

Single Cell Dynamics Driving Vertebrate Heart Valve Interstitial Layer Morphogenesis.

F. Gunawan, A. Gentile, S. Gauvrit, D. Stainier, A. Bensimon-Brito; Max Planck Institute for Heart and Lung Research, Bad Nauheim, GERMANY.

Heart valves are critical structures that close the cardiac lumen to prevent retrograde blood flow. Within the valve, specialized cells called valve interstitial cells (VICs) secrete extracellular matrix (ECM) that confers biomechanical strength to withstand blood flow. Considering that many hereditary congenital heart valve defects in humans arise due to aberrant VIC formation, it is crucial to better understand the mechanisms driving this process. As VICs arise later in development, the in *vivo* dynamics that drive their morphogenesis have not been studied in live animals or at single cell resolution. Using the zebrafish atrioventricular (AV) heart valve, we provide the first detailed analysis of the cellular processes that lead to the establishment of the VIC layer. Initially, a group of endocardial cells (ECs) at the AV canal collectively migrate to establish pre-valvular leaflets at the embryonic stage. Some of these cells then undergo endothelial-to-mesenchymal transition (EMT) and invade the space between two EC monolayers to become the first VICs. Lineage tracing shows that VIC establishment also comprises a smaller contribution from neural crest cells, which persist throughout development. Mature VIC establishment further includes a peak of cell proliferation at the juvenile stage, and a progression of ECM components from a pro-migratory to an elastic profile. Furthermore, the molecular regulation of VIC establishment has been poorly understood. We establish and analyze the first zebrafish model with

defective VIC development: mutations in the gene encoding the NFκB-related transcription factor Nfatc1 lead to significantly fewer VICs, causing valve malformations and retrograde blood flow. *nfatc1* mutants exhibit reduced VIC invasion and proliferation, as well as defects in ECM deposition. Interestingly, similar to symptoms in patients with heart valve defects, *nfatc1* mutants can survive to adulthood, but display severe morphological and functional cardiac defects. We found that Nfatc1 functions at least in part by regulating the expression of one of the EMT-promoting factors, Twist1, suggesting a complex transcriptional network that drives VIC invasion. In summary, our study uncovers the single cell dynamics and molecular signatures underlying VIC morphogenesis. With this unique animal model, we propose to determine the gene regulatory networks that mediate the invasive and proliferative behaviours of VICs.

Evaluation of Regeneration After Cauterization as a Model for Cardiac Injury in Adult Zebrafish.

I. C. VÁSQUEZ[1,2], L. L. Delgado-Murillo[1], M. J. Fernández-Sanchez[2], Z. V. Garavito-Aguilar[1];
[1]Developmental Biology Laboratory - BIOLDES. Department of Biological Science. Universidad de los an des, Bogota D.C., COLOMBIA, [2]Department of Physiological Science – School of Medicine. Pontificia Universidad Javeriana, Bogota D.C., COLOMBIA.

Using the zebrafish with total regenerative capacity, we seek to standardize and describe the process of cardiac regeneration after cauterization. This kind of injury may replicate better the ischemic event that happens in humans. Thus, we describe the process of cardiac regeneration, as well as the electrocardiographic characteristics of zebrafish (*Danio rerio*) in a period of 90 days after cauterization injury (pc). The process is recorded after performing the cauterization injury on day 7, 15, 30 and 60 pc with the corresponding sham controls. At the described times, 5 animals per group are randomly selected for euthanasia and the hearts are preserved. These are evaluated through Masson-Goldner trichrome staining to describe tissue architecture and histopathological features. To evaluate the number of proliferating cardiomyocytes, phosphohistone 3, AuroraB, Phalloidin and cardiac troponine T inmunofluorescence is performed. In order to evaluate function, the electrical activity of the heart is determined for the injured as well as for the control groups on the same times postinjury. At the end point (90 days pc), these animals are also processed for histopathological and immunofluorescense analysis. Preliminary results suggest the loss of ventricular tissue architecture with necrotic regions, fibrotic deposits, and intense inflammatory response according to trichromic staining during the first 15 days after injury. At later times, 30 dpi, the necrotic and fibrotic tissue appear to be replaced, starting the restauration of the original structure. Previous works have shown delayed in the QT segment after injury. However, it has not been determined after cauterization. We expect that electrical function returns to baseline by 90 days pc. Similarly, we expect immunofluorescence shows re-entry into the cell cycle and mitosis of numerous cardiomyocytes not only in the margin of the lesion but in areas distant from it. Our work characterizes the cauterization injury, which has not been fully described previously for zebrafish. We consider, this model can give us a better approach to conditions of a cardiac ischemic event. Thus, bringing new elements to the knowledge of cardiac regeneration and translational research in search of new therapeutic approaches.

The Titin Lifecycle: Sarcomere Dynamics and the Spatial Organization of Protein Turnover.

J. Hüttemeister[1], F. Rudolph[1], K. da Silva Lopes[1,2], R. Jüttner[1], L. Yu[3], N. Bergmann[1], D. Friedrich[4], S. Preibisch[4], E. Wagner[5,6], S. E. Lehnart[5,6], C. Gregorio[3], M. Gotthardt[1,7]; [1]Max Delbrück Center for Molecular Medicine, Berlin, GERMANY, [2]St. Luke's International University, Graduate School of Public Health, Tokyo, JAPAN, [3]Department of Cellular and Molecular Medicine, University of Arizona, Tucson, AZ, [4]Berlin Institute for Medical Systems Biology, Max Delbrück Center for Molecular Medicine, Berlin, GERMANY, [5]Heart Research Center Göttingen, Cellular Biophysics and Translational Cardiology Section, University Medical Center Göttingen, Göttingen, GERMANY, [6]DZHK (German Centre for Cardiovascular Research), Göttingen, GERMANY, [7]DZHK (German Centre for Cardiovascular Research), Berlin, GERMANY.

The giant striated muscle protein titin determines sarcomere structure and elasticity. It integrates into Z-disc and M-band of the sarcomere and thus forms a continuous filament along the myofiber. Transport and turnover of titin provide a unique challenge to striated muscle cells, based on its size and multiple integration sites. We took a visual approach and followed fluorescently labelled titin in developing and adult myocytes to understand how titin is synthesized, transported, integrated into the sarcomere, released, and degraded. Our titin knockin mice express eGFP fused to titin's M-band region or dsRed attached to the Z-disc region and provide a unique view on titin mobility and turnover in cardiomyocytes and myotubes. We localized protein synthesis to the Z-disc by ribosome staining and titin RNA detection by smFISH and found that a significant amount of titin is not integrated into the sarcomere even in mature cells. Using fluorescent recovery after photobleaching, we documented an active exchange between the soluble pool and the sarcomere lattice. The underlying kinetics differ not only between Z-disc and M-band, but also between individual cells - suggesting intercellular heterogeneity of titin protein expression. Titin is distributed not only along the sarcomere, but also along the complete syncytium after the fusion of skeletal muscle myocytes. Here, we find an unexpected arrangement of titin at the Z-disc in developing skeletal muscle, but not in mature fibers of cardiomyocytes. Understanding the role of titin in sarcomere assembly and -dynamics can help understand heart and skeletal muscle remodeling in development and disease.

P1642/B780

Modeling Human Skeletal Muscle Development and Stem Cell Niche Formation in *Vivo*.

M. Hicks, M. Yang, S. Younesi, H. Xi, A. Pyle; UCLA, Los an geles, CA.

We are interested in using human pluripotent stem cells to generate skeletal muscle progenitor cells (hPSC-SMPCs) for development of cell therapies. My previous work showed that increased myogenic ability resides in the ERBB3+NGFR+ fraction of hPSC-SMPCs. We developed a single cell RNA-Sequencing atlas of human PAX7+ cells across fetal, juvenile and adult which identifies that hPSC-SMPCs align between human fetal weeks 8-12 using diffusion map analysis. PAX7+ muscle cells fulfill different functional needs during myogenic development. Understanding how PAX7+ cells behave across different developmental states is critical to understanding their regenerative potential and to evaluating hPSC-SMPCs. We show that human fetal SMPCs and adult satellite cells (SCs) differ in their ability to make myofibers in *vitro* and in *vivo*; and fetal SMPCs have reduced ability to home to the SC niches of mdx-NSG mice compared to adult SCs upon engraftment. We have shown hPSC-SMPCs engraft to restore new myofibers similar to levels seen in uncultured fetal SMPCs. We also found hPSC-SMPCs fuse to form

hundreds small human-specific only myofibers in *vivo*. PAX7+ hPSC-SMPCs were primarily associated with these regenerating human-only myofibers. We found that human-only myofibers continue to grow over 60 days in *vivo*, and PAX7+ hPSC-SMPC associate under the basal lamina of these emerging myofibers over time. This work demonstrates for the first time that fetal and hPSC-SMPCs can be used as a model to study human myofiber formation and niche occupancy in *vivo*. We further hypothesized that human SMPCs did not efficiently home to mouse SC niches due to competition with mouse Pax7+ SCs. Using mdx-NSG Pax7$^{cre/ERT2}$ RosaDTA mice, we evaluated whether population-specific ablation of mouse Pax7 SCs would improve retention of engrafted human PAX7 cells. We found an increase in human PAX7 cells in mdx-NSG PAX7-DTA mice in human niches but not mouse SC niches. Our work suggests that donor cell niche homing occurs in newly regenerating fibers, and not to empty SC niches of established myofibers. Evaluating human niche formation over time will improve our understanding of how human muscle SC niches develop. This could improve our ability to generate *de novo* human niches and better support human PAX7 cells in *vivo* for cell therapy.

Stim2 Splicing Variant Regulates Chondrogenesis.

A. Lee, K. KIM, Y. Lee, K. Jang, C. Park; UNIST, Ulsan, KOREA, REPUBLIC OF.

Ca^{2+} is a ubiquitous second messenger which plays essential roles in many cellular processes, including cell differentiation. Store-operated Ca^{2+} entry (SOCE), a major calcium regulation mechanism in non-excitable cells, tightly regulates dynamic Ca^{2+} signals. Stromal interaction molecule (STIM) senses ER Ca^{2+} depletion and induces Ca^{2+} influx by activating Orai Ca^{2+} channel located in the plasma membrane. Recently, we reported that STIM2 splicing variant plays a role in myogenesis. However, whether this STIM2 splicing variant is involved in chondrogenic cell differentiation remains elusive. Here, we show that STIM2 splicing variant is essential for chondrogenesis. Reverse transcription-polymerase chain reaction revealed increased expression of SOCE components in differentiating ATDC5 chondrogenic cells. To confirm the role of STIM2 splicing variant in chondrogenesis, we generated STIM2 splicing variant knock-out ATDC5 cell by CRISPR-Cas9 system. The deletion of STIM2 splicing variant showed the altered calcium level and delayed physiological processes such as proliferation, migration, and differentiation. These results provide the evidence that STIM2 splicing variant might play an essential role in chondrogenic ATDC5 cell differentiation. This study improves the understanding of cellular differentiation research, particularly mediated by SOCE.

P1644/B782

The Effects of Changing Serum Conditions on Myotube Formation in C2c12 Cells.

M. Wagner, E. F. Marsico, R. L. Penick, G. R. Walker; Youngstown State University, Youngstown, OH.

C2C12 cells are an immortalized mouse myogenic stem cell line, a model for muscle development. Expression of MyoD, Cdk1, and Titin are good genetic markers for cell cycle, myogenesis and sarcomerogenesis, respectively. This study looks tat the effects of different growth media on myogenesis and gene expression during myogenesis. The various serum-based media used are Dulbeccos's Modified media base media supplemented with, either Fetal Bovine Serum (10% or 1%) or Horse serum Media (10% or 1%). In addition to these undefined media (serum) we also looked at defined media, PC-1 defined media (transferrin, insulin like growth factor. The effects of the different medias on C2C12 cell morphology and the gene expression of cdk1, MyoD and the titin isoforms was

determined. Cells were grown over a 12-day time course study with imaging, media change, and pelleting cells for mRNA isolation. Quantitative rtPCR was carried out to measure expression of specific myogenic genes and correlated to changes in morphology. In addition to the time course study a switch-back experiment was done on days 2 and 8 where the cells were changed from their experimental media back into the control 10% FBS. Images and pelleting of cell was done 2 days post-switch-back. The results shows changing culture conditions leads to alteration in cell morphology and genetic expression in C2C12 cells. Cells will proliferate and grow into normal myoblasts however; differentiation does not normally proceed. Myotubes are observed to differentiate but do not do so in the normal fashion or density. In normal differentiation myotubes are observed in long dense sheets of muscle fibers. During myogenic differentiation there is observed an increase in mitochondrial DNA relative to nuclear DNA. In the switch-back experiments cells in the cultures did not differentiate normally and were at low densities. When switched back into 10% FBS the density increased and myotube development begins to resemble the controls. To confirm that the cells at confluency are no longer in the cell division cycle and have started differentiation, flow cytometry analysis on pre-confluent, confluent, and post-confluent C2C12 cells was done. These results agree with the previous observation of a dramatic decrease in cdk1.

P1645/B783

Human Pulmonary Microvascular Endothelial Cell Metabolism Underpins Sex-dependent Vascular Morphogenesis in Lung Development.

B. Hayward-Piatkovskyi, J. Shirazi, S. C. Pyle, J. P. Gleghorn; University of Delaware, Newark, DE.

Premature male infants are twice as likely to develop bronchopulmonary dysplasia (BPD) compared to females, in part due to deficits in pulmonary angiogenesis, a process critical for lung alveolarization. The molecular mechanisms behind this sex difference are poorly understood. Endothelial cells predominantly use glycolysis to generate energy but switch to fatty acid oxidation (FAO) when undergoing angiogenesis. Peroxisome proliferator-activated receptor gamma (PPARγ) is a transcription factor that is responsible for upregulating FAO. While PPARγ has been studied as a pathway to target in BPD, no studies have looked at the sex-specific expression of PPARγ or the influence sex hormones play in this pathway. Understanding the role that sex plays in PPARγ is critical for the development of treatment regimens in male and female premature infants. In this study, our objective was to determine the influence of sex and sex hormones, estradiol and dihydrotestosterone, on the expression of PPARγ and their influence on cellular metabolism. Human pulmonary microvascular endothelial cells (HPMECs, 18-19 weeks gestation) were routinely cultured and used in experiments from passages 3-6. Six donors (3 male, 3 female) were used to test sex differences. Cells were dosed with physiological levels of dihydrotestosterone (DHT) or 17-β estradiol (E2) to determine the influence of these sex hormones on growth, metabolism, and protein expression. Overall, female neonatal HPMECs grow faster than male cells. Whereas there is a sex-dependent difference in growth, neither DHT nor E2 influenced male or female cell growth. Female HPMECs have a two-fold higher expression of PPARγ compared to male cells under baseline conditions. Further, male HPMECs have a two-fold higher expression of glyceraldehyde 3-phosphate dehydrogenase (GAPDH), an enzyme used in glycolysis. Interestingly, PPARγ levels decrease in a dose-dependent manner in male HPMECs treated with E2, while female HPMEC PPARγ levels remain unchanged. The male HPMEC PPARγ response to E2 is especially important given that circulating E2 levels start to increase exponentially around 20 weeks gestation. Even though male HPMECs have a higher baseline compared to female cells, there is no significant change in male or female global metabolism due to treatment with either E2 or DHT hormones. These data demonstrate the importance

of including the sex and sex hormone status of patients when clinically targeting PPARγ pathways because of these sex-dependent, sex hormone sensitive metabolic elements.

P1646/B784

Imaging Epithelial Cell Biology in Ultrathin AT1 Cells.

V. Hutchison[1], J. Chen[2]; [1]Baylor College of Medicine, Houston, TX, [2]MD an derson Cancer Center, Houston, TX.

The lung epithelium is home to one of the thinnest cells in the mammalian body - alveolar type 1 (AT1) cells. Individual AT1 cells are >10,000 um^2 in surface area but merely 0.1 um thick, approaching the diffraction limit of light microscopy, such that they were unknown before the advent of electron microscopy. Nevertheless, such ultrathin morphology is essential for gases to passively diffuse across into the underlying vasculature. Furthermore, these AT1 cells are active in signaling and have to be mechanically strong to withstand the cyclic breathing motion, requiring their subcellular machinery to function within a confined space and over a large distance, reminiscent of axonal transport in neurons. We have found a key step in AT1 cell thinning is cell junction remodeling and a key transcriptional control element is YAP/TAZ, components of the mechanosensing Hippo pathway. However, it is unclear how the cellular components, such as cytoskeletons, organelles, and junctions, drive and adapt to the unique AT1 cell morphology. We are pursuing this using expansion microscopy and a novel Cre-dependent cell biology reporter mouse that marks 6 cellular components with distinct colors and is also amenable to real-time imaging. Our work is expected to reveal untapped cell biology unique to large, thin cells and also introduce a general approach to bridge our vast knowledge of in *vitro* cell biology to its in *vivo* counterpart.

P1647/B785

Cell Identity and Differentiation in the Embryonic Pulmonary Mesenchyme.

K. Goodwin, J. M. Jaslove, C. M. Nelson; Princeton University, Princeton, NJ.

In most organs, morphogenesis requires cooperation between epithelial and mesenchymal tissues to pattern changes in tissue shape and cell differentiation. Smooth muscle and smooth muscle-like tissues guide morphogenesis of multiple branched epithelia, including those in the lung, mammary gland and prostate. Despite its importance for airway morphogenesis, it remains unclear how spatiotemporally patterned smooth muscle differentiation is achieved during lung development and whether smooth muscle is recruited from a distinct mesenchymal progenitor population. Here, we carried out single-cell (sc) RNA-Seq of *E*11.5 mouse lungs. Computationally clustering mesenchymal cells showed transitions from undifferentiated mesenchyme to mature smooth muscle, but did not reveal a distinct progenitor population. We found instead that the pulmonary mesenchyme is a heterogeneous but ultimately closely related population of cells. Variability among mesenchymal cells is associated with distinct expression profiles of genes related to Wnt signaling. Manipulating Wnt signaling in lung explants impacts the relative abundance of undifferentiated mesenchymal cells and airway smooth muscle. By examining gene expression along reconstructed differentiation trajectories obtained using diffusion analysis of our scRNA-Seq data, we identified gene sets that fluctuate in similar patterns over the course of smooth muscle differentiation. Enrichment analyses of these gene sets revealed signaling pathways that may be implicated at different stages of differentiation. In particular, we find major changes in cytoskeleton and extracellular matrix-related genes, suggesting a role for mechanical signals in

regulating airway smooth muscle differentiation. We are carrying out motif discovery in DNase-hypersensitive regions near these gene sets to identify candidate transcription factors that may control smooth muscle patterning. Our work provides the first single-cell view of embryonic airway smooth muscle differentiation and sheds light on how physical and biochemical signals are interpreted by the mesenchyme to pattern smooth muscle.

***Syd/mapk8ip3* Regulates Hippo Signaling to Control Tissue Growth.**

V. Ahmad, C. Y. Chabu; University of Missouri, Columbia, MO.

How organisms control organ size during development is not fully understood. The MAPK scaffolding protein JNK interacting protein 3 (JIP3) has been implicated in organ size regulation in mammals. The underlying mechanisms remain unclear. Depletion of the JIP3 ortholog Sunday Driver (Syd) in the developing wing significantly reduced adult wing size, consistent with mammalian data. It is known that the evolutionarily conserved JNK and Hippo pathways cooperate to control tissue size across species. In *Drosophila*, localized JNK activity modulates Hippo activity to regulate cell proliferation throughout the developing wing, thus controlling adult wing size. Our mechanistic studies revealed that Syd/JIP3 functions downstream of the JNK-Hippo signal relay. Syd/JIP3 inhibition did not interfere with Hippo transcriptional outputs. Instead, Syd/JIP3 is required for the function of DIAP1. Syd/JIP3 inhibition does not affect DIAP1 transcription but it leads to a decrease in DIAP1 protein. This is accompanied by a corresponding increase in cell death and ultimately leads to smaller adult wings. Furthermore, partial restoration of DIAP1 activity using a stabilized *DIAP1* allele was sufficient to rescue *Syd/Jip3* small wing phenotype. Furthermore, we found that tissue size responses to hippo pathway deregulation are sensitive to Syd/JIP3 dosage. Taken together, we conclude that Syd/JIP3 regulates wing size by controlling DIAP1 protein stability, thereby modulating the cellular response to Hippo size control mechanisms. Considering that Hippo and Syd/JIP3 are conserved in flies and mammals, our findings provide potential mechanistic insights explaining the recent and perplexing link between *jip3* mutations and organ size defects in mammals.

P1649/B787

Morphological Characterization of *Small*, *Dumpy*, and *Long* Phenotypes in *Caenorhabditis Elegans*.

S. Lee; Hanyang University, Seoul, KOREA, REPUBLIC OF.

What determines the size of organism is an intriguing question in animal development, but not fully understood, yet. In *Caenorhabditis elegans*, a large number of genes have been identified that regulate the worm's body size as well as morphology. While many collagen genes are known to directly affect the worm size and morphology by molding curticle, several major pathways including TGF-β, RUNX and calcineurin also largely affect body size by controlling cell size and number. Though the body size of *C. elegans* has been recognized as an obvious developmental phenotype, clear and distinct standards have not been established to indicate a worm's appeared size and shape. In this study, we measured the body lengths, body widths, terminal bulb lengths and head sizes of various mutant worms that have small, dumpy or long phenotypes, and plot the ratios of body length/width and of head size/pharyngeal size. We found that mutant worms showing each phenotype of small, dumpy or long tend to cluster, and certain mutants are out of the cluster, indicating that there is a common feature among mutants showing similar phenotype. These results suggest that small phenotypes are proportionally smaller

overall with mild stoutness and dumpy phenotypes are significantly stouter and have disproportionate head sizes. Accordingly, we reassign new body size phenotype to certain mutants, which were previously reported otherwise.

P1650/B788

Reciprocal Regulation between DBL-1/BMP Signaling and Cuticle Collagen Genes.

U. Madaan[1], L. Faure[2], E. Rezaei[3], A. Chowdhury[4], S. Ahmed[4], M. B. Goodman[3], T. L. Gumienny[2], **C. Savage-Dunn**[1]; [1]Queens College and the Graduate Center, CUNY, Flushing, NY, [2]Texas Woman's University, Denton, TX, [3]Stanford University, Stanford, CA, [4]Queens College, CUNY, Flushing, NY.

Cell differentiation and homeostasis depend on interactions with the cellular environment. In addition to responding to their environments, cells shape them, in part by modulating the extracellular matrix (ECM). Disruption of these interactions results in pathologies such as cancer or fibrosis. Signaling by Transforming Growth Factor-β (TGF-β) family ligands is known to modulate ECM, and TGF-β signaling pathways may respond to matrix stiffness. We have established the nematode *C. elegans* as an in *vivo* model to study the interplay of TGF-β signaling and ECM. *C. elegans* DBL-1, a TGF-β family member related to BMP2/4, is a determinant of body size. We previously showed that DBL-1/BMP signaling determines body size through transcriptional regulation of cuticle collagen genes. The *C. elegans* cuticle is a flexible barrier composed of multiple collagen layers with a lipid-rich epicuticle. We have now obtained evidence of feedback regulation of DBL-1/BMP by collagen genes. Inactivation of DBL-1-regulated cuticle collagen genes reduces DBL-1/BMP signaling, as measured by a Smad activity reporter. Furthermore, depletion of these collagens reduces GFP::DBL-1 fluorescence, and acts unexpectedly at the level of *dbl-1* transcription. We conclude that cuticle, a type of ECM that is functionally analogous to the outermost epidermal barrier in mammalian skin, impinges on DBL-1/BMP expression and signaling. The feedback regulation of DBL-1/BMP signaling by collagens is likely to be contact-independent, due to the physical separation of the cuticle from DBL-1-expressing cells in the ventral nerve cord. We are therefore testing the hypothesis that biomechanical inputs regulate DBL-1/BMP signaling. We used atomic force microscopy (AFM) in intact animals to determine how the structure and mechanics of the cuticle differ in genotypes with cuticle collagen mutations. We analyzed two cuticle collagen mutant backgrounds: *rol-6,* a DBL-1-regulated collagen gene, *and dpy-5,* a control collagen gene. Assuming Derjaguin-Muller-Toporov (DMT) model of elastic contact of the AFM probe tip-sample, the average values of the cuticle stiffness are 0.73 MPa, 0.47 MPa, and 0.56 MPa for wild type, *rol-6*, and *dpy-5*, respectively. Therefore, loss of DBL-1-regulated ROL-6 has a greater effect on cuticle stiffness than loss of DPY-5. We will analyze additional genotypes to determine whether changes in stiffness correlate with changes in DBL-1/BMP signaling. In summary, the DBL-1/BMP pathway provides a unique in *vivo* model to study bidirectional interactions between cell signaling and the ECM in the context of the intact organism. We propose that reciprocal interactions permit robust yet environmentally-responsive control of body size.

A Genetic 'Brain-body Axis' of Morphogenesis: Neurotransmitter Receptors as Key Regulators of *Drosophila* Epithelial Morphogenesis.

N. Kumar, F. Huizar, M. Unger, Q. Wu, D. Soundarrajan, V. Velagala, J. Koren, **J. J. Zartman**; University of Notre Dame, Notre Dame, IN.

Organ development relies on a symphony of signals that are coordinated spatiotemporally. Emerging research has implicated the role of neurotransmitter receptors, belonging to the GPCR superfamily, as possible regulators of pattern formation and morphogenesis. However, how these receptors interact amongst themselves and with other complex signaling pathways to regulate organogenesis is still unknown. To address this gap in knowledge, we performed a systematic RNAi-based screen of GPCRs and G-proteins, combined with deep learning based bio-image analysis tools, to characterize cell autonomous roles of these receptors in *Drosophila* wing growth and morphogenesis. A new deep learning-based bioimage analysis platform automated identification of severe phenotypes within a large set of bio-image data consisting of genetically perturbed *Drosophila melanogaster* wings. The machine learning pipeline identified novel neuropeptide GPCRs as regulators of organ growth and morphogenesis in wing development. Machine learning-driven automated feature extraction generated high dimensional phenotypic signatures for each individual wing that was further used to predict protein-protein interactions verified through existing literature and experimental evidence. RT-qPCR and fluorescent labeled gene expression reporters confirmed the predicted, but previously unreported, expression of the identified neurotransmitter receptors in wing imaginal discs. Further, immunohistochemistry assays demonstrated how one of the identified neurotransmitter receptors, 5-HT1B, promotes growth and cell division during wing growth, and severely impacts pupal wing morphogenesis and vein patterning through dysregulation of MAPK signaling. This work elucidates the molecular mechanisms of how multiple neural GPCRs regulate epithelial morphogenesis.

P1652/B790

Altered Cell Cycle Dynamics Enable Whole Organ Regeneration within a Developmental Time Scale in the *Drosophila* Hindgut.

E. Cohen, D. T. Fox; Duke University School of Medicine, Durham, NC.

Development of individual organs is subject to completion within a given time frame, which is set by systemic cues such as hormonal signals. Within this time frame, specific cells and tissues often need to adapt to challenges such as acute injury and cell loss. Since developmental time constraints can limit an organ's regenerative capacity, some injured tissues such as insect imaginal discs can extend developmental timing to allow for organ regeneration. Comparatively, much less is known about how tissues can regenerate an organ without prolonging development. We recently established that the larval *Drosophila* hindgut undergoes whole organ regeneration following acute injury (Cohen et al., 2018). Here, we report that this regenerative response is time-limited and, unlike other *Drosophila* imaginal tissues, does not delay organismal development following injury. Instead, cells of the hindgut pylorus trigger regenerative cell cycles prior to a pulse of the steroid hormone ecdysone. After injury, there is a "race" between these regenerative cycles and developmental ecdysone signaling. At a fixed point in pupal development, ecdysone opens the chromatin landscape within an enhancer of the *fizzy-related* (fzr) gene. We previously found that expression of *fzr,* which has a conserved role in degradation of mitotic cyclins, causes a loss of regenerative potential in favor of non-regenerative hypertrophic cell

cycles. Our results suggest a direct link between developmental cues and limitation of an organ's regenerative capacity. In investigating the mechanism that accomplishes whole organ regeneration before ecdysone-mediated *fzr* expression, we found that pyloric cell cycle dynamics are altered to allow for additional rounds of mitosis upon injury. Cytokines of the JAK-Stat pathway are responsible for driving these additional regenerative cell cycles. Our work demonstrates that the *Drosophila* hindgut is a genetically tractable model to reveal how rapid regeneration can be accomplished during organ development, and will uncover conserved mechanisms of injury repair. Relevant References: Cohen, E., Allen, S. R., Sawyer, J. K., & Fox, D. T. (2018). Fizzy-Related dictates a cell cycle switch during organ repair and tissue growth responses in the Drosophila hindgut. *eLife*, *7*, e38327.

Can Tualang Or Manuka Honey Prevent the Rate of Development Changes and Malformations Seen After Bisphenol a Exposure in *Xenopus Laevis* (clawed Frog) and *Rana Pipiens* (leopard Frog)?

M. P. Verile, C. M. Mortellaro, L. H. Twersky; Saint Peter's University, Jersey City, NJ.

Bisphenol a (BPA), is a well-known environmental endocrine disruptor (EED) used in common household items. The negative health effects of BPA exposure include increased cancer risk, infertility, and birth defects. The EED properties of BPA are due to its ability to interfere with estrogen and thyroid hormone action; BPA has also been correlated with an increase in oxidative DNA base lesions. Thottumari et al. (2019) showed that BPA, and its common substitutes, BPS and BPF, individually and in combination, caused malformations in the metamorphosis of *Xenopus laevis* (clawed frog). Wisniew (2009) exposed rats to BPA; those exposed to only BPA developed ovarian cysts, those treated with Tualang honey (TH) did not. Research suggests Manuka honey (MH) shares similar protective properties as TH, due to at least partly the activity of one of its components, kaempferol, a flavonoid. This study was conducted to determine if TH and/or MH can prevent and/or reverse BPA-induced malformations. *X. laevis* specimens were incubated or pre-incubated at Nieuwkoop and Faber tailbud stage 25 (Nieuwkoop and Faber, 1994). *Rana pipiens* (leopard frog) specimens were incubated at Gosner stage 15 (Gosner, 1960). Specimens were studied under these conditions: (1) pre-incubated in honey solution prior to BPA solution at the same concentration, (2) incubated in BPA prior to honey solution of the same concentration, (3) incubated in either BPA or honey solution, and (4) incubated in combination of equal parts BPA and honey solution of the same concentrations. Concentrations used were: 3μ;g/ml BPA, 3μ;g/ml TH, 3μ;g/ml MH, 3μ;g/ml of kaempferol, 5μ;g/ml BPA, 5μ;g/ml TH, 5μ;g/ml MH, and 5μ;g/ml kaempferol. Preliminary results indicate differences in mortality, length, rate of development, and BPA-induced malformations. Specimens pre-incubated in BPA then treated with a honey solution presented less severe malformations in the presence of TH and/or MH. Specimens pre-incubated in a kaempferol solution, specimens incubated in a BPA-kaempferol mixture, and specimens pre-incubated in BPA solution prior to kaempferol displayed the lowest rates of mortality and greatest average growth. Such findings indicate that kaempferol has a possible protective property against BPA exposure. Also, an updated review of the medicinal effects of Tualang honey and Manuka honey was done. This research was funded by grants from the TriBeta Biological Research Foundation and the Independent College Fund of NJ.

Dchs1 Regulated Mirna Processing and Its Effects on Valve Endocardium Stabilization.

M. K. Rumph, K. Moore, R. Stairley, D. Fulmer, J. Nair-Menon, A. Kourtidis, R. Norris; Medical University of South Carolina, Charleston, SC.

Mitral valve prolapse (MVP) is one of the most common forms of cardiac valve disease and affects 1 in 40individuals worldwide. MVP can lead to arrhythmias, heart failure, and sudden cardiac death and 1 in 10 patients will require valve surgery. Surgery for MVP is now the fastest growing cardiovascular intervention in the Western world. As such, MVP carries a significant burden of morbidity and mortality. Our lab was the first to identify the cause of non-syndromic MVP using a combination of linkage analyses, as well as exome and capture sequencing to identify loss of function mutations in the cadherin gene, *DCHS1.* Two-hybrid screens were undertaken to further understand Dchs1 function and the RNA binding protein, LIX1L was identified as the only interacting protein. LIX1L binds and promotes miRNA processing through interactions with the microprocessor which is made up of the proteins DROSHA and DGCR8. Expression studies have corroborated this theory as DCHS1, LIX1L, and the microprocessor proteins are expressed in endothelial cells in the mitral valve. Cell culture data shows that a loss of DCHS1 compromises processing of target miRNAs through the microprocessor leading to a significant decrease in pre-miRNA expression. Expression studies have also shown that loss of Dchs1 reduces valve endocardial stability, which may be caused by the loss of miRNAs. These studies illustrate the importance of DCHS1 effects on valve endocardium stabilization in MVP. Uncovering how these changes lead to clinically significant pathology later in life is crucial to the characterization of MVP.

P1655/B793

Cytoneme-mediated Cell-cell Communication Depends on Contact-dependent Synaptic Matchmaking Process Mediated by Receptor-ligand Interactions.

L. Du, **S. Roy**; University of Maryland, College Park, MD.

Cytonemes are actin-based signaling filopodia that are essential for direct cell-cell communication of morphogenetic signaling proteins at the point of cell-cell contact. Although cytonemes are found in both vertebrate and invertebrate tissues and are shown to be involved in most signaling pathways, the mechanistic basis of cytoneme-mediated signaling is still poorly understood. This work uses Drosophilatracheal tissue to address a fundamental question: how cytonemes emanating from the cells might find the right target to establish signaling contacts. Tracheoblast cells of Drosophila larval air-sac primordium, a precursor of adult air-sac, extend long polarized cytonemes containing FGFR to contact a group of FGF expressing cells in the wing imaginal discs and receive FGF directly. By live imaging analyses of the developing larval tissue, we discovered that the FGF-expressing cells also extend actin-based cytonemes containing FGF to reach out to the FGFR-containing ASP cytonemes. Dynamic contacts that the source and recipient cytonemes with each other determine their polarized orientation toward each other. Further investigation revealed that the receptor-ligand interaction is the primary molecular determinant of the dynamic interactions of the signaling cytonemes. We further showed that this mode of communication via signaling contacts leads to a coordinated migration of the source and recipient cells contributing to the branching morphogenesis of the ASP.

P1656/B794

Frizzled 6 Disruption Inhibits Osteoblastic Differentiation Induced by Titanium with Nanotopography through Wnt/β-catenin Signaling Pathway.

A. L. Rosa, R. Abuna, F. S. Oliveira, L. F. Adolpho, R. R. Fernandes, M. M. Beloti; University of Sao Paulo, Ribeirao Preto, BRAZIL.

The wingless-related integration site (Wnt) signaling pathways are involved in cell differentiation and homeostasis of adult tissues, including bone. Our group have shown that a unique nanotopography generated on titanium (Ti) surfaces favors osteoblastic differentiation by modulating integrin and bone morphogenetic protein signaling pathways. However, few studies have addressed the role of Wnt on osteoblast response to nanoscale topographies. As both the canonical Wnt/β-catenin and non-canonical Wnt/Ca^{2+} signaling play key roles in osteoblastic differentiation, here we aimed to investigate the participation Wnt signaling in the higher osteogenic potential of Ti with nanotopography (Ti-Nano) and which pathway, Wnt/β-catenin or Wnt/Ca^{2+}, is more relevant to this process. Ti discs were treated with sulphuric acid/hydrogen peroxide solution to produce Ti-Nano and discs without treatment were used as control (Ti-Control). MC3T3-E1 cells were cultured on both surfaces to evaluate the effect of Ti-Nano on the expression of genes related to canonical Wnt/β-catenin and non-canonical Wnt/Ca^{2+} signaling pathways. Based on real-time PCR data, one of the most intensely modulated genes by Ti-Nano, the Wnt/Ca^{2+} pathway-related frizzled 6 (*Fzd6*), was selected and silenced by CRISPR. Then, we investigated the effect of *Fzd6* disruption on osteoblastic differentiation of cells grown on Ti-Nano and Ti-Control. The experiments were repeated at least twice in triplicate (n=3) and the data were compared by Student's t-test or one-way ANOVA ($p \leq 0.05$). The *Fzd6* disruption inhibited osteoblastic differentiation on both Ti surfaces with a more pronounced effect in cells grown on Ti-Nano during early stages of culture development. The analysis of the expression of calcium-calmodulin-dependent protein kinase II (CaMKII) and β-catenin surprisingly demonstrated that the *Fzd6* silencing reduced the osteoblastic differentiation induced by Ti-Nano by preventing the activation of Wnt/β-catenin signaling pathway, but not of Wnt/Ca^{2+}, the most common pathway triggered by Fzd6 receptor. In conclusion, our results shed lights on the biological function of Fzd6 as a gatekeeper that trigger Wnt/β-catenin signaling pathway and in osteoblasts and contribute to the understanding of the cellular mechanisms regulated by nanotopography during osteoblast differentiation. **Grants:** FAPESP (# 2016/14171-0 and 2016/14711-4), CNPq (# 303464/2016-0) and CAPES.

P1657/B795

Assessing the Utility of the Transcription Factor Creb3l1 as a Potential Osteogenic Target Using Crisp/cas9 Induced Truncations in the Zebrafish Model.

T. J. Nawara, H. R. Thomas, P. E. Vanwinkle, P. P. Stasiak, J. M. Parant, E. S. Sztul; UNIVERSITY OF ALABAMA AT BIRMINGHAM, Birmingham, AL.

CREB3L1 is a helix-loop-helix transcription factor required for bone formation, and CREB3L1$^{-/-}$ mice exhibit bone defects similar to those seen in osteoporosis patients. Understanding the mechanisms that facilitate bone development and maintenance is crucial to identify targets for preventing or treating osteoporosis. CREB3L1, unlike most transcription factors, is synthesized as a trans-membrane protein and inserted into the ER membrane with a luminal C-terminal (CTer) domain and a cytosolic N-terminal transactivation (TA) domain that regulates the transcription of genes crucial for bone homeostasis. However, we lack an understanding of the role the CTer region plays in bone formation. We use the

Zebrafish (*Danio rerio*) to perform a structure/function analysis of CREB3L1 by engineering CRISP/Cas9-mediated truncations in exon 2 (CREB3L1$^{-/-}$ allele encoding the N-terminal 63 amino acids) and exon 9 (CREB3L1$^{TA/TA}$) encoding the N-terminal 374 amino acids that encompasses the entire TA. Bone development was assessed in CREB3L1$^{-/-}$ embryos by Alizarin red and Alcian Blue staining and in adult fish by histological and µCT analysis. CREB3L1$^{-/-}$ embryos and adult fish appear to have normal development, tissue morphogenesis, and bone formation. We are in the process of analyzing the CREB3L1$^{TA/TA}$ allele and its impact on development and bone homeostasis in zebrafish. To gain insight into the behavior of the fragments produced by the two alleles, we accessed the localization and dynamics of the fragments in HeLa cells. We uncovered that the 63 aa fragment aggregates in the cytoplasm, and most likely is dysfunctional. In contrast, the TA fragment is efficiently translocated into the nucleus, suggesting that it is constitutively functional in transcribing genes involved in bone development. Our studies have the potential to define CREB3L1 as a prospective target to prevent or treat osteoporosis.

P1658/B796

Centrosomes Are Essential for the Differentiation of Lung Progenitor Cells during Branching Morphogenesis.

C. Xie, J. Reiter; University of California, San Francisco, San Francisco, CA.

Centrosomes are the major microtubule-organizing centers of animal cells that build mitotic spindles during mitosis and axoneme during ciliation. Here we analyzed the roles of centrosome in rapidly dividing mouse endodermal epithelia using Cre under the control of Shh promoter to delete floxed Cenpj allele, which is essential for centriole biogenesis. Centrosomes and cilia were absent from epithelia of the mutant lung. Mutant lungs were much smaller than controls and were defective in branching after major lobes were formed. Lung branching of Epithelia specific IFT88 knockout was indistinguishable from that of controls, indicating that cilia were dispensable for lung branching morphogenesis. To investigate the cell type compositions, I stained the control and mutant lungs for Sox2 and Sox9. The size of mutant lung and the populations of Sox9+ progenitors expanded along the timeline, while no Sox2+ bronchioles were detected, indicating that mutant lung progenitors can't differentiate into Sox2+ bronchioles. RNAseq showed robust upregulation of p21, while a dramatic reduction of Sox2 in the mutant lung. This is consistent with previous studies that p53-p21 pathway suppressed Sox2 expression. Activation of p53 apoptosis pathway was confirmed by Staining of p53, cleaved Casp3 and TUNEL. To test whether Sox2 is the key factor required for normal lung branching, we deleted Sox2 in lung epithelia using Shh-Cre. Surprisingly, branching of the Sox2 conditional knockout mutant is indistinguishable from that of controls, indicating that Sox2 is dispensable for lung branching at the pseudoglandular stage. Then we tested whether p53 dependent apoptosis suppressed the differentiation of Sox9+ progenitor cells and the branching morphogenesis by knocking out p53 in Cenpj conditional knockout mutant. The branching morphogenesis of the mutant lung was successfully rescued by p53 knockout. This indicates that centrosome loss-induced p53 dependent apoptosis blocked the differentiation of Sox9+ progenitor cells and caused the lung branching defect.

Stem Cells-HSCs

A Role for the Tetraspanin CD82 in Modulating Hematopoietic Stem Cell Quiescence, Activation, and Bone Marrow Niche Localization.

E. Pascetti, M. Floren, C. Saito-Reis, V. Balise, J. Gillette; University of New Mexico, Albuquerque, NM.

Hematopoietic stem and progenitor cells (HSPCs) provide the cellular reservoir that gives rise to the highly varied blood and immune cells required to support the lifespan of an organism. Due to high cellular turnover, the hematopoietic system requires an equilibrium between HSC self-renewal, commitment to differentiation, and maintenance of quiescence states in order to preserve a lifelong blood and immune supply. Moreover, tightly orchestrated control of quiescence, self-renewal and differentiation is critical for sustaining the regenerative needs of the hematopoietic system under stress conditions. While normally maintained in a quiescent state, HSPCs can rapidly activate to proliferate and differentiate in response to acute stresses such as the regenerative challenges stimulated following HSPC transplantation. Emerging evidence from our laboratory and others suggests that the tetraspanin CD82 plays a critical role in the regulation of HSPC quiescence and activation. In the present study, we explore how the bone marrow microenvironment contributes to CD82-mediated HSPC quiescence and activation during homeostasis and stress conditions. CD34+ progenitor-like cell lines with differential CD82 expression were generated and injected into NSG mice to evaluate bone marrow distribution and growth in vivo. While control cells appear to grow in site-specific colonies within the bone marrow, CD82KD cells infiltrate the entire marrow cavity, suggesting an augmented bone marrow localization upon CD82KD. Next, we went on to analyze the CD82KO mice, which our lab has previously shown to have a decrease in the number of long-term HSCs and a disruption in their repopulation potential. Complete blood count measurements of wild type (WT) and CD82KO mice suggest that CD82KO mice have an altered number of white blood cells. Moreover, histochemical analysis of long bones suggests that CD82KO mice display aberrant megakaryocytes. As a measure of stress-induced HSPC activation, serial transplantation studies were completed with isolated WT and CD82KO HSPCs. An alysis of primary and secondary transplants indicates that both WT and CD82KO HSPCs engraft and expand the blood and immune cell populations similarly. Interestingly, at the tertiary transplant, WT HSPCs begin to show normal signs of exhaustion, however, in contrast, CD82KO HSPCs appear to stabilize. At the quaternary transplant, the WT HSPCs continued toward exhaustion, whereas the CD82KO HSPCs display a myeloid-specific cell expansion. These data suggest CD82 regulates HSPC microenvironment interactions. Future studies will be directed at determine the mechanism by which CD82 drives HSPC localization to specific bone marrow sites and how this localization impacts homeostatic and stress-induced expansion.

Syndecan-2: a Novel Marker and Regulator of Hematopoietic Stem Cells.

C. M. Termini, A. Pang, M. Li, V. Y. Chang, L. Zhao, J. P. Chute; University of California, Los an geles, Los an geles, CA.

Hematopoietic stem cells (HSCs) maintain the hematopoietic needs of an individual during their lifetime through the careful balance of self-renewal and differentiation. Syndecans are heparan sulfate proteoglycans which regulate cell adhesion, proliferation, and survival. While Syndecans contribute to neural, muscle, and endothelial stem and progenitor cell maintenance, the role of Syndecans in

regulating HSCs is not well understood. To address this, we isolated primary mouse bone marrow (BM) long-term HSCs ($Lin^-/c\text{-}Kit^+/Sca\text{-}1^+/CD34^-/CD48^-/CD150^+$) and lineage negative ($Lin^-$) hematopoietic progenitor cells to quantify Syndecan gene expression. Mouse BM HSCs express fourteenfold increased levels of *Sdc2* compared to Lin^- cells. These findings are further supported by a tenfold increase in Syndecan-2 surface expression on long-term HSCs compared to Lin^- cells, while we do not find increased Syndecan-1, 3 or 4 surface expression on long-term HSCs compared to Lin^- cells. To evaluate the contribution of Syndecan-2 surface expression to hematopoietic differentiation and HSC self-renewal, we performed competitive HSC transplantation assays using fluorescence activated cell sorting to isolate Syndecan-2^+ or Syndecan-2^- HSCs ($Lin^-/c\text{-}Kit^+/Sca\text{-}1^+/CD34^-$). Mice transplanted with Syndecan-2^+ HSCs exhibit a tenfold increase in multi-lineage (B, T, myeloid, and erythroid cell) hematopoietic reconstitution in the blood and bone marrow in primary and secondary transplants compared to mice transplanted with the identical dose of Syndecan-2^- HSCs or unsorted HSCs. Taken together, these data indicate that Syndecan-2 expression can be utilized to isolate HSCs with increased hematopoietic differentiation potential and self-renewal capacity. To test the functional role of Syndecan-2 in regulating HSCs, we performed competitive transplant assays using *Sdc2*$^{-/-}$ knockout mice and littermate *Sdc2*$^{+/+}$ mice. Mice transplanted with BM cells from *Sdc2*$^{-/-}$ donors display significantly decreased multi-lineage (B, T, myeloid, and erythroid cell) hematopoietic engraftment compared to mice transplanted with the identical dose of BM from *SDC2*$^{+/+}$ donors. These data suggest that Syndecan-2 expression is critical for HSC self-renewal in *vivo*. Mechanistically, we find a significant increase in the proportion of apoptotic *Sdc2*$^{-/-}$ HSCs compared to *Sdc2*$^{+/+}$ HSCs, indicating that Syndecan-2 regulates HSCs by controlling cell survival signaling. Collectively, our results suggest that Syndecan-2 is a novel marker for HSCs and has an essential role in regulating HSC differentiation and self-renewal in *vivo*, which has broad applications to the field of stem cell biology.

P1661/B799

Quiescence/mobilization of Hematopoietic Stem Cells Induced by Polyphenols from Green Tea through APC/EPCR/PAR-1 Axis.

C. O. Torello, E. V. de Paula, R. N. Shiraishi, 13083-878, I. Santos, F. I. Della Via, M. Pissarra, M. A. de Prax, F. M. Roversi, M. L. S. Queiroz, S. T. O. Saad; University of Campinas, Campinas, BRAZIL.

Hematopoietic stem cells (HSC) mobilization is induced by thrombin through coagulation thrombin/PAR-1 axis, and quiescence is maintained across the APC/EPCR/PAR-1 axis. Our goal was to investigate the effect of green tea polyphenols (GT) on thrombin/PAR-1 and APC/EPCR/PAR-1 axis. GT extract (250 mg/kg body weight) was given orally (gavage) once every 7 days to mice (n=6) injected i.p. with 100µg lipopolysaccharide (LPS). Controls received vehicle only. After 24h, mice were euthanized; bone marrow (BM) and peripheral blood (PB) were collected for the assays. LPS was chosen because it induces thrombin release in BM. GT partially prevented the reduced EPCR expression in BM HSC (LSK: $Lin^-Sca^+c\text{-}kit^+$) of LPS-injected mice, but did not affect the increased PAR-1 expression in circulating HSC and mature cells. Evans blue analysis revealed a reduction in the vascular permeability of the BM of LPS-injected mice treated with GT. To address whether GT altered NO production, we assayed NO levels and eNOS phosphorylation in immature LT-HSC (LSK $EPCR^{high}$ cells). NO production is activated by eNOS phosphorylation at Ser1177 and negatively regulated by eNOS phosphorylation at Thr495. GT reduced BM LSK $EPCR^{high}$ percentage with higher intracellular NO induced by LPS and increased eNOS phosphorylation at Thr495 in these cells. In order to evaluate the effect of GT on the functional ability of HSC, we performed a BM competitive repopulation assay. Donor mice (C57BL/6J) received or not GT

followed by LPS injection (groups: GT+LPS and LPS). BM donor cells were transplanted (1:1) into lethally irradiated receptors (B6.SJL-Ptprc^{a}Pepc^{b}/BoyJ) together with BM cells from competitors (B6.SJL-Ptprc^{a}Pepc^{b}/BoyJ). Mice were followed for 16 weeks and hematological analysis revealed no difference in circulating leukocytes, platelets, or hemoglobin levels. A higher percentage of donor cells were found in PB of GT+LPS group compared to LPS. We also observed an increase of circulating T lymphocytes and myeloid cells. After 16 weeks, recipients were euthanized. LSK and LSK EPCR^{high} populations were increased in BM of GT+LPS group compared to LPS, although only LSK EPCR^{high} percentage was statistically different. Taken together, our results demonstrate that GT increased the functional ability of HSC showing increased percentage of bone marrow LSK EPCR^{high} (or LT-HSC), which are the most quiescent stem cells with strong self-renewal ability. Furthermore, GT prevented EPCR expression and NO production induced by LPS in immature cells, displaying an anti-inflammatory effect that leads to the maintenance of barrier integrity and quiescence, which was corroborated by reducing BM vascular permeability. Thus, GT appears to modulate quiescence/mobilization of immature HSC through APC/EPCR/PAR-1 axis.

P1662/B800

Exploring the Role of the Notch Signalling Pathway in Human Haematopoietic Stem and Progenitor Cells.

F. Lampreia[1], A. de Soure[2], J. Carmelo[1], F. An jos-Afonso[1]; [1]European Cancer Stem Cell Research Institute, Cardiff, UNITED KINGDOM, [2]Instituto de Biotecnologia e Bioengenharia, Lisbon, PORTUGAL.

Notch is an evolutionarily conserved signalling pathway with roles in stem cell maintenance, survival and differentiation. While studies in the murine haematopoietic system have proposed different roles for Notch signalling under stress and steady-state conditions, whether this is involved in the regulation of human haematopoietic stem/progenitor cells (HSPCs) has been scarcely explored. Here, we employed not only pharmacological inhibition by using the γ-secretase inhibitor DAPT but most importantly using shRNA-mediated silencing of Notch pathway members to evaluate the potential functions of Notch may have in the regulation of human HSPC biology. Immunodeficient (NSG) mice were transplanted with human CD34^{+}CD38^{-} HSPCs. Six-to-seven weeks later, DAPT or vehicle was administered to different cohorts of animals, and at twelve weeks post-transplantation the bone marrows of the recipients were analysed. Notch inhibition caused a significant reduction in human engraftment in mice and deregulation of most stem (HSC) and progenitor cell fractions. Specifically, the HSC population was reduced by 7-fold when compared to the control cohort. Using limiting cell dose assay in secondary transplantation to evaluate the self-renewal capacity of HSPCs, we observed a 2-fold reduction in the secondary repopulating frequency from HSPCs that had been treated with DAPT. To address whether these effects were caused by cell-autonomous loss of Notch signalling, HSPCs were transduced with shRNAs targeting the *NCSTN* or *RBPJ* genes. *NCSTN* encodes for the protease Nicastrin (a component of the γ-secretase complex), the loss of which blocks the processing of Notch receptors. Silencing *RBPJ* (encoding for Notch co-activator RBPJκ) specifically inhibits canonical Notch signalling. Both the loss of Nicastrin and RBPJκ resulted in a significant loss of primitive cells in *vitro*. Transplanting *NCSTN* or *RBPJ*-silenced HSPCs into NSG mice led to a reduction in human engraftment at 12 weeks. While a 3-fold reduction was observed in the sh*NCSTN* cohort, a dramatic 68-fold decrease in sh*RBPJ*-transplanted animals was noted. In agreement with our previous observations, the HSC compartment was significantly reduced in both conditions when compared to the control cohort. A trending increase in downstream progenitors suggests enforced differentiation from the HSCs compartment. Furthermore,

Notch inhibition led to an overall shift toward myeloid cell differentiation at the expense of the lymphoid fraction - an effect that was specific to RBPJκ loss. Altogether, these results support that blocking Notch signalling impaired human HSCs in *vivo in* a cell-autonomous manner *and* differ from studies that support little role of this pathway in regulating murine HSPCs.

Microtubules Deform the Nucleus and Force Chromatin Reorganization during Early Differentiation of Human Hematopoietic Stem Cells.

S. Biedzinski[1], L. Faivre[2], B. Vianay[1], M. Delord[3], L. Blanchoin[1], J. Larghero[2], S. Brunet[1], **M. Thery**[1]; [1]CytoMorpho Lab, Hopital Saint Louis, Paris, FRANCE, [2]APHP, Hopital Saint Louis, Paris, FRANCE, [3]INSERM, Hopital Saint Louis, Paris, FRANCE.

Hematopoietic Stem Cells (HSC) can differentiate into all hematopoietic lineages in order to support hematopoiesis. Cells from the myeloid and lymphoid lineages fulfill distinct functions with specific shapes and intra-cellular architectures. The role of cytokines in the regulation of HSC differentiation has been intensively studied but our understanding of the potential contribution of inner cell architecture is relatively poor. Here we show that large invaginations are generated by microtubule constrains on the swelling nucleus of human HSCs during early commitment toward the myeloid lineage. These invaginations are associated with chromatin reorganisation, local loss of histone methylation and changes in expression of specific hematopoietic genes. This establishes the role of microtubules in defining the unique lobulated nuclear shape observed in myeloid progenitor cells and suggests that this shape is important to establish the gene expression profile specific to this hematopoietic lineage. It opens new perspectives on the implications of microtubule-generated forces, in the early specification of the myeloid lineage.

The Role of Galectins and *O*-GlcNAc in Regulating Promyelocytic Cell Stemness and Differentiation.

A. V. Timoshenko; University of Western Ontario, London, ON, CANADA.

Cell differentiation is associated with multiple changes in gene and protein expression profiles, and specific post-translational modification of regulatory proteins. Our recent studies with promyelocytic HL-60 stem-like progenitor cells demonstrate that neutrophilic differentiation leads to significant down-regulation of global *O*-GlcNAcylation of intracellular proteins and changes in expression of galectins, soluble beta-galactoside-binding proteins with diverse glycan-dependent and glycan-independent functions outside and inside cells. Molecular mechanisms controlling secretion of galectins remain poorly understood since these proteins do not have an ER-targeting N-terminal signal sequence or hydrophobic segment and therefore use unconventional transport pathways. Bioinformatics analysis reveals that galectins have sites for *O*-GlcNAcylation, which potentially can control protein trafficking and distribution between intracellular compartments. Considering these findings, we elaborate the novel hypothesis that regulatory functions of galectins toward self-renewal and differentiation of promyeloid cells depends on the localization of galectins in cells which is driven by *O*-GlcNAc signaling mechanisms. In particular, we propose that high levels of *O*-GlcNAc promote intracellular accumulation of galectins in stem cells while low levels of *O*-GlcNAc promote galectin secretion and cell differentiation. This concept and results of our on-going experiments will be presented. Supported by NSERC Discovery Grant (RGPIN-2019-06628).

Revealing the Function of the E3 Ubiquitin Ligase Cullin-9 in Neural Stem Cell Differentiation.

N. A. Ortolano[1], P. Joshi[1], C. Bodnya[1], A. I. Romero-Morales[1], B. A. Millis[1,2], K. Rose[3,4], V. Gama[1,5]; [1]Vanderbilt University Department of Cell and Developmental Biology, Nashville, TN, [2]Vanderbilt University Cell Imaging Shared Resource, Nashville, TN, [3]Vanderbilt University Department of Biochemistry, Nashville, TN, [4]Vanderbilt University MSRC Proteomics Core, Nashville, TN, [5]Vanderbilt University Center for Stem Cell Biology, Nashville, TN.

The cullin-ring ligase (CRL) family of E3 ubiquitin ligases plays a critical role in the regulation of early developmental processes, including synapse formation and axon guidance. However, Cullin-9 (CUL9) has proven to be a unique CRL with an elusive function. CRLs generally form large complexes that ubiquitinate a set of specific substrates. CUL9 has not been shown to form large complexes and has only two identified substrates. My data suggest a role for CUL9 in the early neural induction phase of cortical differentiation. CUL9 protein levels are induced during cortical glutamatergic differentiation. Interestingly, differentiation of CUL9 knockout (KO) human pluripotent stem cells (hPSCs) to neural progenitor cells (hNPCs) and early born neurons results in inconstant expression of neural-specific markers. Additionally, CUL9 KO hNPCs form smaller embryoid bodies and neural rosettes with variable lumenal areas. This finding suggests that hNPCs produced from CUL9 depleted hPSCs may have aberrant differentiation potential or self-renewal capacity. We hypothesize that CUL9 may be critical for proper neural rosette formation and subsequent neurogenesis through its regulation of substrates key for neural cell fate. Our main goal is to identify the CUL9 substrates critical for proper neural rosette formation. Previous mass spectrometry analysis of CUL9 immunoprecipitation from hPSCs and hNPCs have identified the cell cycle regulator the anaphase-promoting complex/cyclosome (APC/C) as a potential negative regulator of CUL9 in hPSCs. We are currently performing a quantitative proteomics screen using Isobaric Tags for Relative and Absolute Quantification (iTRAQ) in hPSC, hNPC and cortical neuron CUL9 KO cells to identify proteins enriched in the absence of CUL9. Proteins identified by iTRAQ will be screened as potential CUL9 substrates. I anticipate that elucidating the function of CUL9 in neural induction will provide key insight into the underlying mechanisms linking ubiquitin-mediated regulation in control of neural cell fate, neural rosette formation, and cortical differentiation, setting a framework for studying CUL9's potential involvement in neurodevelopmental disorders.

P1666/B804

Dynamics and Lineage Fate of Proteolipid Protein (plp) Promoter-expressing Cells in the Central Nervous System.

S. I. Guo, 95817[1,2,3], A. Wang, 95817[1,2], Y. Wang, 95817[1,2]; [1]Shriners Hospitals for Children, Northern California, Sacramento, CA, [2]Department of Neurology, School of Medicine, UC Davis, Sacramento, CA, [3]Mira Loma High School, 4000 Edison Ave, Sacramento, CA.

The proteolipid protein (PLP) is the most abundant protein in the myelin sheath and the Plp gene is highly expressed in oligodendrocytes that form myelin in the central nervous system. Previous studies suggest that Plp gene is expressed in neural progenitors cells much earlier prior to the generation of oligodendrocytes. However, the identity and the fate of Plp promoter-expressing cells are still elusive. We used genetic approaches to permanently label Plp promoter-expressing cells with the reporter gene

enhanced yellow fluorescence protein (EYFP) and employed multi-colored immunohistochemistry to characterize their identity and their lineage fate. We found that Plp promoter-expressing cells were distributed evenly in the embryonic spinal cord and gradually restricted to the ventral domains in the embryonic spinal cord. We showed that, during early neural development stages, Plp promoter-expressing cells were multi-potent neural progenitor cells that gave rise to not only neurons but also glial cells whereas Plp promoter-expressing cells during the late neural development stages only gave rise to glial cells including astrocytes, oligodendrocytes, and ependymal cells. Intriguingly, astrocytes generated from Plp promoter-expressing cells were located only in the ventral spinal cord. Taken together, our study reveals that Plp promoter-expressing cells display a dynamic distribution during neural development and have a broader lineage fate during neural development than oligodendroglial lineage.

P1667/B805

Profiling Genes Regulated by the Neural Crest-Essential Lysine Methyltransferase NSD3 in the Premigratory Neural Crest.

B. T. Jacques-Fricke[1], J. Roffers-Agarwal[2], L. S. Gammill[2]; [1]Hamline University, Saint Paul, MN, [2]University of Minnesota, Minneapolis, MN.

The neural crest is a transient, stem cell-like population in vertebrate embryos that migrate extensively during development and form a variety of derivatives, including craniofacial skeleton, melanocytes, and the majority of the peripheral nervous system. In our previous work, we identified NSD3 as the first lysine methyltransferase required for proper neural crest specification and migration. While we demonstrated that NSD3 is essential for expression of several key neural crest transcription factors, the extent of gene expression regulated by NSD3 was unknown. To identify NSD3-dependent changes in the transcriptome of premigratory neural crest cells, we performed RNA-seq analysis of dorsal neural tubes isolated from chick embryos electroporated with NSD3 or mismatch control morpholinos. We identified 769 genes with significant changes in expression levels when comparing NSD3 knockdown and mismatch control samples. Using gene ontology analysis, we found groupings of downregulated genes involved in neurogenesis, neuronal differentiation and regulation of cell differentiation, while genes involved in RNA processing and ribosome biogenesis were upregulated when NSD3 was knocked down. To verify the RNA-seq expression level changes, we performed in situ hybridization for select genes of interest in chick embryos electroporated with NSD3 or mismatch control morpholinos. For example, when NSD3 was knocked down in neural folds, we confirmed that the adhesion molecule *astrotactin 1* was downregulated, while the actin binding molecule *tropomyosin 1* was upregulated. From this work, we have identified a collection of putative targets of NSD3 function and potential novel regulators of neural crest development that will be the focus of future studies.

The Role of Sox11 during Development and Disease: Insights from Coffin Siris Syndrome.

P. Silva Rodriguez, E. Silva; Georgetown University, Washington, DC, DC.

The development of the complex vertebrate central nervous system (CNS) is tightly regulated to ensure correct temporal and spatial formation of neurons and glia. Progression from neural stem cell to neuron is controlled by the sequential expression of a hierarchy of transcription factors and Sox11, a member of the large Sox HMG transcription factor family is essential in this process. *Sox11* has been shown to play

roles in neuronal differentiation and maturation in a variety of vertebrates. Additionally, our studies in *X. laevis* demonstrate that Sox11 is also involved in the promotion or maintenance of neural stem cells. Studies that examine the loss of Sox11 function demonstrate that it is required for CNS development and mutations in the HMG domain of Sox11 are associated with Coffin Siris Syndrome (CSS). CSS patients have microcephaly associated with reduced cortical tissue and **our results show that these mutations lead to altered CNS development in frog. To** determine how Sox11 plays all these different roles, we identified Sox11 targets during neural cell fate specification (blastula stage) and later at the onset of neurogenesis (mid-gastrula stage). **Our RNA-Seq data confirms that Sox11 is involved early in neural specification and later in development in neural differentiation.** Since Sox11 specificity is determined by protein interactions, we will identify novel partner proteins and Sox11 consensus binding elements, to test the hypothesis that Sox11 is regulating different downstream targets at different times in neural development due to its interaction with different pools of protein partners. With these partners, we will test whether altered partner protein interactions are the cause of the CSS-related phenotype.

Notch-mediated Polarity Decisions in Lateral Line Hair Cells.

A. Jacobo, A. Dasgupta, A. Erzberger, K. Siletti, A. Hudspeth; Rockefeller University, New York, NY.

The development of mechanosensory epithelia, such as those of the auditory and vestibular systems, results in the precise orientation of mechanosensory hair cells and consequently directional sensitivity. After division of a precursor cell in the zebrafish's lateral line, the daughter hair cells differentiate with opposite mechanical sensitivity. This process produces neuromasts containing equal numbers of hair cells of two opposite polarities, half of them sensitive to caudad water movement and half to rostrad flow. Through a combination of theoretical and experimental approaches, we show that Notch1a-mediated lateral inhibition produces a bistable switch that reliably gives rise to hair cell pairs of opposite polarity. Using our mathematical model of the process, we predict the outcome of several genetic and chemical alterations to the system, which we then confirm experimentally. Following the predictions of our model, we are able to alter the ratio of rostrad to caudad cells in the neuromast by titrating the concentration of different inhibitors of the Notch pathway. We confirm these results by generating a transgenic fish line that constitutively expresses the Notch intracellular domain in hair cells, and also by analyzing Notch1a mutant fish. We then show that Notch1a downregulates the expression of Emx2, a transcription factor known to be involved in polarity specification, and acts in parallel with the planar-cell-polarity system to determine the orientation of hair bundles. By analyzing the effect of simultaneous genetic perturbations to Notch1a and Emx2 we infer that the gene-regulatory network determining cell polarity includes undiscovered polarity effectors.

Doublesex-F as a Novel Cofactor of Abdominal-B in Promoting Female Specific Apoptosis in *Drosophila* Central Nervous System.

N. Ghosh, 500039; Centre for DNA Fingerprinting and Diagnostics, HYDERABAD, INDIA.

Highly conserved DM domain containing transcription factors (Doublesex/MAB-3/DMRT1) are responsible for generating sexually dimorphic features. In *Drosophila* CNS a set of Doublesex (Dsx) expressing neuroblasts undergo apoptosis in females while their male counterparts proliferate and give

rise to serotonergic neurons crucial for adult mating behaviour. Our study demonstrates that female specific isoform of Doublesex collaborates with Hox gene Abdominal-B (AbdB) to bring about this apoptosis. Biochemical results suggest AbdB and Dsx interact through their highly conserved Homeodomain and DM domains respectively. This interaction is translated into a cooperative binding of the two proteins (AbdB and Dsx) on the apoptotic enhancer in case of females but not in case of males, resulting in female specific activation of apoptotic genes. The capacity of AbdB to utilize sex specific isoform of Dsx as a cofactor underlines the possibility that two classes of proteins are capable of cooperating in selection and regulation of target genes in tissue and sex specific manner. We propose that this interaction could be a common theme in generating sexual dimorphism in different tissues across different species.

P1671/B809

Mutations in the Cholesterol Synthesis Pathway Reveal Independent Functions for Cholesterol and Isoprenoids during Erythropoiesis.

J. A. Hernandez, V. L. Castro, A. M. Quintana; University of Texas at El Paso, El Paso, TX.

Erythropoiesis is a tightly regulated and conserved process by which new red blood cells (RBCs) are produced. Defects in erythropoiesis lead to human disorders such as anemia and acute megakaryocytic leukemia. Erythropoiesis is divided into two distinct waves, producing primitive or definitive RBCs. Several essential players that drive erythropoiesis, including the transcription factors GATA1 and FOG, have been previously characterized. We demonstrated previously that the cholesterol synthesis pathway (CSP) is a regulator of erythropoiesis. However, the mechanisms underlying such phenotypes have not been completely elucidated. Therefore, the goal of this study is to determine the mechanism by which CSP regulates RBC differentiation during primitive erythropoiesis. Using a zebrafish transgenic line harboring a mutation in the *hmgcs1* gene, which encodes the enzyme above the rate-limiting step of the CSP, we analyzed RBC differentiation and total number of RBCs. Our results show that mutations in *hmgcs1* led to a decrease of mature RBCs. Further analysis revealed decreased expression of GATA1. Mutations in *hmgcs1* lead to an inhibition of cholesterol and isoprenoid synthesis. Therefore, we used pharmaceutical inhibition to block the synthesis of each individual product. Using this approach, we demonstrate that both cholesterol and isoprenoids regulate RBC development, albeit by distinct cellular mechanisms. Taken together, these results provide evidence of two new upstream regulators of primitive erythropoiesis.

P1672/B810

Interactome an alysis to Study the Molecular Mechanism of Heparin-induced Cardiomyocyte Differentiation.

G. Chen, R. Zhili, Y. Meng, W. Liu; University of Macau, Macau, MACAO.

Human embryonic stem cells (hESCs) are a powerful model to understand the molecular mechanisms involved in human embryogenesis. Heparin and albumin are common cell culture components, and they are widely used in various cell type-specific differentiation from hESCs. However, their molecular mechanisms in differentiation are often unclear, because it is difficult to identify the functional target among their numerous binding partners. Both heparin and albumin positively promote cardiomyocyte differentiation, and heparin can even generate cardiomyocytes in the absence of WNT inhibitors. Through interactome analysis, we identified a set of binding or functional partners shared by albumin

and heparin from hundreds of candidates. Further analysis identified novel target proteins involved in cardiomyocyte determination. This study highlights interactome analysis as an effective method to study the molecular mechanisms of complicated proteins, and we also revealed new mechanisms involved in cardiomyocyte differentiation.

P1673/B811

Osteogenic Effect of Bmp-9 on Bone Marrow and Adipose Tissue Mesenchymal Stem Cells.

H. B. Lopes, G. P. Freitas, A. T. P. Souza, M. P. O. Gomes, J. Lima, M. M. Beloti, **A. L. Rosa**; University of Sao Paulo, Ribeirão Preto, BRAZIL.

The cell therapy for bone repair using mesenchymal stem cells (MSC) from bone marrow (BMMSC) or adipose tissue (ATMSC), at least in part, relies on their osteoblast differentiation that can be stimulated by bone morphogenetic proteins (BMP). Within the BMP family, BMP-9 could be a good choice thanks to its high osteogenic potential. The aim of this study was to evaluate the dose-dependent effect of BMP-9 on osteoblast differentiation of BMMSC and ATMSC. Rat BMMSC harvested from femurs and ATMSC harvested from inguinal adipose tissue were cultured under non-osteogenic condition. The media was not supplemented with BMP-9 (Control-C) or supplemented with 25, 50 or 100 ng/mL of BMP-9. The gene expression of the bone markers *Runx2*, alkaline phosphatase (*Alp*) and osteocalcin (*Oc*), and ALP activity were evaluated on day 7 and the mineralized matrix deposition, on day 17. Data were compared by one-way ANOVA and Tukey's test ($p \leq 0.05$). The expression of all evaluated genes was increased by BMP-9 in both BMMSC (*Runx2:* C=50<25<100; *Alp*: C<25<50<100; *Oc*: C=25=50<100) and ATMSC (Runx2: C<50<25=100; *Alp*: C<25<50<100; *Oc*: C<25=50=100) as well as ALP activity BMMSC (C=25=50<100) and ATMSC (C=25<50=100). The mineralized matrix deposition was not affected by BMP-9 in BMMSC but it was increased in ATMSC (C<25=50=100). Despite of not having a dose-dependent effect, BMP-9 showed osteogenic potential and it seems that the more pronounced effects were reached by 100ng/mL. Altogether, these results show that even under non-osteogenic condition BMP-9 was capable of differentiating MSC into osteoblasts and therefore could be useful in MSC-based therapy to regenerate bone tissue.

P1674/B812

Differential Role of Histone Deacetylases in the Differentiation of Chick Embryo Wing Bud Mesenchymal Cells.

J. Kim, **J. Sonn**; Kyungpook National University, Daegu, KOREA, REPUBLIC OF.

Endochondral bone formation is a complex developmental process involving the differentiation of mesenchymal cells to osteoblasts and well regulated by varieties of factors. Histone deacetylase (HDAC) has been known to be implicated in the differentiation of mesenchymal cells. In this study, we aimed to identify the HDACs and their substrates that are involved in the different stage of differentiation of mesenchymal cells in micromass culture. Pan-HDAC inhibitor trichostatin a (TSA) and class I HDAC inhibitor UF010 suppressed chondrogenesis evidenced by PNA staining, Alcian blue staining, and western blot assay for the expression of type II collagen whereas HDAC4/5 inhibitor LMK-235 and HDAC6 inhibitor showed weaker or little effect on chondrogenesis. While TSA and UF010 significantly enhanced acetylation of histone H3 and TSA, LMK-235, and HDAC6 inhibitor increased acetylation of Runx2. In addition, inhibition of chondrogenesis and cell aggregation by TSA and UF010 was most effective when they were treated for the first two days of culture. Presence of LMK-235 and HDAC6

inhibitor for 10 days promoted osteoblast differentiation evidenced by Alizarin red staining and osteopontin expression. LMK-235 and HDAC6 inhibitor also increased acetylation of Runx2 in day 10 cultured cells. However, they did not affect cell aggregation. The present study show that class I and class II HDACs deacetylate histone H3 and Runx2, respectively and suggest that they play different roles in the differentiation of mesenchymal cells.

P1675/B813

Molecular Characterisation of an Epigenetic Regulatory Circuit Comprising Smad 3 and Ezh2 in an Ipsc-derived Model of Retinal Degeneration.

C. Kennedy, D. An drews, J. Davis, G. Oliviero, G. Cagney, J. Crean; University College Dublin, Dublin, IRELAND.

Cell fate decisions underpin lineage specification during development and cell differentiation in disease, yet these decisions remain a relatively poorly understood area of cell biology. A core regulator of these events is the Polycomb Repressive Complex 2 (PRC2), which di- and tri-methylates histone 3 at lysine 27 to regulate gene transcription and chromatin organisation, yet little is known about how PRC2 is guided to target specific areas of the genome. Previously in our lab, we identified a functional interaction between Smad3 and EzH2, the catalytic component of PRC2, in multiple cellular contexts. Here we explore this interaction using an induced pluripotent stem cell (IPSC)-derived Retinal Pigmented Epithelium (IRPE) model of TGF-β induced cell fate transition. WTSIi028-A IPSCs, obtained from the European Bank for induced pluripotent Stem Cells, were directed to RPE over 14 days by treatment with combinations of growth factors and small molecule inhibitors including Nicotinamide, Noggin, Dkk-1, IGF-1, bFGF, Activin A, SU5402 and CHIR99021. iRPEs were characterised by RT-PCR and immunocytochemistry for the expression of retinal specific markers. Cell differentiation was induced by treatment with TGF-β 2 for 7 days. RNA-seq was then performed on the BGISEQ platform. Cells were also treated with drugs targeting both TGF-β signalling (SB43152) and EzH2 (GSK343, DzNEP) during this differentiation to further inform signalling events during this process. An alysis of the RNAseq data showed that upon TGF-β treatment, these cells activated a program of extracellular matrix remodelling, promotion of angiogenesis and complement activation, resulting in upregulation of genes such as IGF1, MFAP4, TGFβ1, ECM1 and C1QL1 and downregulation of genes such as CLDN2, AIPL1 and CD46. Further interrogation of the differentially expressed genes with the ENCODE-BROAD institute EzH2 CHIP-Seq dataset in H1 embryonic stem cells (ESCs)(GSM831028) found enrichment of genes with EzH2-bound promotors in ESCs in the set of genes repressed in our cells in response to TGF-β when compared with the upregulated genes. Pharmacological inhibition of EzH2 activity also appears to mitigate some of these TGF-β-induced changes in these cells. The data presented here shows a clear link between TGF-β /Smad3 signalling and EzH2 mediated gene repression in the TGF-β -induced differentiation of iRPE cells which may lead to an exploitable target in certain forms of retinal degeneration.

P1676/B814

TGFβ Signals to Chromatin Via Complexing Interaction of Smad3 with the Polycomb Repressive Complex during the Determination of Renal Epithelial Fate.

J. L. Davis[1], T. K. Dodd[1], S. Clerkin[1], N. Treacy[1], D. An drews[2], A. Hoban[3], J. Crean[1]; [1]Diabetic Complications Research Center, School of Biomolecular and Biomedical Science, UCD Conway Institute, Dublin, IRELAND, [2]Diabetic Complications Research Center, School of Medicine, UCD Conway Institute, Dublin, IRELAND, [3]School of Biomolecular and Biomedical Science, UCD Conway Institute, Dublin, IRELAND.

Critical pathological features of diabetic nephropathy are now accepted to include dysregulation of epigenetic processes as evidenced by the observed differential methylation in patients with or without progressive disease. TGFβ resides at the centre of therapeutic approaches for the treatment of renal fibrosis, but few intervention studies have demonstrated clinical efficacy. We recently demonstrated a novel direct interaction between Smad3 and EZH2, the enzymatic component of the polycomb repressive complex 2 (PRC2) during cell fate specification. Targeting the interaction between Smad3 and EZH2 in iPSC derived renal organoids protected against TGFβ mediated tubular epithelial dedifferentiation. Here, we delineate the molecular mechanism underlying this interaction. We have performed ChIP-seq using validated antibodies for Smad3 and EZH2 at specific time points during the derivation of $Six2^{+ve}$nephron progenitors, from iPSCs following the ENCODE Consortium guidelines with optimisation on the Illumina HiSeq platform. Using this genome wide approach, we identified a number of regions throughout the genome that are co-occupied by Smad3 and EZH2 in both undifferentiated iPSCs and during in *vitro* nephrogenesis; ~69% of Smad3 peaks overlapped with EZH2 bound regions in iPSCs and ~32% in the $Six2^{+ve}$nephron progenitor population. Perhaps most significantly, *de novo* motif analysis identified enrichment of the GAGA motif at sites co-occupied by Smad3 and EZH2. This motif was first identified as a Polycomb Response Element (PRE) in Drosophila Melanogaster and subsequently as a region enriched for Mothers Against Decapentaplegic (MAD), the drosophila homolog of mammalian Smads. To the best of our knowledge this is the first description of an analogous PRE in vertebrates. As predicted from our in *silico* analysis, Smad3 and EZH2 were almost exclusively identified at enhancers and superenhancers. An alysis of putative superenhancer target genes by real-time PCR indicated a TGFβ dependent downregulation suggesting a novel mechanism of gene repression during both development and disease. We propose that this complex forms a molecular switch that regulates enhancer and/or promoter access through epigenetic mechanisms and controls gene silencing, informing the fundamental mechanisms through which subsets of genes are switched on and off during fate specification and during the pathogenesis of diabetic nephropathy.

P1677/B815

Growth and Differentiation of Induced Pluripotent Stem Cell-Derived Kidney Organoids Using Fully Synthetic Peptide Hydrogels.

S. Clerkin[1], N. Treacy[1], J. Davis[1], T. Dodd[1], K. Singh[2], J. Wychowaniec[2], D. Brougham[2], J. Crean[1]; [1]Diabetes Complications Research Centre, School of Biomolecular and Biomedical Science, UCD Conway Institute, Dublin, IRELAND, [2]UCD School of Chemistry, Dublin, IRELAND.

Induced pluripotent stem cell (iPSC)-derived kidney organoids have been shown to closely recapitulate fundamental tissue developmental processes and represent a useful method to examine aberrant gene regulatory mechanisms that occur in diseases such as diabetic nephropathy. Despite significant progress

made towards understanding signalling mechanisms and refining organoid models over the last number of years, there is a growing necessity to increase complexity, reduce variability and improve maturity and genetic authenticity. We propose that organoid development will benefit from 'tunability' of the biophysical properties of the cellular microenvironment. Synthetic hydrogel scaffolds represent a promising alternative to circumvent limitations associated with tissues grown on traditional, naturally-derived extracellular matrices. These scaffolds are also more amenable to generating tuneable mechanical and signalling gradients that more accurately mimic the in *vivo* environment. We differentiated iPSC-derived nephron progenitors into kidney organoids within fully defined, self-assembling peptide hydrogel scaffolds of variable stiffness and component peptide charges. Transmission electron microscopy of these hydrogels revealed a fibrous structural architecture similar to that of matrigel like-extracellular matrices. Haematoxylin and Eosin staining of encapsulated organoids exhibited variable morphological self-organisation of epithelial cell tubular structures within hydrogels by day 24, particularly between highly charged peptide hydrogels with Young's Moduli of 1 and 14 kPa. Interestingly, immunofluorescent characterisation also showed differential proximal (LTL^{+ve}) and tubular epithelial ($ZO\text{-}1^{+ve}$, $ECAD^{+ve}$) expression between the embedded organoids. Most notably, increased proximal tubule (LTL^{+ve}) formation was observed within softer peptide hydrogels (1 kPa). Additionally, we have identified distinct combinations of extracellular matrix components, including vitronectin and laminin-511, that support differentiation of iPSCs towards renal lineages in two-dimensional culture. Cellular self-organisation into $LTL^{+ve}$and $ZO\text{-}1^{+ve}$ structures accompanied by laminin basement membrane formation was observed by day 18 of differentiation. Functionalisation of these substrates within peptide hydrogels will likely further enhance processes of renal differentiation. To the best of our knowledge, this is the first investigation of iPSC-derived kidney organoids within fully synthetic, self-assembling peptide hydrogels. These results will further support the use of designer matrices that will improve iPSC differentiation towards renal cell fate trajectories.

P1678/B816

Intracellular Ph Dynamics Regulates Intestinal Stem Cell Differentiation.

Y. Liu, T. Nystul, D. Barber; UCSF, San Francisco, CA.

Emerging evidence is revealing that intracellular pH (pHi) dynamics regulates different types of epithelial plasticity, including stem cell differentiation, epithelial-mesenchymal transition, and epithelial transformation. In testing the centrality of pHi dynamics in stem cell differentiation we found that increased pHi is necessary for intestinal stem cell (ISC) differentiation, using the well-established 3D *ex vivo* model of adult mouse small intestinal organoids. Using cells expressing the genetically encoded pHi biosensor pHluorin, we identified a pHi gradient along the crypt-villus axis, from lower pHi in crypt cells that include ISCs to higher pHi in differentiated villus cells. Dissipating this gradient and decreasing pHi by inhibiting H+ efflux by the plasma membrane Na-H exchanger NHE1 blocks two stages of organoid development: crypt budding and differentiation to the secretory cell linage. Inhibiting NHE1 activity completely blocks crypt budding over three days despite no effect on polarized expression of the crypt marker CD44. However, increased phosphorylation of myosin light chain 2 (pMLC) seen in controls is lost, which supports a role for actinomyosin contractility regulating budding. Additionally, inhibiting NHE1 and lowering pHi after crypt budding reduces the number of daughter cells expressing ATOH1, a master transcription factor for cells in the secretory lineage, as indicated by $ATOH1^{+}$cell-lineage tracing. Our data reveal a previously unrecognized critical role for pHi dynamics in intestinal epithelial

development and further support an emerging view of pHi dynamics being a conserved regulator of stem cell differentiation.

The Midbody Is A Novel Translating Organelle Mediating Intercellular Communication. Y. Liu, R. Dahn[1], S. Park[1], E. Kurt[1], A. Presle[2], J. Gilbert[1], K. VanDenHeuvel[1], A. Jambhekar[3], J. Shivas[4], L. Qin[1], O. Olukoga[1], A. Echard[2], M. Blower[5], **A. R. Skop**[1]; [1]University Wisconsin-Madison, Madison, WI, [2]Instit Pasteur, Paris, FRANCE, [3]Harvard, Boston, WI, [4]Leica Microsystems, Buffalo Grove, IL, [5]Harvard, Boston, MA.

The midbody is a transient structure at the spindle midzone that is required for the terminal stage of cell division, cytokinesis. Long ignored as a vestigial remnant of cytokinesis, emerging data suggest midbodies are released from post-mitotic cells and can modulate cell fate decisions, proliferative state, tissue polarity, cilia formation, neuronal architecture and function, and oncogenesis. Our 'structure reveals function' approach first demonstrated that the midbody matrix- a mysterious electron-dense region of unknown composition- is the assembly site of a phase-separated biomolecular condensate, enriched for mRNAs encoding proteins involved in cytokinesis, oncogenesis and pluripotency regulation, including transcription factors. Hexanediol-sensitivity and FRAP analysis confirmed that the midbody matrix exhibits biophysical properties expected of an RNP condensate. SUnSET analysis of protein synthesis showed that both the mitotic and post-mitotic midbody are sites of active translation. Consistent with this, ribosomal subunits and elongation factors colocalize with puromycin labeling in a ring structure surrounding the midbody RNA core. We discovered that translation of midbody-enriched mRNAs is under tight temporal regulation, beginning in G1 after cells have formally exited mitosis, and continues after the midbody is abscised and released extracellularly from the daughters that birthed it. Our data suggest a model in which the midbody functions as a novel organelle with a complex life cycle comprised of both membraneless and membrane-bound phases: 1) an RNP condensate is assembled at the spindle overlap; 2) spatiotemporally regulated translation is initiated as the daughter cells leave mitosis and reenter G1; 3) abscission occurs and the membrane-bound RNP granule is released; 4) the midbody is bound, internalized, and transfers information to recipient cells.

Z Ring Assembly Is Regulated by FtsZ Filament Binding Proteins.

G. R. Squyres[1], S. R. Barger[2], B. R. Pennycook[3], J. Ryan[4], V. Yan[5], E. C. Garner[1]; [1]Harvard University, Cambridge, MA, [2]SUNY Upstate Medical University, Syracuse, NY, [3]Imperial College London, London, UNITED KINGDOM, [4]Ludwig Maximilian University of Munich, Munich, GERMANY, [5]Technische Universität Dresden, Dresden, GERMANY.

Cell division in bacteria is orchestrated by a group of proteins that work together to carry out cytokinesis and synthesize new cell wall at the division site. Filaments of FtsZ, a bacterial homolog of tubulin, form a "Z ring" at the middle of the cell that recruits other cell division proteins and constricts as the cell divides. While many of these proteins have been identified, the mechanisms of cell division remain poorly understood. Recent work has emphasized the importance of the properties of FtsZ filaments in the cytokinesis process. Using TIRF microscopy, we have shown that FtsZ filaments treadmill around the division site in the gram-positive bacterium *Bacillus subtilis*, and that these dynamics are of key

significance in bacterial cell division. Now, we investigate whether and how FtsZ filament assembly and treadmilling dynamics are regulated. We specifically investigate the FtsZ binding proteins, a group of proteins known to bind directly to FtsZ at the division site. These proteins have been proposed to regulate both FtsZ dynamics and bundling in *vitro*. To investigate this, we use live-cell single molecule lifetime measurements as a quantitative reporter of FtsZ's treadmilling dynamics independent of both spatial resolution and local filament density. We ask whether and how FtsZ binding proteins control filament structure and/or dynamics during the bacterial cell cycle. Surprisingly, our results suggest that these FtsZ binding proteins do not regulate FtsZ filament kinetics directly, but rather mediate Z ring assembly through filament bundling. Functional regulation of filaments by bundling, mediated by accessory filament-binding proteins, is a common feature of eukaryotic cytoskeletal systems, but has rarely been seen in bacteria. We propose that this regulated FtsZ filament bundling is a prerequisite for normal Z ring formation and cytokinesis.

P1680/B819

Single-molecule Imaging Reveals Distinct Subcomplexes of the *Bacillus Subtilis* Division Machinery.

M. J. Holmes, E. C. Garner; Harvard University, Cambridge, MA.

Despite decades of research, the fundamental molecular mechanisms underlying bacterial cytokinesis remain poorly understood. Recently, it has become clear that protein dynamics in the bacterial division complex, and in particular those of the tubulin homolog FtsZ, play a key role in this process. FtsZ polymers localize in a ring at future division sites and recruit cell-wall-synthesis enzymes that build a septum between daughter cells. FtsZ filaments move around this ring by treadmilling: subunits are added to one end of the filament and removed from the other. This results in the filament as a whole moving, but individual subunits remaining stationary. Filament treadmilling is required for the coincident motion of the associated cell wall synthesis enzyme Pbp2B around the division site, as well as efficient cell division. Strikingly, single molecules of Pbp2B move along with the treadmilling filament and are highly processive. Single-molecule processive motion along filaments is typically associated with molecular motors in eukaryotic systems, but neither Pbp2B nor any other protein associated with the division complex has homology to any known motors. How is this motion achieved? in addition to FtsZ, the division complex (or divisome) contains many other proteins whose dynamics have not been characterized. We imaged single molecule motions of each divisome protein using HaloTag fusions labelled with Janelia Fluor dyes. Two classes of motions were observed. Cytoplasmic proteins that bind directly to FtsZ remain immobile with FtsZ subunits. In contrast, the divisome proteins with periplasmic domains all move around the division site. This latter group contains the other division cell wall synthesis enzyme FtsW, and three non-enzymatic proteins which interact with one another but have unknown function. All four proteins move at the division site with velocities comparable to Pbp2B, and these directional motions require cell wall synthesis. We propose that these periplasmic proteins move around the cell in complex in a manner dependent on treadmilling FtsZ filaments. We are currently working to identify the molecular interfaces between the stationary and moving components. Additionally, we are uncovering how the localization and motion of these mobile proteins depends on specific FtsZ architectures.

P1681/B820

Cell Division Proteins Follow Treadmilling FtsZ Filaments by Diffusion-and-Capture.

N. Baranova[1], **M. Loose**[1], P. Radler[1], V. M. Hernández-Rocamora[2], W. Vollmer[2]; [1]Institute of Science and Technology Austria, Klosterneuburg, AUSTRIA, [2]Newcastle University, Newcastle, UNITED KINGDOM.

The tubulin homolog FtsZ plays a key role for bacterial cytokinesis, but the molecular mechanisms underlying its function are largely unknown. Treadmilling filaments of FtsZ are thought to actively move proteins within the division plane to distribute cell wall synthesis for the generation of the two new cell poles. To study how FtsZ filament dynamics are coupled to cell wall synthesis, we reconstituted part of the bacterial cell division machinery using its purified components FtsZ, FtsA and truncated transmembrane proteins essential for cell division. We found that the membrane-bound cytosolic peptides of FtsN and FtsQ co-migrated with treadmilling FtsZ-FtsA filaments. Remarkably, despite their directed behavior on the ensemble level, individual peptides showed random motion and transient confinement. Our work suggests that divisome proteins dynamically follow treadmilling FtsZ filaments at the cell division site by a diffusion-and-capture mechanism and highlights the importance of transient interactions for the self-organization of complex biological structures.

Transpeptidase Pbp2 Governs Initial Localization and Activity of Major Cell-wall Synthesis Machinery in *Escherichia Coli*.

G. Ozbaykal, E. Wollrab, A. Vigouroux, B. Cordier, S. van Teeffelen; Institut Pasteur, Paris, FRANCE.

Bacterial shape is physically determined by the peptidoglycan cell wall. The cell-wall-synthesis machinery responsible for rod shape in *Escherichia coli* is the processive 'Rod complex'. Previously, cytoplasmic MreB filaments were thought to govern formation and localization of Rod complexes based on local cell-envelope curvature. However, using single-particle tracking of the transpeptidase PBP2, we found strong evidence that PBP2 initiates new Rod complexes by binding to a substrate different from MreB or any known Rod-complex component. This substrate is likely the cell wall. Consistently, we found only weak correlations between MreB and envelope curvature in the cylindrical part of cells. Residual correlations do not require any curvature-based Rod-complex initiation but can be attributed to persistent rotational motion. Therefore, local cell-wall architecture likely provides the cue for PBP2 binding and subsequent Rod-complex initiation. We also found that PBP2 has a limiting role for Rod-complex activity, thus supporting its central role.

P1683/B822

LetB Forms a Tunnel for Lipid Transport Across the Bacterial Periplasm.

G. Isom, N. Coudray, M. MacRae, C. McManus, G. Bhabha, **D. C. Ekiert**; New York University School of Medicine, New York, NY.

Gram-negative bacteria are surrounded by an outer membrane composed of phospholipids and lipopolysaccharide (LPS), which acts as a barrier to the environment and contributes to antibiotic resistance. While mechanisms of LPS transport have been well characterized, systems that translocate phospholipids across the periplasm, such as MCE transport systems, are less well understood. Here we show that *E. coli* LetB (formerly YebT), uses multiple MCE domains to form a ~0.6 megadalton complex in the periplasm. Our cryo EM structure reveals that LetB consists of a stack of 7 modular rings, creating

a long hydrophobic tunnel through the center of the complex. LetB is sufficiently large to span the gap between the inner and outer membranes, and mutations that shorten the tunnel abolish function. Lipids bind inside the tunnel, suggesting that it functions as a pathway for lipid transport. Together, our results support a model in which LetB establishes a physical link between the bacterial inner and outer membranes, and creates a hydrophobic pathway for the translocation of lipids across the periplasm, supporting the integrity of the outer membrane permeability barrier.

P1684/B823

Liquid-Like Protein Behavior Involved in the Spatial Regulation of Carbon-fixing Organelles.

J. Basalla, A. Vecchiarelli; University of Michigan - Molecular, Cellular, and Developmental Biology, an n Arbor, MI.

Carbon fixation is one of the most fundamental biological processes, and is almost entirely catalyzed by the enzyme RuBisCO. While typically associated with plants, nearly half of all carbon fixation is carried out by bacteria. However, bacteria fix carbon via a slightly different mechanism, as they have evolved specialized organelles known as carboxysomes to aid in the process. These carboxysomes function by concentrating and encapsulating RuBisCO and CO2 within a protein shell, effectively saturating RuBisCO with its substrate to create a highly efficient carbon-fixing reaction compared to plants. As a result, carboxysomes have piqued interest for engineering alternative and more efficient carbon-fixing pathways to address the climate crisis and need for green energy. Despite their applications and importance in the global carbon cycle though, little is known about how carboxysomes form or are spatially regulated in carbon-fixing bacteria. A recent focus of ours has been the spatial regulation of carboxysomes in the model cyanobacterium *Synechococcus elongatus.* We have identified the maintenance of carboxysome distribution system (McdAB) as the two-factor system that equally spaces carboxysomes down the cell to ensure their inheritance after cell division. The first factor, McdA, is an ATPase that coats the nucleoid. The second factor, McdB, binds carboxysomes and removes McdA from the nucleoid in the vicinity of each carboxysome. The resulting McdA gradients drive the positioning of carboxysomes. Although we have identified the two-factor system, the specific interactions behind gradient formation and carboxysome positioning remain unknown. My results indicate that McdB, the protein that associates with carboxysomes, undergoes liquid-liquid phase separation (LLPS), a physical process by which proteins condense into their own liquid phase. The results I cover here show McdB displaying hallmark liquid behaviors (e.g. droplet fusions, wetting, internal diffusions, etc.) that are highly responsive to physical conditions such as pH and salt levels. Interestingly, carboxysomes have also been shown to undergo LLPS to facilitate their assembly. These data are striking since our results indicate that McdB interacts strongly with the components responsible for driving carboxysome LLPS. It is further known that carboxysomes facilitate and respond to changes in cytoplasmic pH. Taken together, these data lead us to hypothesize that local fluctuations in pH may regulate LLPS in relation to McdB and carboxysome assembly and spatial regulation.

P1685/B824

Protein Gradients on the Nucleoid Position the Carbon-fixing Organelles of Cyanobacteria.

J. S. MacCready; University of Michigan, an n Arbor, MI.

Carboxysomes are protein-based bacterial organelles encapsulating key enzymes of the Calvin-Benson-Bassham cycle. Previous work has implicated a ParA-like protein (hereafter McdA) as important for

spatially organizing carboxysomes along the longitudinal axis of the model rod-shaped cyanobacterium *Synechococcus elongatus* PCC 7942. Yet, how self-organization of McdA emerges and contributes to carboxysome positioning is unknown. Here, we identify a small protein, termed McdB that localizes to carboxysomes and drives emergent oscillatory patterning of McdA on the nucleoid. Our results demonstrate that McdB directly stimulates McdA ATPase activity and its release from DNA, driving carboxysome-dependent depletion of McdA locally on the nucleoid and promoting directed motion of carboxysomes towards increased concentrations of McdA. We propose that McdA and McdB are a previously unknown class of self-organizing proteins that utilize a Brownian-ratchet mechanism to position carboxysomes in cyanobacteria, rather than a cytoskeletal system. We further demonstrate that McdA/B levels influence carboxysome ultrastructure and size. Finally, we show that the McdAB system is widespread among all known cyanobacterial taxonomic orders and morphologies and that McdB is an intrinsically disordered protein across evolutionary time. These results have broader implications for understanding spatial organization/biogenesis of protein mega-complexes and organelles in bacteria.

P1686/B825

Xylan Metabolism by *Caulobacter Crescentus*.

V. Bui, G. Periyannan; Eastern Illinois University, Charleston, IL.

Bacteria present unique opportunities to explore the molecular mechanisms of nutrient acquisition processes at single cell level under various experimental conditions. *Caulobacter crescentus* is a gram-negative oligotrophic environmental bacterium with adaptive physiological responses, like slow growth or complete arrest of cell cycle; the presence of sessile and motile progenies, with the sessile cells growing stalk to enhance nutrient uptake for growth in low-nutrient conditions. Details of carbon source, such as cellobiose, maltose, and xylose, utilization by *C. crescentus* can be found but molecular details or mechanisms of polysaccharide, such as xylan, utilization has not been reported. Database analyses indicate *C. crescentus* has a repertoire of xylanases and carbohydrate-modifying enzymes, along with membrane-bound transporters for efficient breakdown and uptake of xylan. Growth and metabolic properties of *C. crescentus* in M2 minimal medium containing xylan as the sole carbon source was investigated. Growth curves of *C. crescentus* in xylan show typical phases as seen in other mono- and disaccharide carbon sources in similar conditions but with significantly extended lag phase. Enzyme assays using *p*-nitrophenol xylopyranoside substrate and xylo-oligosaccharides show high level expression of periplasmic xylosidases on the second day of growth on xylan substrate coinciding with the beginning of the log phase as well as possible membrane-bound xyloside hydrolases as well as glucuronidase. Gene expression analysis of cells grown in xylan show expression of a select number of xylanases, suggesting induced expression of genes. 2D gel electrophoresis based proteomic and genomic database analyses further revealed several xylosidases as well as TonB-dependent receptor mediated transporters expression indicating that these enzymes and proteins work in a concerted manner to access metabolizable xylose and other monosaccharide derivatives. Chromatography (HPLC & TLC) and ^{1}H-NMR based metabolomic analyses of the extracellular medium combined with enzyme assay data suggest xylan binding onto the bacterial surface and xylan fragment uptake across the outer membrane. A comprehensive model emerges for *C. crescentus* that resembles both gut and environmental bacterial xylan utilization models further advancing the molecular level understanding of xylan derived nutrient acquisition in bacteria.

P1687/B826

A Molecular Rack and Pinion Machinery Enables Bacterial Gliding Motility.

A. Shrivastava[1,2], H. C. Berg[2]; [1]School of Life Sciences and the Biodesign Institute, Arizona State University, Tempe, AZ, [2]Department of Molecular and Cellular Biology, Harvard University, Cambridge, MA.

Bacterial gliding has fascinated biologists and physicists for a long time, yet we know very little about its mechanism. The gliding bacterium *Flavobacterium johnsoniae* is known to have an adhesin, SprB, that moves along the cell surface on a spiral track. When cells are sheared, they stop gliding but can be tethered by addition of an anti-SprB antibody. Tethered cells spin about 3 Hz. We labeled the Type 9 protein secretion system (T9SS) with a yellow-fluorescent-protein (YFP). When labeled cells were tethered, a YFP spot was found near the rotation axis, which shows that the molecular motor that drives rotation localizes with the T9SS. The spiral track was labeled by following the motion of Cy3-labeled SprB. The distance between the rotation axis and the track was determined by a measurement involving both labels, YFP and Cy3, yielding 90 nm. If a rotary motor spins a pinion of radius 90 nm 3 Hz, a spot on its periphery will move 1.5 μm/s, the speed at which cells glide. Our data argue for the presence of a molecular rack and pinion machinery. The pinion drives a flexible tread that carries SprB along a track fixed to the cell surface. Cells glide when such an adhesin adheres to the solid substratum.

P1688/B827

Structural, Functional and Transcriptional Characterization of Novel Identified hipBAXn2 Toxin-Antitoxin (TA) Module from *Xenorhabdus nematophila*.

M. Yadav, J. S. Rathore; Gautam Buddha University, Greater Noida, INDIA.

This is the first report to characterize genomic *hipBA*^{Xn2} TA module from *Xenorhabdus nematophila*, a species-specific mutualist of entomopathogenic nematode *Steinernema carpocapsae*. *hipBA*^{Xn2} was identified in the genome of *X. nematophila* ATCC 19061 (NCBI Refseq NC_014228) at position 3774379-3775635 bp. It is a type II TA module which consists of *hipA*^{Xn2} toxin gene encoding 270 amino acid residues protein and *hipB*^{Xn2} encoding antitoxin of 135 amino acid residues protein. Structural models for both proteins were deduced by threading approach and molecular movements of models were also validated by Molecular Dynamics (MD) simulation analysis. For functional analysis *hipA*^{Xn2} toxin, *hipB*^{Xn2} antitoxin and an operon having both genes were cloned in pBAD/His (c) vector and transformed in *Escherichia coli* TOP10 cells. All proteins were purified by using Ni-NTA affinity chromatographic technique and confirmed by Western blot analysis using anti-His antibody. Purification results showed the yield of of 0.37 mg/mL and 0.535 mg/mL for recombinant HipA^{Xn2} toxin and HipB^{Xn2} antitoxin protein respectively. For endogenous toxicity assay of *hipBA*^{Xn2} TA module, growth profile and cell viability of *E. coli* cells expressing recombinant HipA^{Xn2} toxin and HipB^{Xn2} antitoxin proteins was studied. After 4h of induction with 0.2% L-arabinose, cells expressing HipA^{Xn2} toxin retard the growth (measured as CFU and OD_{600}) by more than 2.5-fold as compared to the control cells and as induction time period increased, difference between cell viability was also increased. However, cells expressing both *hipA*^{Xn2} toxin and *hipB*^{Xn2} antitoxin genes simultaneously, HipB^{Xn2} antitoxin protein reduced the lethal toxic effect of HipA^{Xn2} toxin by more than two- fold. To determine the active amino-acids residues responsible for HipA^{Xn2} toxicity, site-directed mutagenesis (SDM) was performed. It was observed that amino-acid H164, N167 and S169 were key residues for the toxicity of HipA^{Xn2} toxin. In transcriptional analysis, we have predicted 529 bp upstream region of *hipBA*^{Xn2} and *LacZ* reporter construct was prepared. *LacZ* assay was

performed in different stress conditions like elevated temperature, nutrient deprivation and antibiotic treatments. In all the three stress conditions, promoter of *hipBA*^{Xn2} TA module was found significantly up-regulated as compared to normal growth condition. Auto regulation mechanism of *hipBA*^{Xn2} module was also confirmed by *in-vitro* Electrophoretic Mobility Shift Assay (EMSA), where 529 bp promoter region was interacting with purified recombinant HipA^{Xn2} toxin and HipB^{Xn2} antitoxin proteins. This study provides a comprehensive characterization of *hipBA*^{Xn2} TA module comprising a bright spotlight towards structural, functional and transcriptional features.

P1689/B828

***In Silico* Identification of Novel Cry Toxins and Assessment of Domain-specific Evolutionary Impact on the *Bacillus Thuringiensis* Toxin Adaptive Radiation.**

Y. V. Malovichko[1,2], A. E. Shikov[1,2], R. K. Skitchenko[3], A. A. Nizhnikov[1,2], K. S. An tonets[1,2]; [1]All-Russia Research Institute for Agricultural Microbiology, Saint Petersburg, RUSSIAN FEDERATION, [2]Saint Petersburg State University, Saint Petersburg, RUSSIAN FEDERATION, [3]ITMO University, Saint Petersburg, RUSSIAN FEDERATION.

Cry toxins pose major proteinaceous virulence factors of the insecticide bacterium *Bacillus thuringiensis*, a potent biopesticide widely used for crop protection. These proteins affect numerous species among Insecta class including those of orders Leipdoptera, Diptera, Hymenoptera and Coleoptera as well as several mite species and nematodes of Rhabtida order. To date, several prominent groups of Cry toxins have been identified of which three domain toxins (3D-Cry) prevail with more than 700 entities already discovered. Just like their name supposes, 3D-Cry toxins consist of three domains, with domain I responsible for toxin oligomerization and pore formation and domains II and III involved in binding to insect midgut receptors. Despite Cry toxins being excessively studied, neither their evolutionary origin and diversification nor mechanisms underlying their host specificity have been elucidated plausibly so far. Beyond that, due to their structural similarity Cry toxins tend to be misannotated in genomic and proteomic data indicating that a vast part of their true diversity is being overlooked. In the present work, we stepped towards expansion of existing Cry toxin database and revealing their evolutionary relationship. Recently, we have developed an HMM-based tool capable of mining novel toxins from both assembled sequences and raw reads. By applying this tool to all open access *Bacillus*-related sequences we managed to find more than 300 undescribed entities. The same tool was then used for performance of domain layout of both novel and trivial toxins to obtain sequences standing for mature processed toxins. Maximum likelihood phylogenetic trees of full-size processed toxins underpinned the discovery of novel high-rank groups of Cry toxins, while domain-restricted trees indicated unequal identity rate distribution and dN/dS ratio in three Cry domains implying differences in their contribution to protein radiation and putative host specificity, with domain III surprisingly being more conservative among neighboring clades than two other domains. Taken together, these data might shed light on all three Cry toxin actual diversity, evolutionary radiation and host specificity development. This work was supported by the Russian Science Foundation (Grant No 18-76-00028).

P1690/B829

Insights into the Zinc Homeostasis of *Bacillus an thracis by* Characterization of Its Zinc Uptake Regulator.

D. Kandari, R. Bhatnagar; Jawaharlal Nehru University- New Delhi, New Delhi, INDIA.

Zinc (Zn) has abounding occurrence in the living systems. It plays paramount roles including catalytic, structural and regulatory, both in prokaryotes and eukaryotes. Many Zn-dependent proteins are known to manifest virulence in pathogenic bacteria. In addition to the varying Zn levels in the external environment, the pathogenic bacteria encounters Zn inconstancies within the host i.e. either hyper- or hypo-zincemic conditions. Thus for successful survival, maintenance of Zn homeostasis is imperative at all times. Zn uptake regulator (Zur), a Fur family transcriptional regulator, is connoted in maintaining Zn homeostasis in pathogenic bacteria. Zn homeostasis has been marginally scrutinized in *Bacillus anthracis*, the top-rated bio-terror agent and causative organism of the fatal disease anthrax, with no decipherment of the role of Zur. BAS4181 is annotated as Zn-specific transcriptional regulator, further substantiated by computational and experimental analyses. BAS4181 gene (*ba zur*) lies *in* a three-gene operon, co-transcribed with *znuB* and *znuC* homologs, the components of a high-affinity Zn ABC transporter. The residues critical for Zn and DNA binding were delineated by homology modelling and sequence/structure analysis. Purified BaZur prodigiously exists in dimeric form as indicated by size exclusion chromatography and blue native-polyacrylamide gel electrophoresis. Computational and manual strategies were employed to decipher the putative regulon of *ba zur*, comprising of 11 genes, controlled by 6 promoters, each harbouring at least 1 Zur box. The DNA binding ability of BaZur to the promoter regions of the regulon candidates and itself was ascertained by electrophoretic mobility shift assays. Most of the regulon genes lacked functional annotation hence comprehensive in *silico* analysis was employed, revealing their role in Zn uptake, mobilization and as Zn chaperones. BaZur was found to exert negative regulation on most of the regulon genes including it. A downregulation was observed in the expression of *ba zur* under Zn excess conditions and marked upregulation under N, N, N′, N′-Tetrakis (2-pyridylmethyl) ethylenediamine (TPEN) mediated Zn-depleted environment, adding credence to its negative autoregulation. Moreover, an increase in the transcript levels of the regulon genes upon exposure of cells to TPEN connoted their role in combating hypo-zincemic conditions. Therefore it is proposed that under conditions of Zn feast, Zn bound BaZur represses the expression of its regulon genes and under Zn famine, BaZur exists in non-Zn bound form, causing their derepression. Thus, this study provides an insightful investigation of Zur and its connotation in Zn homeostasis in *B. An thracis*.

Identification and Characterization of Marine Bacteria Associated with Sea Urchin *Lytechinus variegatus*.

J. Oh[1], K. Romeus[2], L. Jayant[2]; [1]Columbia University, New York, NY, [2]Borough of Manhattan Community College, New York, NY.

Many symbiotic bacteria coexist on the surfaces of sessile marine invertebrates and are rich sources of unusual metabolites. This study focuses on identifying and characterizing bacterial flora that coexist on the tests and orifices of the sea urchin *Lytechinus variegatus*. Several bacterial strains were isolated from wild type sea urchins by gently swabbing their external surfaces and plating them onto marine agar plates. Out of the initial samples, 14 were chosen for identification and characterization. All 14 bacteria were gram negative rods. They tested positive for the oxidase tests and did not ferment sucrose. None of the tested bacteria showed any antibacterial properties. Kirby-Bauer tests revealed that many were resistant to both common and some rare antibiotics. Some of the isolated bacteria harbored endogenous cryptic plasmids of around 20 Kbp. When grown on starch and cellulose plates, some exhibited amylase and cellulase activities. One of the isolated bacteria was agarolytic in nature. The conserved 500bp of the 16S rDNA was sequenced for all 14 bacteria samples. Future studies involve

phylogenetically identifying these bacteria isolates. The raw DNA sequence obtained will be analyzed against an up-to-date bioinformatics database using an open source software, namely QIIME2. This includes taxonomic assignment, phylogenetic reconstruction and diversity analysis and visualizations. Additional tests might include antimicrobial assays to further determine its sensitivities to other microbial agents.

P1692/B831

***E. coli* Mutant Library Screen with Lacritin Bactericidal Peptide N-104 Identifies Potential Roles for PotH and Common Virulence Factor FeoB in N-104 Dependent Cell Death.**

M. Sharifian Gh.[1], F. Norouzi[1], G. W. Laurie[1,2]; [1]Cell Biology, University of Virginia, Charlottesville, VA, [2]Ophthalmology, University of Virginia, Charlottesville, VA.

Antimicrobial peptides play important roles in the innate defense of multicellular organisms. Recently, we discovered that a cleavage potentiated fragment of the prosecretory mitogen lacritin in tears, known as 'N-104', is bactericidal towards *E. coli*, *P. Aeruginosa* and *S. epidermidis* (J. Biol. Chem. 289:22172-22182, 2014), thereby substantially contributing to the sterility of human tears. To elucidate the mechanism-of-action, we screened for N-104 resistant mutants among 3,985 single gene knockout mutants of the *E. coli* K-12 Keio collection. Although effective at lower doses, 100 µM N-104 was applied to ensure complete killing of ~10^6 cfu/ml suspensions. AlamarBlue served as the end-point assay to monitor bacterial cell viability and proliferation. Fluorescence of a 200 µl suspension of each knockout strain was monitored in duplicate for 5 hours at 34°C (surface temperature of the eye) after which N-104 was added and viability monitored for the next 5 hours. A viability slope ratio of >0.75 (treated to untreated) distinguished several resistant mutants including *potH* and *feoB*, and uncharacterized *yhfZ*, *ybdM* and *ybaE*. FeoB is ferrous iron transport protein B, a virulence factor for *P. Aeruginosa* in chronic cystic fibrosis and of *E. coli* in urinary tract infections. The PotH is a membrane protein subunit for transporting putrescine which is strongly involved in proliferation and viability of bacteria. How N-104 dependent cell death is initiated by FeoB or PotH at the inner membrane of *E. coli* for presumed transduction to other gene products or via metabolites remains to be determined.

P1693/B832

Characterization of Antibiotic Resistant Bacteria Present on the Lane College Campus.

L. Allen, C. Armstrong, J. Armstrong, K. Saul, M. Van Stry; Lane College, Jackson, TN.

Antibiotics are medications that destroy or slow down the growth of bacteria. Beta-lactam antibiotics, such as penicillin, consist of a beta-lactam ring that inhibits transpeptidase, an enzyme needed for cell wall biosynthesis in bacterial organisms. Since antibiotics are among the most highly prescribed medication, many pathogenic bacteria have developed resistance towards them. The soil is a natural reservoir of antibiotic resistant bacteria, and characterization of these bacteria can enhance our understanding of the evolution of antibiotic resistance. Our goal for this project is to isolate and characterize soil bacteria that are resistant to beta-lactams. We hypothesize that antibiotic resistant bacteria are present in the soil in the Lane College campus. Furthermore, we hypothesize that these bacteria have a beta-lactamase gene, which is an enzyme that inactivates the bacteria by cleaving the beta-lactam ring. We collected soil samples from the Lane College campus and cultured the bacteria a nutrient agar at room temperature. To screen for antibiotic resistant bacteria in this culture, we then replica plated the bacteria onto nutrient agar containing 100 ug/ml of ampicillin. We then selected two

colonies for further characterization. We tested the bacteria for resistance to additional beta-lactams, penicillin and amoxicillin. We then further characterized by Gram staining and morphological observation. Lastly, we used PCR to screen for the presence of beta-lactamase genes, TEM-1 and Bla-1, two common beta-lactamases. The two strains were resistant to ampicillin, penicillin, and amoxicillin. Both samples were Gram negative and the cells were a coccus shape. The beta-lactamase genes TEM-1 and Bla-1 were not detected by PCR. We are planning to use the 16S rDNA gene to identify the bacteria, and to look for presence of other beta-lactamase genes and further characterize the transpeptidase gene. This work is supported by NSF HRD 1623340 to MVS.

P1694/B833

Effect of *Xylopia Aethiopica* Aqueous Fruit Extract on Bacterial Growth Kinetics.

C. Priano, F. Yerima; Borough of Manhattan Community College, NEW YORK, NY.

Xylopia aethiopica is an evergreen, aromatic tree of the an nonaceae family. It is native to the lowland rainforest and moist fringe forests in the savanna zones of Africa where it is widely eaten and used in traditional medicine. The essential oil of *X. Aethiopica,* extracted from the seeds or the bark, has been shown to have antiseptic activity. The purpose of this project was to measure the effect of an aqueous *Xylopia* fruit extract on growth kinetics of gram-negative *Escherichia coli* and gram-positive *Bacillus subtilis. The* extract was prepared by grinding the *Xylopia* fruit and boiling in distilled water for 30 minutes. Liquid cultures of *E. coli* and *B. subtilis* were each grown in microplate wells at 37 °C with shaking in either the presence or absence of the *Xylopia* extract. Bacterial growth was monitored over the course of seven hours by measuring optical density at 600 nm using a BioTek microplate reader. Results demonstrated that whereas growth of *E. coli* was slightly suppressed in the presence of the extract, growth of *B. subtilis* was completely inhibited. Experiments were repeated several times yielding the same results. It was concluded that the aqueous *Xylopia* fruit extract exerted differential antibacterial activity on these strains, possibly due to their differences in cell wall structure. Further experiments will examine growth kinetics of different gram-positive and gram-negative strains to address this question.

P1695/B834

Tick-borne Lyme Disease: Investigating the Role of Micronutrients On*Borrelia Burgdorferi* Population Growth.

L. Hritzo, D. Serva; Wheeling Jesuit University, Wheeling, WV.

Lyme disease (LD), caused by the spirochete *Borrelia burgdorferi* (*B.b.*) that is transmitted by *Ixodes* species ticks, is the most common vector-borne illness in the U.S., Europe, and in the Northern Hemisphere. Recently revised estimates from the CDC suggest that there are likely over 300,000 new cases per year in the U.S., but the actual number is probably much higher as many cases are underreported and undiagnosed. Clinical data indicates that certain vitamins affect the outcome of antibiotic treatment of LD, while other clinical work recounts that levels of serum vitamins for LD patients differ from healthy patients. As LD is so prevalent, especially in Appalachia, with not many researchers studying it, it is important to investigate Tick Borne LD *B.b. In*teraction and effects with vitamins, which could lead to a better approach to treatment and effectiveness of antibiotics. The goal of this study is to examine the direct effects of vitamins on *B.b*. populations when cultured with micronutrients. I hypothesized that the vitamins A, B, B6, B12, C and E would have a positive effect upon

*B.b.*growth, as shown by an increase in the *B.b.* count. I also expected the results to confirm that vitamin D3 and Ca would have a negative effect upon the *B.b.* population counts, therefore a decrease in counts. It is important to note in the final results that positive *B.b.* growth, therefore an increase in counts correlate to a negative outcome for LD patients, and a decrease in *B.b.* population counts are a positive outcome for the patient with decreased bacteria in the patient. The results showed that the B vitamins & Ca have a positive effect on the *B.b.* counts, thus, would cause the *B.b. To* multiply and worsen the disease in the patient. Also, vitamins A, C, E, and D3 had a negative effect on the *B.b.* counts, and therefore a patient with LD could benefit by taking these vitamins to combat the *B.b.* growth. The implications of this project are key, as the CDC recently released a study that LD-carrying ticks are now in half of all U.S. counties. If patients with LD can take a vitamin that can decrease *B.b.* counts, then this can help patients not only in Appalachia, but those without access to higher level medical care including proper antibiotics. This has not previously been studied individually and research on this widespread, harmful, understudied disease gives valuable insight into a disease affecting many especially the local population of Appalachia.

P1696/B835

Flagellum Is Responsible for Promoting Effects of Viable *Escherichia Coli* on Calcium Oxalate Crystallization, Crystal Growth and Aggregation: an in *Vitro* Model for Kidney Stone Formation.

R. Kanlaya, O. Naruepantawart, **V. Thongboonkerd**; Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok, THAILAND.

Urease-producing bacteria (especially *Proteus mirabilis*) can cause infection kidney stone. However, recent studies have shown that intact viable non-urease-producing bacteria such as *Escherichia coli* could also promote calcium oxalate (CaOx) kidney stone formation but with unclear mechanism. We thus hypothesized that some relevant bacterial components might be responsible for such promoting effects of the intact viable *E. coli*. Flagellum, capsule, lipopolysaccharide (LPS), and outer membrane vesicles (OMVs) were isolated/purified and their stone modulatory activities were evaluated using CaOx crystallization, crystal growth, and crystal aggregation assays. Among these, flagellum had the most potent promoting effects on CaOx crystallization, crystal growth, and crystal aggregation. Validation was performed by deflagellation demonstrating that the deflagellated intact viable *E. coli* had markedly reduced CaOx crystal modulating activities in all aspects, comparable to those of the negative controls. These findings provide the direct in *vitro* evidence indicating that flagellum is responsible for promoting effects of viable *E. coli* on CaOx crystallization, crystal growth and aggregation, which are the important mechanisms for kidney stone formation.

Far-Red Light Photoacclimation in Endolithic Cyanobacteria.

B. Murray[1], J. DiRuggiero[2]; [1]The Triple Helix at Johns Hopkins, Baltimore, MD, [2]Johns Hopkins University, Baltimore, MD.

In hyper-arid deserts, cyanobacteria colonize the pore spaces of rocks to exploit their water retention properties and shield themselves from harsh winds and solar radiation. These endolithic cyanobacteria provide carbon to the associated microbial community and photosynthesize using chlorophyll a, phycobilisomes, and two major photosystems (PS I & PS II). We previously found that the solar spectrum within the colonization zone of rocks is shifted towards far-red light (>710nm), which chlorophyll a is

unable to absorb. To understand how this light condition influences photosynthesis, we analyzed enrichment cultures grown under white and far-red light with spectrophotometry, genome sequencing, RT-qPCR, and pigment extractions. Our analysis revealed the presence of chlorophyll f and a canonical 21-gene cluster that allows these endolithic cyanobacteria to make use of light in the far red. We also found that chlorophyll f synthase, which catalyzes the conversion of chlorophyll a into f, was highly expressed only in cells exposed to far red light, demonstrating the ability of endolithic cyanobacteria to use far-red light to photosynthesize.

P1698/B837

Investigation of Potential for Green Tea and Honey as Natural Anti-biofilm Agents.

S. Britz, **B. Schoffstall**; Barry University, Miami, FL.

Biofilm is an accumulation of multicellular and sometimes multi-species microbial mass embedded in polysaccharide matrix with adhesive abilities; this matrix is known as “extracellular polymeric substance” (EPS). Complex biofilm has remarkable ability to impede normal immune responses and aggressive anti-microbial medical interventions, leading to difficulties in treating wound infections. Honey and green tea extract have been previously identified as natural substances that appear to possess anti-biofilm properties with potential for promotion of wound healing. Previous studies have targeted the ability of green tea and/or honey to prevent single-species biofilm formation, which could be purely an antibiotic effect rather than targeting EPS production. In wound infections, biofilm typically involves multiple species of microorganisms. Here we utilize in *vitro* biofilm growth and mixed bacterial cultures to gain further understanding of the potential for prevention and/or eradication of biofilm using green tea and honey. The model strains of bacteria used in our study are: *Staphylococcus epidermidis* RP62A (WT)--a robust biofilm former, *Staphylococcus epidermidis* (ATCC 12228)--a very weak biofilm former, *Staphylococcus aureus* (ATCC 6538)--a moderate biofilm former and known wound pathogen, and *Pseudomonas aeruginosa* (ATCC 9027)--a moderate biofilm former and known wound pathogen. With all species incubated under the same testing conditions, our preliminary findings suggest that 20% green tea extract is capable of preventing single-species bacterial growth and biofilm formation when applied to planktonic cultures, yet does not appear to be capable of disrupting established biofilms. In contrast, 1% honey has ability to prevent biofilm formation in all three Staphylococcal species, and is capable of disrupting established Staphylococcal biofilm. In mixed-species cultures, co-incubation of *S. Aureus* with *S. epidermidis* RP62A appears to have an antagonistic effect on the ability of RP62A to form a robust biofilm. In contrast, co-incubation of *P. Aeruginosa* with *S. Aureus* appears to have a synergistic effect, allowing formation of a more robust biofilm than *S. Aureus* alone. With all mixed cultures, 20% green tea extract and 3% honey are both capable of preventing biofilm formation when added to planktonic mixed cultures before incubation, 3% honey reduces biomass of established mixed biofilm, but 20% green tea has essentially no effect on established mixed biofilm. Future studies will investigate the effects of green tea and honey on multi-species biofilm that naturally forms in infected "wounds" using *ex vivo* zebrafish explants cultures.

P1699/B838

Characterization of Amino Acids Involved Polymer Nucleation and Turnover for Tubz, a Bacterial Tubulin Homolog That Powers Plasmid Partitioning.

L. Romberg, Z. Zhang, G. King, A. Bock-Hughes, E. Romani; Oberlin College, Oberlin, OH.

TubZ is a tubulin homolog that moves plasmids, phage genomes or virions inside of bacterial cells. In *Bacillus thuringiensis*, TubZ polymers treadmill and help partition a large virulence plasmid. In a system reconstituted in vitro, DNA from these plasmids can associate with one end of a TubZ filament and be pulled along as the filament grows at the other end. TubZ initially assembles into GTP-containing, two-stranded filaments. After GTP hydrolysis, the polymers rearrange to form a four-stranded filament before finally disassembling. TubZ has an extended C-terminal tail that forms connections between subunits along a protofilament. This tail appears to play a role in filament assembly, rearrangement and disassembly. We are mutating amino acids predicted to be necessary for each stage in assembly and then characterizing the effects on subunit assembly and GTP turnover. Results to date support the idea that GTP turnover is limited by the stability of the 4-stranded filaments. Mutations that destabilize the 4-stranded filaments can increase GTP turnover up to 40-fold. The extended C-terminal tail may also affect the stability of 4-stranded filaments, in addition to affecting the nucleation of hydrolysis-competent filaments. By deleting a portion of this tail or by mutating amino acids that might interact with the tail, the GTP turnover rate can be raised 5-fold, or the critical concentration for GTP hydrolysis can be either raised or lowered 5-fold without affecting steady state GTP turnover rates. We are continuing to define how of these and other mutations affect TubZ assembly and disassembly.

P1700/B839

Degradation of Cyanogens by Bacteria Isolated from the Solid Waste Leachates of a Landfill Site in Lagos, Nigeria and an alysis of the Unculturable Microbial Communities.

A. OGUNYEMI, A. SAMUEL, **M. O. ILORI**, O. AMUND; University of Lagos, Lagos, NIGERIA.

Landfills are environmental repository for most organic and inorganic discarded materials. Microorganisms are responsible for the degradation of organic compounds in landfills. Despite the known toxicity of cyanide to man, it is still used and released into the environment by mining, galvanic and chemical industries. Bacterial strains capable of utilizing glutaronitrile as the sole source of carbon and nitrogen were isolated from solid waste leachates (SWL) by selective enrichment culture. Isolates were grown in media containing glutaronitrile and benzonitrile. Samples were processed for metagenomic DNA extraction which were followed by 16S rDNA amplification and sequencing. *Bacillus* sp. WOD8 KX774193 and *Corynebacterium* sp. WOIS2 KX774194 strains were obtained and both demonstrated broad specificities for nitriles degradation. Nitralase genes in WOD8 and WOIS2 were amplified as 1400bp and 1000bp respectively and then sequenced. The result of metagenomic analysis showed that twenty megabyte (20Mb) of data (2x300bp long paired end reads) was produced from the pooled sample with bacteria constituting 99.87% of the total read counts (i.e. 74766 read count). These findings provide genetic evidence of the involvement of WOD8 and WOIS2 in the degradation of the cyanogens. The study also revealed a high diversity of bacterial community in a major landfill in Lagos with potential that can be harnessed for cyanide containing waste management strategies.

Single Cell Lineage Dynamics of the Endosymbiotic Cell Type in a Soft Coral *Xenia* Species.

M. Hu, X. Zheng, C. Fan, Y. Zheng; Carnegie Institution for Science, Baltimore, MD.

Many hard and soft corals harbor algae for photosynthesis. The algae live inside coral cells in a specialized membrane compartment called symbiosome, which shares the photosynthetically fixed carbon with coral host cells, while host cells provide inorganic carbon for photosynthesis. This endosymbiotic relationship is critical for corals, but increased environmental stresses are causing corals to expel their endosymbiotic algae, i.e. coral bleaching, leading to coral death and degradation of marine ecosystem. To date, the molecular pathways that orchestrate algal recognition, uptake, and maintenance in coral cells remain poorly understood. We report chromosome-level genome assembly of a fast-growing soft coral, *Xenia* species (*sp.*), and its use as a model to decipher the coral-algae endosymbiosis. Single cell RNA-sequencing (scRNA-seq) identified 13 cell types, including gastrodermis and cnidocytes, in *Xenia sp*.Importantly, we identified the endosymbiotic cell type that expresses a unique set of genes implicated in the recognition, phagocytosis/endocytosis, maintenance of algae, and host coral cell immune modulation. By applying scRNA-seq to investigate algal uptake in our new *Xenia sp.* regeneration model, we uncovered a dynamic lineage progression from endosymbiotic progenitor state to mature endosymbiotic and post-endosymbiotic cell states. The evolutionarily conserved genes associated with the endosymbiotic process reported herein open the door to decipher common principles by which different corals uptake and expel their endosymbionts. Our study demonstrates the potential of single cell analyses to examine the similarities and differences of the endosymbiotic lifestyle among different coral species.

Putative Hookworm (*Ancylostoma Ceylanicum*) G-protein-coupled Receptor Expression in *Caenorhabditis Elegans*.

P. T. Erickson[1], B. Norman[1], L. DeLong[1], M. Dickey[1], M. Jewell[1], R. Ratnappan[2], J. P. Bernot[2], D. O'Halloran[2], J. M. Hawdon[2]; [1]Salisbury University, Salisbury, MD, [2]The George Washington University, Washington, DC.

Many parasites, including hookworms of the genus an *cylostoma*, are specialists that require host-specific signals to resume development upon infection. Although little is known about the nature of these signaling mechanisms, evolutionary conservation between hookworms and the model nematode, *Caenorhabditis elegans,* suggests that hookworm host-signal receptors are likely to be G-protein coupled receptors (GPCRs) expressed in amphid neurons. Based on analysis of developmental stage-specific RNA-Seq data from *A. caninum* and *A. ceylanicum*, predicted hookworm GPCRs with increased expression levels during the infective larval stage 3 (iL3) were identified. Stable transgenic lines of *C. elegans* transformed with putative promoter-GFP transcriptional fusions of candidate *A. ceylanicum* GPCRs were established. Of nine hookworm promoter fusions tested, four conferred differential GFP expression in *C. elegans* tissues, including the digestive tract, pharynx, and neuron pairs during both normal development and dauer arrest. The putative GPCR encoded by one neuronally expressed gene is

upregulated in both *A. ceylanicum* and *A. caninum*, suggesting that it may play a general role in hookworm development during host infection. To confirm protein localization, a carboxy terminal GFP-fusion of a neuronally-expressed, putative hookworm GPCR was generated using the 5' intergenic sequence and the entire coding sequence, including introns. Within the five independently transformed transgenic lines examined, no GFP expression was observed during normal growth or dauer developmental arrest. An amino terminal GFP translational fusion with a Gly-Ser linker has been generated to reassess protein expression. This work demonstrates that hookworm promoters can differentially regulate gene expression in *C. elegans*, providing a heterologous system for the study of hookworm gene expression patterns.

P1703/B842

***Caenorhabditis Elegans* Innate Immune Response to *Bartonella Bacilliformis*.**

E. R. Fajardo, K. L. Schmidt, 22802; Eastern Mennonite University, Harrisonburg, VA.

The genus *Bartonella* encompasses aerobic or microaerophilic, Gram-negative, facultative intracellular bacteria with a peculiar intraerythrocytic lifestyle. These pathogens have been detected in a wide range of animals. *Bartonella bacilliformis* (*Bb*) is among the species that can affect humans. Carrion's disease, a two-stage disease that encompasses the Oroya fever and Peruvian warts, is caused by *Bb*. This pathology can result in death for more than 80% of infected patients if they are not treated with antibiotics; likewise, its increase in the pediatric population is alarming. *Bb* is known to evade the innate immune system of its host. A primary amino acid sequence change in the flagellin prevents the flagella from being recognized by the Toll-like receptor (TLR) thus promoting its evasion. After it bypasses the innate immune system, *Bb* is said to find its niche in the endothelial cells. During *Bb* infection, signs of endothelial cell proliferation are evidenced by vascular tumors known as Peruvian warts. In *vitro* models have shown that *Bb* stimulates endothelial cell growth and also induces angiogenesis. In this research, *Caenorhabditis elegans* (*C. elegans*) is used to study the host-pathogen factors determining susceptibility to *Bb* infections. In our study, we exposed wild-type *C. elegans* to both dead and alive *Bb* and non-pathogenic *E. coli OP50*, simultaneously. We determined that *C. elegans* preferred alive *E. coli* instead of alive *Bb*. Over 48 hours, 81.5% of the *C. elegans* chose the alive *E. coli* as opposed to a 9.2 % that chose the alive *Bb*. No nematodes were found on the dead *E. coli* or *Bb*. The remaining *C. elegans* were found outside of either bacteria. These findings suggest that nematodes have an aversion towards *Bb*. Experiments are being conducted to determine the innate immunity pathways used by *C. elegans* (p38 MAPK, DAF-2/DAF-16, TOL-1) in response to *Bb* infections.

P1704/B843

***Leishmania Amazonensis* Hijacks Host Cell Lysosomes Involved in Plasma Membrane Repair to Induce Invasion in Fibroblasts.**

V. Cavalcante-Costa[1], M. Costa-Reginaldo[1], T. Queiroz-Oliveira[1], A. Oliveira[1], N. Couto[1], D. An jos[2], J. Lima-Santos[2], L. An drade[1], M. Horta[1], **T. Castro-Gomes**[1]; [1]Federal University of Minas Gerais - Brasil, Belo Horizonte, BRAZIL, [2]Universidade Estadual de Santa Cruz - Bahia, Ilhéus, BRAZIL.

Intracellular parasites of the genus Leishmania are the causative agents of human leishmaniasis, a widespread emergent tropical disease. The parasite is transmitted by the bite of a hematophagous sandfly vector that inoculates motile flagellated promastigote forms into the dermis of the mammalian host. After inoculation, parasites are ultimately captured by macrophages and multiply as round-shaped

amastigote forms. Macrophages seem not to be the first infected cells since parasites were observed invading neutrophils first whose leishmania-containing apoptotic bodies were latter captured by macrophages, thereby becoming infected. The fact that *Leishmania* spp are able to live and replicate inside immune phagocytic cells and that macrophages are the main cell type found infected in chronicity created the perception that Leishmania spp are passive players waiting to be captured by phagocytes. However, several groups have described the infection of non-phagocytic cells in vivo and in vitro. The objective of this work was to study the cellular mechanisms involved in the invasion of non-professional phagocytes by *Leishmania*. We show that promastigotes of *L.amazonensis* actively induces invasion in fibroblasts without cytoskeleton activity, thus by a mechanism that is distinct from phagocytosis. Inside fibroblasts parasites transformed in amastigotes, remained viable for at least two weeks and re-transformed in promastigotes when returned to insect vector conditions. Similarly to what was observed for *T. cruzi,* infection involves calcium signaling, recruitment and exocytosis of lysosomes involved in plasma membrane repair and lysosome-triggered endocytosis. Conditions that alter lysosomal function such as cytochalasin-D and brefeldin-A treatment or the knockout of host cell lysosomal proteins LAMP-1 and 2 dramatically affected invasion. Likewise, triggering of lysosomal exocytosis and lysosome-dependent plasma membrane repair by low doses of streptolysin-O dramatically increased parasite entry. Together our results show that *L.amazonensis* promastigotes are able to take advantage of calcium-dependent lysosomal exocytosis and lysosome-induced endocytosis to invade and persist in non-phagocytic cells.

P1705/B844

***Trypanosoma Cruzi*-Induced Epithelial Turnover in the Placenta Might Be Mediated by the Micro Rnas 19b-3p and 515-5p.**

U. Kemmerling, 8380453, L. Medina, C. Castillo, A. LIempi, C. Espinoza, E. Corradi, J. Maya; Universidad De Chile, Santiago de Chile, CHILE.

Trypanosoma cruzi (*T. cruzi*), a protozoan parasite, is the causative agent of Congenital Chagas Disease[1]. For this infection to be successful, the parasite must cross the placental barrier and evade the host immune system. We have previously proposed that cellular proliferation, differentiation and apoptosis of the trophoblast (Trophoblast Turnover) can be considered as an antiparasitic local response. As most of the cellular processes, the trophoblast turnover is also regulated post-transcriptionally by small non-coding RNAs inlcuding miRNAs. However, if the *T. cruzi*-induced trophoblast turnover, and particularly the trophoblast differentiation, is mediated by miRNAs is currently unknown. MiR-515-3p and miR-19b-3p regulates trophoblast differentiation by hGCM1 gene repression. The aim of the present study was to determine if the expression of miR-515-3p, miR-19b-3p and their target gene changes in presence of *T. cruzi*. Human placental explants (HPE) were incubated in presence and absence of *T. cruzi* (Y strain) (10^5 trypomastigotes/ml) or Foskolin (100 uM) during 2 hours. MiR-515-3p and miR-19b-3p expression was further analyzed by real-time PCR by the comparative Control (ΔΔCt) method and hGCM1 expression was determined by Western blotting. *T. cruzi* decreases miR-19b-3p and miR-515-5p levels and increases hGCM1 protein expression in HPE. We conclude that the *T. cruzi*-induced trophoblast differentiation is regulated, at least partially, by miR-515-3p and miR-19b-3p. References: 1) Kemmerling U. et al. Defining the Functional Secretory Proteome of *Toxoplasma during* Host Cell Invasion.

E. A. Costa, E. Shortt, S. Lourido; Whitehead Institute for Biomedical Research, Cambridge, MA.

Apicomplexans, including *Toxoplasma gondii*, are obligate intracellular parasites that rely on active invasion of host cells for their survival and replication. Secretion of proteins from specialized organelles called micronemes is essential for parasite motility, attachment to, and invasion of host cells, yet most characterized microneme proteins are dispensable for growth in human fibroblasts, suggesting extensive redundancy and/or context-specific functions. Recent identification of several microneme proteins with novel domains indicates that our current understanding of micronemes is incomplete. To define and characterize their contents, we affinity purified intact micronemes and performed quantitative mass spectroscopy. We identified most known microneme proteins in addition to many uncharacterized proteins with unusual domain architectures. We are currently employing biochemical and genetic approaches to characterize the roles of these novel microneme proteins in host cell recognition and invasion. To systematically dissect functional relationships within the microneme proteome, we have also developed a CRISPR-based screen to assess all pair-wise deletions. This genetic interaction map will define functionally related proteins and probe the phenotypes of redundant components. By defining and characterizing the microneme proteome, our results will elucidate fundamental principles of host-parasite interactions during the crucial step of invasion.

How Do Malaria Parasites Break Two Membranes to Egress from Erythrocytes?

S. E. Glushakova[1], J. R. Beck[2], M. Garten[1], B. L. Busse[1], A. S. Nasamu[3], T. Tenkova-Heuser[1], J. Heuser[1], D. E. Goldberg[3], J. J. Zimmerberg[1]; [1]National Institute of Child Health and Human Development, NIH, Bethesda, MD, [2]Iowa State University, Ames, IA, [3]Washington University School of Medicine, St. Louis, MO.

Asexual replicative cycle of *Plasmodium falciparum* within human erythrocytes causes malaria. The parasite, a single cell organism, isolates itself from the host cytoplasm by a parasitophorous vacuolar membrane (PVM), thus both PVM and erythrocyte membrane must be breached by the time of parasite egress to initiate a new replicative cycle. Parasites developed a highly regulated parasite egress program that relies on a set of kinases and proteases and is regulated by intracellular messengers such as parasite [Ca^{2+}_{free}]. Spatial and temporal coordination of this mechanism is critical to define the targets of the different molecules of the egress program. We used *P. falciparum* with differential fluorescence labeling of the PVM and PV lumen. The natural parasite egress from erythrocytes was followed by employing time-lapse super- resolution fluorescence confocal microscopy and scanning differential interference contrast microscopy. A new obligatory stage in egress was discovered: rounding of the parasitophorous vacuole minutes before egress. Application of known inhibitors of parasite egress allowed us to clearly link sequential, morphologically definable stages of the egress pathway. The first event in the egress program was vacuole rounding, lasted approximately 1.5 minutes and controlled by parasite intracellular calcium. The next step, PVM rupture, was under control of PfPKG and SUB1 and

characterized by a progressive pattern of membrane deterioration over the following ~6 minutes up to parasite egress time. PVM rupture leads to release of vacuolar contents and initiated red blood cell membrane distortion, lasting until the last minute before egress. The newly formed parasites then mobilizes and the red cell permeabilize just before the cascade of events culminates in egress. Erythrocyte membrane rupture is controlled by cysteine proteases, possibly of parasite origin. Taken together, dissection of the membrane degradation events gives us a framework to classify yet undiscovered processes leading to parasite egress from erythrocytes.

P1708/B847

Observation of Cholesterol Sorting in *P. Falciparum* -erythrocytes by 3D Label Free Holotomographic Imaging.

E. H. Hayakawa[1], G. Nardone[2], K. Yamaguchi[3,4], H. Matsuoka[1], H. Kato[1], M. Mori[5], J. Usukura[6]; [1]Jichi Med Univ/Division of Medical Zoology, Shimotsuke, JAPAN, [2]Research Technology Branch, NIAID, NIH, Bethesda, MD, [3]LMS Co., Ltd.,, Tokyo, JAPAN, [4]BIOTEC Co., Ltd.,, Tokyo, JAPAN, [5]Faculty of Pharmaceutical Sciences, Chiba Institute of Science, Choshi, JAPAN, [6]Institute of Material and Systems for Sustainability, Nagoya University, Nagoya, JAPAN.

Cholesterol is essential for the growth and survival of human malaria parasite, *Plasmodium falciparum,* that is the globally important and frequently deadly for young ages. *P. falciparum* lacks a cholesterol synthesis pathway and patients infected with it often have low blood cholesterol and lipoprotein levels. We speculated that *P. falciparum* acquires cholesterol from its external environment. However, it is not completely known from where the source of cholesterol is taken up by parasitized erythrocytes, and how it crosses multiple membranes and enter parasites. To answer these questions, we used different inhibitors; statin, ezetimibe and fibrate, and investigated the effects of those reagents on *P. falciparum* growth in erythrocyte stages with and without existence of hepatocytes. The growth rate of *P. falciparum* was inhibited under the presence of ezetimibe but without hepatocyte. In co-culture system, statin strongly facilitated a better parasite growth than *P. falciparum* alone. To observe cholesterol trafficking in live *P. falciparum* in erythrocytes, we used 3D holotomographic microscopy, which mapped high refractive index for individual cellular components. After *P. falciparum* initially captured free and/or inner erythrocyte membrane-derived cholesterol, we found that the budding lipid membranes elongated and/or migrated into the cytosol and eventually fuse with the parasitophorous vacuole membrane (PVM). Under treatment of ezetimibe, membrane cholesterol accumulated in cytosol of parasitized erythrocytes and did not reach parasite. It is known that the ezetimibe targets Niemann Pick C1 like 1 (NPC1L1) in human and recent study reported that *P. falciparum* has Niemann-Pick type C1-related protein (PfNCR1). Taken together this report and our data, this study suggests; (1) *P. falciparum* imported cholesterol from extracellular environment. (2) Cholesterol is transported as a part of membrane in erythrocyte cytosol. (3) Cholesterol was taken up at the PVM by membrane fusion. (4) Cholesterol finally reaches to parasite via PfNCR1 or homology to NPC1L1. This cholesterol sorting pathway also involves the possible membrane recycling system between PVM and erythrocyte membrane. With few effective antimalarial drugs and no versatile vaccines, cholesterol transport in *P. falciparum* may become an interesting investigation target.

P1709/B848

Battle for Iron between *Leishmania* and Its Host Macrophages: Role of Phagosomal Iron Transporter Nramp1.

S. BANERJEE, R. DATTA; Indian Institute of Science Education & Research Kolkata (IISER K), Mohanpur, Nadia, INDIA.

Iron is critical for the proliferation of the protozoan parasites, *Leishmania* which infect and survive within the phagolysosomal compartment of mammalian macrophages. The underlying mechanism by which *Leishmania* manipulates the iron regulatory mechanism of macrophages to acquire iron for its own survival is still not clear. Natural resistance associated macrophage protein 1 (Nramp1) is an iron transporter which is expressed in the phagosomal compartment of macrophages. This protein was originally discovered because of its association with the host resistance against various intracellular pathogens, including *Leishmania*. However, the exact mechanism by which activity of Nramp1 determines the pathogenesis of *Leishmania* is yet to be discovered. Thus, the aim of this current study is to understand how *Leishmania* modulates macrophage Nramp1 to acquire iron within phagolysosomal compartment. To evaluate this J774A.1 and peritoneal macrophages of BALB/c mice has been infected with *Leishmania major* (*L. major*) and the expression level of Nramp1 was determined using Western blot and qRT-PCR and compared between uninfected and infected cells in a time dependent manner. Altered localization of the protein during infection has been studied using immunofluorescence. The total intracellular and phagosomal iron content of uninfected and infected macrophage cells was measured using ferrozine based assay. Moreover, pharmacological inhibition study has been performed to check whether Nramp1 follows proteasomal degradation pathway during *L. major* infection. Our results show infection of macrophage cells with *L. major* temporally modulates the expression of Nramp1 at the protein level without effecting its transcription. Interestingly, Nramp1 is largely present in the phagosomal compartment of uninfected macrophages but it moves to phagolysosomes during infection. Further, our results clearly demonstrate during infection downregulation of Nramp1 significantly increases the total as well as phagosomal iron content of macrophages. This increased level iron due to the loss of Nramp1 stimulates the replication of the parasite within infected macrophages. Importantly, we have established that degradation of Nramp1 during infection follows the proteasomal pathway. Collectively, this is the first report which provides direct evidences of Nramp1 to be an iron exporter and explains how *Leishmania* parasites impair the iron homeostasis of its host macrophages orchestrating the inhibition of Nramp1 for its own survival within phagolysosomes.

Ire1 Activation Leads to *Toxoplasma*-infected Cell Migration.

L. Augusto[1], P. Amin[2], N. Alakhras[3], M. Kaplan[3], R. Wek[2], W. Sullivan Jr[4]; [1]Department of Biochemistry & Molecular Biology, Department of Pharmacology & Toxicology-Indiana University School of Medicine, Indianapolis, IN, [2]Department of Biochemistry & Molecular Biology-Indiana University School of Medicine, Indianapolis, IN, [3]Department of Pediatrics, Herman B Wells Center for Pediatric Research-Indiana University School of Medicine, Indianapolis, IN, [4]Department of Microbiology & Immunology ,Department of Pharmacology & Toxicology-Indiana University School of Medicine, Indianapolis, IN.

Homeostasis of the endoplasmic reticulum (ER) is maintained by regulation of the unfolded protein response (UPR). The UPR is induced by three ER-resident proteins, ATF6, PERK, and IRE1, which each sense perturbations in protein folding in the ER. Induction of the UPR sensory proteins trigger

transcriptional and translational modes of gene expression that serve to expand the ER processing capacity and restore homeostasis. Calcium plays an essential role inside the ER, as calcium imbalance is suggested to alter protein folding and activate the UPR. The intracellular apicomplexan parasite *Toxoplasma gondii* manipulates its infected host cells, using some as "Trojan Horses" to disseminate throughout the body. In the present study, we addressed the mechanisms by which *Toxoplasma* strategically alters ER function and protein homeostasis in host cells, thereby enhancing migration of infected cells. Our results show that association of the parasitophorous vacuole with the host ER increases calcium levels in the host cytosol, leading to activation of IRE1. It has been reported that IRE1 can modulate actin remodeling by binding filamin A, resulting in expansion of processing capacity of the ER. Our results demonstrate that *Toxoplasma* induces IRE1 dimerization leading to an increase of interaction between IRE1 and filamin A, resulting in high levels of cell migration. Our findings identify the underlying mechanisms used by *Toxoplasma* to induce dissemination of infected cells. These findings provide new insights into strategies for treatment of toxoplasmosis.

P1711/B850

Short, Minimal Viral Fusogens Hijack the Actin Cytoskeleton to Drive Cell-cell Fusion.

K. Chan[1,2,3], S. Son[2,3], E. M. Schmid[2,3], A. L. Arthur[3], A. Bhat[3], J. Morstein[3], D. Schlesinger[3], D. A. Stevens[3], D. A. Fletcher[1,2,3]; [1]UC-Berkeley/UC-San Francisco Graduate Group in Bioengineering, Berkeley, CA, [2]Department of Bioengineering, University of California, Berkeley, Berkeley, CA, [3]Marine Biology Laboratory, Physiology Course, Woods Hole, MA.

Cell-cell fusion is essential for fertilization and tissue development in metazoans, and it is sometimes used by some viruses to form pathological syncytia. Cell-cell fusion is typically driven by fusogenic membrane proteins with tall (>10 nm) ectodomains that are similar to fusogens involved in enveloped viral entry. Their height likely enables them to bridge the gap between the densely-crowded plasma membranes and anchors into the opposing membrane. These fusogens then fold back to bring the two membranes into close contact to drive fusion. However, some fusogenic proteins, such as the non-structural fusion-associated small transmembrane (FAST) proteins from orthoreovirus and aquareovirus, have surprisingly short ectodomains (<2 nm) that reside within the repulsive hydration barrier that prevents membranes from coming in close contact. Yet, expression of FAST proteins in cells is sufficient to drive fusion with naïve neighboring cells, raising the question of how they bring plasma membranes in close contact for fusion. We found that p14, the reptilian reovirus FAST protein, hijacks the actin cytoskeleton to drive cell-cell fusion. Using bioinformatics, in vitro kinase and motility assays, splitYFP cell-cell fusion assay, fluorescence imaging and molecular biology techniques, we found that a tyrosine in the disordered cytoplasmic domain of p14 is important for fusion and is phosphorylated by c-src kinase. Upon phosphorylation, p14 binds to an adaptor protein, Grb2, and subsequently binds to N-WASP to nucleate branched actin assembly. This molecular pathway can be replaced by directly coupling p14 to actin assembly by using a 47-residue peptide to relieve the auto-inhibition of N-WASP. We propose that actin assembly coupled to the cytoplasmic tail of p14 provides localized force generation necessary to overcome the repulsive hydration barrier and to bring the plasma membranes in close contact so that fusion can occur. To investigate if other members of the FAST family also hijack the host actin cytoskeleton to drive cell-cell fusion, we used bioinformatics to screen all known FAST proteins for binding motifs to adaptor proteins. Interestingly, while none contained the same Grb2-binding motif found in p14, other actin-related adaptor proteins were predicted. Preliminary evidence suggests that other FAST proteins could couple to the actin cytoskeleton using these adaptor proteins to drive cell-cell

fusion, suggesting a conserved mechanism. This work reveals that overcoming energetic barriers to cell-cell fusion does not require conformational changes of tall fusogens but can instead be driven by locally harnessing the actin cytoskeleton.

Flaviviruses Exploit Src-family Kinases to Orchestrate Secretion of Progeny Virions.

M. Li[1], T. Shivaprasad Naik[1], L. Siu[1], N. Porciello[2], E. Spooner[3], J. Ashour[4], P. Wang[5], Y. Lin[6], **R. Bruzzone**[1], S. Sanyal[1]; [1]HKU-Pasteur Research Pole, Hong Kong, CHINA, [2]University of Oxford, Oxford, UNITED KINGDOM, [3]Whitehead Institute for Biomedical Research, Cambridge, MA, [4]Icahn School of Medicine at Mount Sinai, New York, NY, [5]Capital Medical University, Beijing, CHINA, [6]The First Affiliated Hospital of Guangzhou Medical University, Guangdong, CHINA.

Among the various host cellular processes that are hijacked by flaviviruses, very few mechanisms have been described with regard to viral secretion. Here we investigated how flaviviruses exploit the Src family kinases (SFKs) for transport and release through the host secretory pathway. We isolated three members of the SFK family - Src, Fyn and Lyn - that were activated upon Dengue and Zika infection, and also during secretion of the corresponding virus like particles (VLPs). Inhibiting their activity by pharmacological means or individual gene-depletions blocked virus production. Lyn-depletion displayed the most significant defect; we therefore generated $Lyn^{-/-}$ cells using CRISPR/Cas9 and reconstituted with its wild-type and mutant variants. Virus secretion was significantly impaired in $Lyn^{-/-}$ cells, and was rescued when reconstituted with wild-type Lyn, but not a kinase- or palmitoylation-deficient Lyn mutant. Using biochemical and imaging analyses, we established that Lyn, via its palmitoylation-dependent membrane association, triggered post-Golgi virus transport in Rab11 and Transferrin receptor positive vesicles, indicative of secretory exosomes. In the absence of Lyn activity or its aberrant membrane association, virions were sorted into the lysosomal pathway for degradation. Interestingly, Lck, a Lyn-homologous kinase, could rescue this defect in the $Lyn^{-/-}$ cells when expressing the wild-type, but not its palmitoylation-deficient mutants, indicating that members within SFK subfamilies equipped with similar biophysical properties can compensate for this mechanism of virus secretion.

Employing a Cardiotropic Mouse Adenovirus to Model Acute Viral Myocarditis and Investigate Mechanisms of Arrhythmogenesis.

R. Padget[1,2], M. North[3], D. King[1,2], P. Calhoun[4,2], S. Barrett[5], S. Poelzing[2,6,3], J. Smyth[2,4,3]; [1]Translational Biology Medicine and Health Graduate Program, Virginia Tech, Blacksburg, VA, [2]Fralin Biomedical Research Institute, Roanoke, VA, [3]Virginia Tech Carilion School of Medicine, Roanoke, VA, [4]Biological Sciences, College of Science, Virginia Tech, Blacksburg, VA, [5]Biomedical Sciences and Pathobiology, Virginia Tech, Blacksburg, VA, [6]Department of Biomedical Engineering and Mechanics, College of Engineering, Virginia Tech, Blacksburg, VA.

Cardiovascular disease remains the leading cause of death in the United States with up to 42% of sudden cardiac death in young adults caused by myocarditis. Subcellular remodeling of the cardiomyocyte occurs during cardiomyopathy with disruptions in gap junction-mediated electrical coupling known to lead to fatal arrhythmias. The primary cardiac gap junction protein, connexin43 (Cx43), propagates innate and adaptive antiviral immune responses, leading us to hypothesize perturbations in gap junction function during active viral infection contribute to sudden cardiac death in

young adults. Adenovirus is a major etiological agent of viral myocarditis but our understanding of adenoviral infection in the heart is lacking due to viral host species specificity. Moreover, data on late-stage illness dominate in the clinic and laboratory with a resulting paucity of research focusing on mechanisms of acute viral myocarditis, and the effect of active adenoviral infection on cardiomyocyte function and arrhythmogenesis prior to induction of the immune response. Currently, Coxsackievirus and parvovirus predominate in modeling viral myocarditis but these pathogens are molecularly distinct from adenovirus in mechanisms of replication and cardiac pathology. Mouse adenovirus Type-3 (MAdV-3) was previously identified to be cardiotropic, therefore, we hypothesize that MAdV-3 can be used to model acute adenoviral myocarditis and induces an arrhythmogenic substrate. C57BL/6 adult male mice were infected via retro-orbital injection of MAdV-3 with viral tissue tropism and cardiac function assessed 7 days post-infection. Our results confirm MAdV-3 is cardiotropism by quantitative PCR of viral genomes across tissues. No significant changes in histopathology or cardiac function by echocardiography were detected in infected hearts as well so no apparent immune cell infiltration. Molecular assays, however, reveal alterations in Cx43 by western blot and immunofluorescence indicative of arrhythmogenic subcellular alterations during MAdV-3 infection. Current work includes *ex vivo* pacing of Langendorff-perfused hearts to measure conduction velocity and susceptibility of arrhythmogenesis. Taken together, our data confirm MAdV-3 as a significant and relevant model of acute adenoviral myocarditis in which antiviral and anti-arrhythmia therapeutic strategies can be developed and tested.

P1714/B853

The Intrinsic Link between Metabolic and Antiviral States of the Cell.

S. Shi, A. Compton; National Cancer Institute, Frederick, MD.

Acute treatment of cells with Rapamycin promotes gene delivery by facilitating lentiviral vector entry into cells. We recently showed that mTOR inhibitors lower an intrinsic antiviral barrier mediated by the interferon induced transmembrane proteins (IFITMs), in particular IFITM3. Rapamycin-mediated degradation of IFITM3 requires endosomal trafficking, ubiquitination, endosomal sorting complex required for transport (ESCRT) machinery, and lysosomal acidification. Lentiviral transduction of diverse human and murine cells, including CD34+ hematopoietic stem progenitor cells and fibroblasts, was enhanced following acute Rapamycin treatment and enhancement was diminished upon *IFITM* knock-down or knock-out. In addition to enhancing infection by lentiviral vectors, we found that Rapamycin increased infection of replication-competent Influenza a virus by more than 10-fold. We have subsequently shown that rapamycin downregulates interferon-induced IFITM3 in the microglial cell line CHME and in monocyte-derived macrophages, which results in increased permissiveness to HIV-1 infection. Here, we describe our efforts to characterize the signaling pathway(s) that result in the negative regulation of IFITM3 during mTOR inhibition. We found that mTOR complex 2 (mTORC2) is the likely complex controlling IFITM3 levels in cells because cell starvation had minimal effect on IFITM3 while it was downregulated following knockdown of Rictor, an mTORC2 component. This result suggests that mTORC2 activity promotes the stability and function of IFITM3, linking a central metabolic regulatory network to the cell-intrinsic antiviral response. Interestingly, we found the knockdown of IFITM3 in HeLa cells resulted in decreased levels of p-Akt Ser473, suggesting that IFITM3 positively regulates Akt activation. This finding suggests a functional interdependence of IFITM3, Akt, mTORC2. Our data may suggest that 1) IFITM3 promotes Akt function by positively regulating mTORC2 signaling, and 2) a negative feedback mechanism exists which results in IFITM3 degradation following mTORC2

inactivation. We are now in the process of identifying other cellular factors that populate these interconnected pathways. Future work will include how IFITM3 influences Akt signaling during oncogenesis, since the upregulation of both are associated with cancers. Lastly, mechanistic studies of rapamycin and other mTOR inhibitors are important because these clinically important drugs, while beneficial in the setting of gene therapy *ex vivo*, may be deleterious to antiviral immunity in *vivo*.

P1716/B855

A Peptide Derived from Beclin1 Promotes Lentivirus Infection of Diverse Cell Types by Promoting Virus-cell Adhesion and Fusion.

S. MAJDOUL, A. A. Compton; National Cancer Institute, NIH, Frederick, MD.

The development and use of transduction enhancers can facilitate the infective potential of gene delivery vectors, such as modified lentivirus. We previously found that a Tat-Beclin1 fusion peptide, which consists of the cell-penetrating peptide Tat from HIV-1 and the evolutionarily conserved domain (ECD) of Beclin1, potently enhances VSV-G-mediated transduction of CD34+ HSC by lentiviral vectors. Here we report that Tat-Beclin1 selectively promotes transduction mediated by some, but not all, viral envelope glycoproteins in a cell-dependent manner. These results indicate that enhancement of infection by Tat-Beclin1 involves an interaction between viral and cellular factors. Notably, Tat-Beclin1 increased infection by replication-competent HIV-1 in permissive cells but had no effect on Influenza a replication. To uncover the mechanism of action, we took advantage of a single residues mutation (F207S) in Tat-Beclin1 that completely abrogates its ability to promote infection. It has previously shown that the ECD of Beclin1 exhibits membrane binding activity. By studying the ability of WT and mutant peptides to associate with cells, we found that F207S prevents efficient cell association and endocytic uptake. Thus, the ability of Tat-Beclin1 to promote virus infection is linked to its ability to associate with cells. Next, we focused on the stage of the virus infection cycle that is promoted by Tat-Beclin1. We found that Tat-Beclin1 promotes the adhesion of virus to the surface of cells, which subsequently promotes the steps of virus-cell fusion and transduction. We are now in the process of identifying the membrane lipids that are preferentially targeted by Tat-Beclin1, by measuring in vitro binding between Tat-Beclin1 and liposomes of different compositions. Overall, our results reveal the potential of a Beclin1-derived peptide in gene therapy applications and further identify cell surface lipid composition as a determinant for HIV-1 entry into human cells.

P1717/B856

NUDT21 Links Cytoplasmic Stress Granules to Mitochondrial IPS-1 and Activates Host Defense Responses Against Viral Infection.

S. Aoyama-Ishiwatari, 1130033, T. Okazaki, Y. Gotoh; Graduate School of Pharmaceutical Sciences, the University of Tokyo, Tokyo, JAPAN.

Host cells recognize viral RNAs as “nonself” and trigger anti-viral responses to eliminate invading pathogens. RIG-I like receptors (RLRs) recognize viral RNA in cytoplasmic anti-viral stress granule (avSG), and subsequently activate the mitochondrial adaptor protein interferon-beta promoter stimulator 1 (IPS-1). However, it is not fully understood how RLRs in avSG can activate mitochondrial IPS-1 although they are spatially segregated. In this study, we revealed that Nucleoside diphosphatelinked moiety X (Nudix)-type motif 21 (NUDT21), an RNA-binding protein that regulates alternative polyadenylation in the nucleus, physically associates with IPS-1 and mediates its association with RLRs and activation of its

antiviral functions. We found that a fraction of NUDT21 was localized to mitochondria and, in response to transfection of a viral RNA mimic poly(I:C), it became co-localized to avSG. A fraction of IPS-1 was also found to localized to avSG in response to poly(I:C) transfection, and importantly, NUDT21 was required for this localization change of IPS-1. Furthermore, our data indicated that NUDT21 promotes efficient induction of type I interferons in response to RNA viral infection. These results together suggest that NUDT21 links cytoplasmic RLRs to mitochondrial IPS-1 and activates host defense responses against viral infection.

Defining Therapeutic Targets and New Therapeutics 2

Paneth Cell Dysfunction in Pathophysiology of Nonalcoholic Steatohepatitis.

S. Nakamura[1,2], K. Nakamura[1,3], M. Kikuchi[1], Y. Yokoi[1], S. Ohira[1], Y. Shimizu[1], T. Nishida[1], T. Ayabe[1,3]; [1]Graduate School of Life Science, Hokkaido University, Sapporo, JAPAN, [2]Hokkaido laboratory, Corporate Research & Development Division, Nitto Denko Corporation, Sapporo, JAPAN, [3]Department of Cell Biological Science, Faculty of Advanced Life Science, Hokkaido University, Sapporo, JAPAN.

Background: the prevalence of nonalcoholic steatohepatitis (NASH) is rapidly increasing worldwide. Because fibrosis, a key aspect of the pathophysiology of NASH, plays a crucial role in causing liver cirrhosis and cancer, NASH has become a global health problem. The pathophysiological mechanisms of NASH is not well understood, but emerging evidence indicated involvement of dysbiosis, an imbalance of intestinal microbiota as well as increased intestinal permeability (IP) in NASH, implicating the gut-liver axis. Paneth cells in small intestinal crypts secrete granules containing α-defensins and regulate the intestinal microbiota by potent microbicidal activities against pathogens and less activity against commensal bacteria. Paneth cells further constitute the stem cell niche and contribute to intestinal homeostasis. Thus, we hypothesize that Paneth cell dysfunction is involved in the onset of NASH via dysbiosis and increased IP. **Objective:** We aim to clarify the relationship between disruption of intestinal homeostasis due to Paneth cell dysfunction and onset of NASH. **Methods**: C57BL/6 mice were fed a choline-deficient, L-amino acid-defined, high-fat diet (CDAHFD) for 12 weeks (w) to induce NASH or a standard diet, and were assessed at 3, 6, and 12 w. Secreted α-defensin cryptdin-1 was measured in fecal pellets by ELISA. Paneth cell morphology was analyzed by immunohistochemistry and transmission electron microscopy. The intestinal microbiota was analyzed by 16S rRNA gene sequencing. Serum zonulin, a biomarker for IP, was measured by ELISA. To determine bacterial translocation, homogenized spleen was plated on LB plates and the number of colonies was counted. **Results:** Liver fibrosis was observed in CDAHFD-fed mice slightly at 3 w and progressed gradually over 12 w. α-Defensin secretion was decreased significantly at 3 w and throughout until 12 w. Morphological analysis of Paneth cells revealed the presence of aberrant secretory granules and disruption of endoplasmic reticulum structure at 3 w, evidence of impaired granule secretion and ER stress. CDAHFD-fed mice showed dysbiosis with significantly decreased diversity and altered the composition, increased serum zonulin levels, and bacterial translocation to the spleen. **Conclusion:** These results indicate that along with reduction of Paneth cell α-defensins, dysbiosis accompanied by increased IP occurred in CDAHFD-fed mice from early on, and further suggest Paneth cell dysfunction contributes to pathophysiology of NASH via the gut-liver axis.

Hepatokine Induction by Colchicine Prevents Systemic Inflammation Via Activating PTPN6 Inhibitory Signaling.

J. WENG[1], P. Koch[2], K. Shimada[1], T. J. Mitchison[1]; [1]Harvard Medical School, Boston, MA, [2]Massachusetts General Hospital, Boston, MA.

Inflammation is a protective response to challenges including infection, injury, and tissue stresses. However, failure to resolve inflammation could lead to various diseases. The liver controls tissue metabolism and energy homeostasis by releasing secretory proteins called hepatokines. It is not clear whether liver-hepatokine-leukocyte communication contributes to inflammation regulation. Colchicine, an anti-microtubule and anti-inflammatory medication, is frequently prescribed for gout, Familial Mediterranean Fever, pericarditis, and is being clinically tested for a wide spectrum of diseases. Yet, its usage is limited by its unclear systemic action.By measuring biomarkers of microtubule perturbation and using hepatocyte-specific siRNAs, we uncovered hepatocytes are preferentially targeted by colchicine. Colchicine depolymerizes microtubules of hepatocytes and activates the transcription factor Nrf2, which regulates expression of protective genes, through promoting P62-dependent Keap1 degradation. Targeted hepatocytes subsequently secrete a novel hepatokine, GDF15, into circulation. As a divergent member of the TGF-b family, GDF15 activates inhibitory protein tyrosine phosphatase PTPN6 and inhibits inflammation via blocking leukocyte adhesion, extravasation, and IL-1b production. Our work indicates the liver mediates the anti-inflammatory activity of colchicine and opens the possibility of using anti-inflammatory hepatokines for prevention or treatment of inflammatory diseases, starting with GDF15.

Some Cellular Effects of Triphenylphosphonium Derivatives of Acetylsalicylic Acid.

O. Tsepaeva[1], L. Grigor'eva[2], T. Salikhova[3], T. Dang[3], R. Ishkaeva[3], A. Nemtarev[1], T. Abdullin[3], V. Mironov[1]; [1]Arbuzov Institute of Organic and Physical Chemistry, FRC Kazan Scientific Center of RAS, Kazan, RUSSIAN FEDERATION, [2]Alexander Butlerov Institute of Chemistry, Kazan (Volga region) federal university, Kazan, RUSSIAN FEDERATION, [3]Institute of Fundamental Medicine and Biology, Kazan (Volga region) federal university, Kazan, RUSSIAN FEDERATION.

Conjugation of natural compounds and active molecules with triphenylphosphonium (TPP) group has proved to be a powerful strategy for the development of effective cellular modulators and drug candidates with various activities. In this study, the TPP conjugates of acetylsalicylic acid (acetyl phosphonioalkyl-$(CH_2)_n$-salicylates (compounds 1-6)) were synthesized and characterized. The compounds 1-6 inhibited fluorescence of 2',7'-dichlorofluorescin (diacetate) probe (DCF) upon oxidation in proportion to the alkyl linker length. Effective accumulation of the TPP- acetylsalicylic acid conjugates in bacterial and mammalian cells at micromolar concentrations was detected using DCF as an intracellular probe. Bacteriostatic and antiproliferative effects of the TPP-acetylsalicylic acid conjugates were studied with the aid of broth microdilution method and MTT assay, respectively. The TPP group provided enhanced activity of the compounds against both Gram-positive bacteria and cancer cell lines with MIC and IC_{50} values as low as c.a. 1 μM. The cellular effects of the compounds were also linker-dependent. According to dynamic light scattering technique, the selected conjugate differently affected the zeta potential of E. coli and S. Aureus after 1 h treatment of the bacteria with the compound. The results suggest potential antibacterial and anticancer activities of the synthesized TPP-acetylsalicylic acid

conjugates. In vitro mechanisms of their action are under investigation. This work was funded by the subsidy allocated to Kazan Federal University (4.5151.2017/6.7) and by the Program of Competitive Growth of KFU.

P1721/B861

Explaining the Relative Inactivation Efficiencies of FAAH Inhibitors BIA 10-2474, JNJ-42165279 and PF-04457845.

M. Neves, N. M. F. S. A. Cerqueira, N. Palma, **P. Soares-da-Silva**; Bial – Portela & Companhia, S.A., Coronado (S. Mamede & S. Romão), PORTUGAL.

BIA 10-2474 is a fatty acid amide hydrolase (FAAH) inhibitor which was under clinical development [1], when a phase I trial was ended prematurely in 2016, after one person passed away and four other subjects suffered severe emergent CNS adverse events. The inactivation efficiency (k_{inact}/K_I) of BIA 10-2474 was previously studied and compared to those of other FAAH inactivators (JNJ-42165279 and PF-04457845) under clinical evaluation. All three molecules are time-dependent FAAH inactivators and PF-04457845 is the most efficient one, whereas JNJ-42165279 and BIA 10-2474 present lower in vitro inactivation efficiencies. [2] Advanced computational chemistry methods were employed to study the mechanisms of enzyme inactivation induced by the three investigational drugs. Based on these results the nature of the differences in their inactivation efficiencies is discussed. The molecular interactions were studied by extended molecular docking and dynamics simulations, whereas the detailed inactivation mechanisms of the reaction with the enzyme were studied using hybrid quantum mechanics/molecular mechanics (QM/MM). In the initial step of time-dependent inactivation, the inhibitor is required to enter and explore the enzyme's active site, where non-covalent interactions will eventually steer the molecule towards a near-reactive configuration, before it may react with the catalytic triad and form an irreversible adduct. The kinetic efficiency of this initial process affects the rate of the time-dependent inhibition. Our results show that PF-04457845 is the most efficient of the three inhibitors, followed by JNJ-42165279 and by BIA 10-2474. On the other hand, our QM/MM calculations confirmed that all three inhibitors may readily react with the enzyme's catalytic triad and form irreversible adducts, even though through distinct reaction mechanisms. Overall, our results allow to conclude that the rate-limiting step of the time-dependent inactivation of FAAH by all three compounds, is the formation of a specific near-reactive configuration between enzyme and inhibitor. Anthrax Edema Toxin Co-opts IGF1R and EGFR Signaling to Promote Cell-cell Barrier Dysfunction.

P. Jain[1], M. Moayeri[2], A. Guichard[1], E. Bier[1]; [1]University of California, San Diego, San Diego, CA, [2]National Institute for Allergy and Infectious Disease, Bethesda, MD.

Cell-cell barrier dysfunction induced by *Bacillus anthracis* edema toxin (ET) is central to bacterial dissemination and lethal vascular collapse manifested during the fulminant, late-stages of infection. Available treatments including antimicrobial and early-stage antitoxin measures offer very limited protection against anthrax-induced fatality once the toxins released by the vegetative bacilli enter host cells and tissues and exert their intracellular function. Therapeutic measures that specifically mitigate

the consequences of cellular intoxication by anthrax toxins could effectively stem and potentially reverse the extreme morbidity and high fatality rates associated with systemic anthrax. This study identifies cell-based therapeutic measures that target the late-stage intracellular activities of ET and their potential to mitigate the consequences of ET toxemia. Using cell-based mechanistic studies, we uncover a critical involvement of receptor tyrosine kinases EGFR and IGF1R in promoting ET-dependent barrier disruption through effects on cellular F-actin network dynamics that are separate from, but have an impact upon, previously characterized EF-mediated inhibition of Rab11-dependent vesicular trafficking. ET rapidly trans-activates IGF1R and EGFR, resulting in the activation of downstream effectors PI3K and MEK, and subsequently a Rac1- and cofilin-dependent actin remodeling. Furthermore, we provide in *vivo* pre-clinical validation of the therapeutic potential of PI3K, MEK and Rac1 inhibitors in preventing ET-dependent edema in a mouse footpad model. In conclusion, we identify a combinatorial set of druggable cellular targets that mitigate late-stage effects of anthrax ET. Antitoxin measures targeting ET should significantly enhance patient survival during advanced, systemic stages of the disease.

P1723/B863

Claudin Targeting by Modular Biologicals Based on *Clostridium Perfringens* Enterotoxin.

L. Beier[1], A. Piontek[2], M. Eichner[1], J. Protze[2], D. Zwanziger[3], J. Rossa[2], S. Bergmann[4], J. M. Brandner[4], N. Zitzmann[5], G. Krause[2], J. Piontek[1]; [1]Charité - Universitätsmedizin Berlin, Institute of Clinical Physiology, Berlin, GERMANY, [2]Leibniz-Forschungsinstitut für Molekulare Pharmakologie (FMP), Berlin, GERMANY, [3]University Hospital Essen, Department of Endocrinology, Diabetes and Metabolism and Clinical Chemistry – Division of Laboratory Research, Essen, GERMANY, [4]Department of Dermatology and Venerology, University Hospital Hamburg Eppendorf, Hamburg, Hamburg, GERMANY, [5]Oxford Glycobiology Institute, Department of Biochemistry, South Parks Road, University of Oxford, Oxford OX1 3QU, Oxford, UNITED KINGDOM.

Clostridium perfringens enterotoxin (CPE) is a bacterial, ß-pore-forming toxin. It binds to the extracellular domain of some claudins, e.g. claudin-3 (Cldn3), -4 or -7. CPE-insensitive claudins include Cldn1, -2 and -5. Upon binding to its receptors via its C-terminal domain (cCPE), the CPE-claudin complexes rapidly oligomerizes and the N-terminal domains form a ß-pore in the plasma membrane leading to Ca^{2+}-influx induced cell death. Structure-guided mutagenesis of full length CPE and the non-toxic cCPE enabled targeting of otherwise CPE-insensitive claudins. The mutations S305P/S307R/S313H facilitates binding to Cldn1-9, whereas mutation S231R/S313H improved Cldn1-binding properties. Here we present different applications of modified (c)CPE (i) Cldn1 and CD81 constitute an essential entry factor for hepatitis C virus (HCV). We showed that, in contrast to cCPEwt, cCPE-S305P/S307R/S313H efficiently inhibits HCV infection of human Huh7.5 hepatoma cells. Homology models suggest that cCPE-SSS masks residues in the extracellular domain of Cldn1 which are required for interaction between Cldn1 and CD81. FRET analysis in HEK-293 cells co-transfected with CFP-Cldn1 and YFP-CD81 affirms this theory.(ii) Various cancer entities have deregulated and delocalized claudin expression. Cldn1 expression is upregulated in a broad spectrum of cancers, e.g. thyroid and lung cancer. Substitution S231R/S313H enabled targeting of Cldn1-overexpressing papillary thyroid carcinoma cells (K1) and improved that of non-small cell lung cancer (PC-9). Cell line-derived xenografts of PC-9 and K1 tumors had a markedly reduced growth rate after intra-tumoral injection with CPE-S231R/S313H. Histological and immunofluorescence staining revealed that this effect is due to an increase in necrotic tissue and reduced proliferative activity of the cancer cells.(iii) Tight junctions in the *stratum granulosum*,

containing Cldn1 and -4, contribute to the epidermal barrier. Treatment of reconstructed human epidermis with cCPE variants weakened the epidermal barrier as suggested by transepithelial resistance and Lucifer Yellow flux measurements. A transient opening of the epidermal barrier might improve transdermal drug delivery.In sum, we were able to show that directed mutagenesis of cCPE and CPE facilitates targeting of otherwise CPE-insensitive claudins. This opens up new possibilities of therapeutic application of cCPE and CPE where a claudin-directed approach is advantageous.

***In Vitro* Effects of Fluoroacetate and Fluorocitrate Toxicity.**

V. E. DeLey Cox, M. Racine, M. A. Hartog, A. Dukes, E. Pueblo, L. Jennings, J. Tressler, W. Y. Tuet, S. Stone, S. Pierce, L. Thompson, H. Hoard-Fruchey, B. Wong, B. J. McCranor; USAMRICD, Aberdeen Proving Ground, MD.

Despite its early application as a rodenticide, fluoroacetate, an acutely toxic metabolic poison, is restricted in the United States due to comparable lethality to other mammals, including humans. Although the mechanism of action is known, no countermeasures have been identified, and accidental ingestion by humans commonly results in death. Once internalized, fluoroacetate undergoes a “lethal synthesis” and is converted to fluorocitrate, a tightly binding competitive inhibitor of mitochondrial aconitase, effectively halting mitochondrial respiration. This disruption of the citric acid cycle leads to mitochondrial dysfunction with physiological symptoms including cardiac dysfunction, neurological effects, and renal failure. By characterizing the cellular effects of the toxicant fluoroacetate, and the toxin fluorocitrate, we can more effectively evaluate possible courses of treatment and better understand how to defend against metabolic poisons that target the citric acid cycle. Using an in *vitro* model, we have increased understanding of fluoroacetate toxicity. Since only a small amount of fluoroacetate is converted to fluorocitrate, the toxicant was not an effective compound to study the effects on human cells in *vitro*. However, in response to fluorocitrate, mitochondrial respiration in cardiomyocytes showed concentration- and time-dependent responses with decreases in maximal and spare respiratory capacity ($p < 0.01$), thereby generating a baseline against which to evaluate potential medical countermeasures. Multiple classes of therapeutics were analyzed: antioxidants, for their ability to minimize cellular damage; TCA substrates, which enter the citric acid cycle downstream of aconitase, in an effort to rescue cellular respiration; and mediators of alternative energy pathways for their ability to improve cellular viability with the goal of allowing an organism the opportunity to clear the toxin over time. In hepatocytes, the antioxidants glutathione and N-acetyl-L-cysteine and citric acid cycle substrates D,L-isocitric acid and glycerol monoacetate showed the greatest promise. Together, these analyses offer a comprehensive view of the cellular effects of fluoroacetate/fluorocitrate intoxication and provide critical direction to the search for effective medical countermeasures to this and other metabolic poisons.

Binding and Inactivation Mechanisms of the Fatty Acid Amide Hydrolase Inhibitor BIA 10-2474.

N. M. F. S. A. Cerqueira, M. Neves, N. Palma, **P. Soares-da-Silva**; Bial – Portela & Companhia, S.A., Coronado (S. Romão e S. Mamede), PORTUGAL.

Several inhibitors of fatty acid amide hydrolase (FAAH) have been developed as a strategy for the treatment of various nervous system disorders [1]. In 2016, during a phase I clinical trial with the FAAH

inhibitor BIA 10-2474, five subjects suffered severe emergent CNS adverse events, with one fatal outcome. The mechanism of FAAH inactivation by BIA 10-2474 was wherein studied with atomistic resolution using molecular docking, molecular dynamics simulations and hybrid quantum mechanics/molecular mechanics (QM/MM) simulations. These results were also compared with the catalytic mechanism of the FAAH natural substrate oleamide. Our results are consistent with the observed time-dependent FAAH inactivation by BIA 10-2474 [2]. Upon binding to the active site, the inhibitor eventually adopts a low energy near-reactive configuration, where the urea moiety is effectively cleaved by the enzyme's catalytic triad (Ser-*cis*Ser-Lys) and forms a stable carbamoyl adduct. The QM/MM results demonstrate that the hydrolysis of this adduct, as well as the reverse reaction have very high activation free energies and are not possible under physiological conditions, therefore leading to the irreversible inactivation of the enzyme. The results also reveal the important role played by FAAH Thr236 in the reaction with BIA 10-2474, which is specific of FAAH and is not present in other serine hydrolases. It forms a hydrogen bond with the imidazole nitrogen of the inhibitor, and helps lowering the activation free energy of the first step of the reaction, by pre-orienting and stabilizing the inhibitor in a near-reactive configuration. Finally, the comparison with the catalytic mechanism of the natural substrate oleamide also reveals key differences between substrate and inactivator. The inhibitor shows a faster and more effective reaction with the enzyme to form a stable and irreversible carbamoyl adduct, whereas the substrate forms a transient acyl adduct that can be readily hydrolyzed by water to complete the catalytic cycle and regenerate the active enzyme. 1. Identification of Cathepsin D as a Plasma Biomarker Candidate for Alzheimer's Disease.

J. Kim[1], Y. Kim[1], S. Jung[1], S. Lee[2], J. Chang[1]; [1]Ajou University School of Medicine, Suwon, KOREA, REPUBLIC OF, [2]Inha University College of Medicine, Incheon, KOREA, REPUBLIC OF.

Although Alzheimer's disease (AD) is the most common neurodegenerative disease, there are still no drugs available to treat or prevent AD effectively. However, efforts to develop early diagnostic ways should also be made along with the development of treatment of AD for appropriate medical intervention from the early stage of the disease. Here, we examined changes in levels of selected proteins implicated in the pathogenesis of AD using plasma samples of control subjects and patients with cognition impairment. To precisely categorize the disease, fifty-six participants were examined with clinical cognitive tests, amyloid PET scan and white matter hyperintensities were scored by magnetic resonance imaging. Plasma cathepsin D levels of the subjects were examined by immunoblotting and ELISA and compared between groups. Correlation of plasma cathepsin D levels with AD-related factors and clinical characteristics was examined by statistical analysis. By analyzing quantitative immunoblot and ELISA, we found that the plasma level of cathepsin D, a major lysosomal protease, was significantly decreased in the group with amyloid plaque deposition at the brain compared to the control group. The level of plasma cathepsin D was negatively correlated with CDR-SB scores. These results suggest that the plasma cathepsin D level could be developed as a diagnostic biomarker candidate of AD. Results of this study also suggest that lysosomal degradation activity could be associated with the onset or progression of AD.

P1727/B867

Brain Somatic Mutations in Mtor Reveal Translational Dysregulations Underlying Intractable Focal Epilepsy.

J. Kim; KAIST, Daejeon, KOREA, REPUBLIC OF.

Brain somatic mutations confer genomic diversity in the human brain and cause neurodevelopmental disorders. Recently, brain somatic activating mutations in *MTOR* have been identified as a major etiology of intractable epilepsy in patients with cortical malformations. However, the molecular genetic mechanism of how brain somatic mutations in *MTOR* causes intractable epilepsy has remained elusive. In this study, translational profiling of intractable epilepsy mouse models with brain somatic mutations and genome-edited cells revealed a novel translational dysregulation mechanism and mTOR activation-sensitive targets mediated by human *MTOR* mutations that lead to intractable epilepsy with cortical malformation. These mTOR targets were found to be regulated by novel mTOR-responsive 5′ UTR motifs, distinct from known mTOR inhibition-sensitive targets regulated by 5′ TOP motifs. Novel mTOR target genes were validated in patient brain tissues, and the mTOR downstream effector eIF4E was identified as a new therapeutic target in intractable epilepsy via pharmacological or genetic inhibition. We show that metformin, an FDA-approved eIF4E inhibitor, suppresses intractable epilepsy. Altogether, the present study describes translational dysregulation resulting from brain somatic mutations in *MTOR*, as well as the pathogenesis and potential therapeutic targets of intractable epilepsy.

P1728/B868

Identifying Loss-of-function Mutants That Confer Resistance to Antidepressants in *Saccharomyces Cerevisiae*.

P. A. Elizalde, J. Ou, J. S. Choy; the Catholic University of America, Washington, DC.

Serotonin transporters are the primary targets of one of the most highly prescribed classes of antidepressants, the selective serotonin reuptake inhibitors (SSRIs). Yet, it is unknown what additional biological pathways and targets SSRIs might have. To address this question, there have been several studies of antidepressants in the budding yeast, *S. cerevisiae* investigating possible “off-target” effects of SSRIs. Budding yeast is an ideal organism for “off-target” effects since they lack serotonin transporters. However, most reports have focused on loss-of-function mutations that render cells hypersensitive to SSRIs. While this work has pointed to new activities such as chromatin remodeling, it remains challenging to determine the direct target(s). We sought to complement these results by screening for mutations that confer resistance. Isolating resistant mutants has the potential to identify direct drug targets or activities required for drug toxicity, giving important insights into drug mechanism. In this work, we screened a yeast library comprised of 4,577 gene deletions for deletions resistant to fluoxetine, also known as Prozac. The primary screen identified 103 deletions that were resistant to an otherwise lethal dose of fluoxetine. We performed spot test assays for resistance to fluoxetine as well as another SSRI, sertraline (Zoloft), and a non-SSRI, amitriptyline (Elavil). We confirmed 48 gene deletions conferred some degree of resistance to at least one of the drugs. We remade 18 of the most resistant deletions to fluoxetine and observed that 10 of the *de novo* deletions displayed resistance to fluoxetine, suggesting that the majority of the 48 deletions are true positives. In addition to genes that function in vacuolar-ATPase activity, which were previously implicated, we found several genes with functions in protein homeostasis (e.g. protein degradation and synthesis). We are working toward understanding how changes in protein homeostasis confer resistance to SSRIs. We have so far tested the hypothesis

that these mutants increase drug efflux activity and found that most do not change the activity of the major efflux pump, Pdr5. Efforts are underway to characterize the physiology of cells treated with SSRIs in order to understand how protein homeostasis mutants may be able to confer resistance. This work will contribute to a better understanding of how antidepressants might act in neuronal cells by revealing new targets apart from the serotonin reuptake transporter. Considering that antidepressants are orally taken, homologous microbial targets might lead to changes in gut microbial activity and/or composition, that may play an important role in antidepressant efficacy.

P1729/B869

Lack of Association of Tnf-α Functional Variant (-308 G/A) with Turkish Schizophrenia Patients.

K. Ozdilli, 34156[1], H. Aytac[2], F. Tuncel[3], M. Pehlivan[4], M. Yazar[2], S. Pehlivan[3]; [1]Medipol University, Faculty of Medicine, Department of Medical Biology, Istanbul, TURKEY, [2]Bakirkoy Research and Training Hospital for Psychiatry, Neurology and Neurosurgery, Istanbul, TURKEY, [3]Istanbul University, Istanbul Faculty of Medicine, Department of Medical Biology, Istanbul, TURKEY, [4]Department of Internal Medicine (Haematology), Gaziantep Univesity, Faculty of Medicine, Gaziantep, TURKEY.

Schizophrenia (SCZ) is one of the most common devastating psychiatric disorders that negatively affects the quality of life and psychosocial functions. Inflammatory markers are well-known etiological factors for psychiatric disorders, including schizophrenia. Tumor necrosis factor (TNF), encoded by TNF-α gene has an important role in the apoptotic mechanisms of autoimmune diseases. Recently, TNF-α polymorphisms and autoimmune/psychiatric disorders have been reported to be related. This study aims to determine the impact of functional variant in the TNF- α gene (-308 G/A) on the susceptibility of schizophrenia. The TNF- α gene variant (-308 G/A) were genotyped 119 individuals with SCZ patients and 94 healthy controls. Through applying salting out procedure, we extracted DNA from peripheral blood samples. These variant were analyzed using PCR-RFLP. De Finetti program and SPSS version 14.0 for Windows were used for analyzing the data. The presence of genotypes with SCZ patients were A/A 86.5%,G/A 11.7% and G/G 1.6% whereas A/A 81.9%,G/A14.9% and G/G3.2% in healty controls. No significant differences were observed between groups for TNF- α gene variant (-308 G/A) genotypes and allele frequencies in SCH patients. Our results showed that functional variant of the TNF- α gene (-308 G/A) might not play a potential role in SCZ pathophysiology. However, further studies are warranted involving a larger sample size to strengthen our findings.

(-)-Epigallocatechin-3-gallate Treatment Increases Survival of Pml/rarα Mice, Reduces Leukemic Burden and Induces Cell Differentiation.

F. I. Della Via[1], R. N. Shiraishi[1], I. Santos[1], K. P. Ferro[1], M. J. S. Terreros[1], F. M. Roversi[1], G. C. Franchi Junior[2], E. M. Rego[3], S. T. O. Saad[1], **C. O. Torello**[1]; [1]Hematology and Transfusion Medicine Centre – Hemocentro, University of Campinas, Campinas, BRAZIL, [2]Onco-Hematological Child Centre, Faculty of Medical Sciences, University of Campinas, Campinas, BRAZIL, [3]Hematology and Clinical Oncology Divisions, Department of Internal Medicine, University of São Paulo, Ribeirão Preto, BRAZIL.

(-)-Epigallocatechin-3-gallate (EGCG) is a gallate ester obtained by the condensation of gallic acid with the (3R)-hydroxy group of (-)-epigallocatechin. This component, extracted from green tea, has multiple effects on signal transduction pathways and enzyme activities which could enhance apoptosis and suppress of cell proliferation, invasion, angiogenesis and metastasis in cancers. This study aims to

evaluate the effect of EGCG in an experimental model of leukemia. NOD.CB17-Prkdc^{scid}/J mice received 2*Gy* irradiation followed by transplantation of leukemia cells obtained from hCG-PML-RARα transgenic mice by i.v. Injection in the caudal vein. Establishment of disease was confirmed at day 12 through presence of leukocytosis, and/or anemia, and/or thrombocytopenia, associated to the presence of blasts in blood. At 12th day, mice (n=10/group) were randomly selected to receive EGCG (25mg/kg/day) or vehicle i.p. For five consecutive days. Mice were then sacrificed and peripheral blood (PB), bone marrow (BM) and spleens were collected for flow cytometry and western blot analysis. Hematological analysis revealed that EGCG treatment reversed leukocytosis (p=0.0371), anemia (p=0.0155) and thrombocytopenia (p=0.0179) and prolonged survival of PML/RARα mice (p=0.0017). Notably, EGCG reduced leukemia immature cells (CD45$^+$CD34$^+$)(p=0.0060) and promyelocytes (CD45$^+$CD117$^+$)(p=0.0157) in BM of mice whereas increased mature myeloid cells (CD11b$^+$Gr-1$^+$)(p=0.0051), possibly by inducing cellular differentiation. These results were corroborated by the reduction in promyelocytes (p=0.0154), and the increase in neutrophils (CD45$^+$Gr-1$^+$)(p=0.0178) and monocytes (CD45$^+$CD11b$^+$)(p=0.0463) detected in PB. We then evaluated the effect of EGCG on cellular differentiation by studying degradation of PML/RARα oncoprotein. EGCG increased the percentage of cells with aggregated PML bodies stain in the BM of PML-RARα mice, suggestive of higher degradation of oncoprotein, parallel to a reduction in PIN1 expression in BM cells. Higher intracellular levels of reactive oxygen species (ROS) were also detected in leukemia immature cells (p=0.0051), promyelocytes (p=0.0271) and neutrophils (p=0.0033) of BM. These results are consistent with literature data demonstrating that the ablation of PIN1 and/or induction of ROS could trigger PML/RARα degradation. Furthermore, apoptosis was detected in spleen cells of PML-RARα mice (p=0.0197) in parallel to increased expression of BAX, reduced expression of BCL-2, and reduction of spleen weight (p=0.0085). Collectively, our results support further evaluation of EGCG in clinical trials for acute myeloid leukemia.

P1731/B871

Rac1 Stimulation of Oxidative Stress Signaling Contributes to Epithelial to Mesenchymal Transition in Ovarian Cancer Cells.

M. Grimes, D. R. Dominguez, M. R. Granados, A. Rosales, M. Rivera, A. Wandinger-Ness, L. G. Hudson; University of New Mexico, Albuquerque, NM.

The Rho family of small GTPases, including Rac1 and Cdc42 are often overexpressed in cancer and associated with poor patient outcomes. Elevated Rac1 activity promotes cell proliferation, quiescence, epithelial to mesenchymal transition (EMT) and transcriptional programs relevant to tumor development, progression and chemoresistance. In this study, modest (~4-fold) overexpression of Rac1 in ovarian tumor cells caused morphological changes consistent with EMT. Rac1 overexpression decreased colony number, increased colony area, and increased cell invasion through an artificial basement membrane 10-fold when compared to vector control cells. An increase in mesenchymal markers (e.g. N-cadherin and vimentin) and decrease in epithelial markers (e.g. E-cadherin, claudin) was observed as a consequence of Rac1 expression. Rac1 overexpression was associated with selective up-regulation of certain EMT transcriptional regulators with increased mRNA expression of Slug/Snai2 (8-fold) and Zeb2 (100-fold) and little impact on Snai1, Twist or Zeb1. Slug/Snai2 expression is induced by oxidative stress and treatment of six ovarian tumor cell lines with tert-butyl hydroperoxide (TBHP) to generate oxidative stress increased the expression Slug/Snai2, Snai1 and heme oxygenase-1, an indicator of oxidative stress response. Because activation of NADPH oxidases 1, 2 & 3 is dependent upon Rac1 activity thereby leading to generation of reactive oxygen species (ROS), we tested oxidative stress

signaling as a consequence of Rac1 overexpression. The basal level of ROS was elevated in cells overexpressing Rac1 compared to vector control cells as detected by the fluorescent probe Dihydroethidium. Similarly, elevated Rac1 increased expression of the oxidative stress response genes heme oxygenase-1 (17-fold) and superoxide dismutase-1 (12-fold) further supporting that Rac1 stimulated ROS signaling in these cells. We further tested the impact of Rac1 inhibition in *vivo* using R-ketorolac. An alysis of tumor tissue from mice showed decreased expression of KRT19, heme-oxygenase-1 and Slug/Snai2 in mice treated with R-ketorolac compared to placebo controls. Collectively, these findings demonstrate the functional impact of Rac1 overexpression in ovarian cancer cells and suggest that Rac1-dependent activation of oxidative stress signaling in ovarian cancer may contribute to EMT in ovarian tumors.

P1732/B872

Porcine Placental Extract Exerts Fibroblast Growth Factor Activity and Suppresses Hair Growth.

H. Kagoshima, R. Yamada, K. Ito, R. Ogawa, M. Kawai, T. Imamura; Tokyo Univercity of Technology, Tokyo, JAPAN.

[Objectives] the placenta is a multifaceted, transient organ expressing a variety of biologically active molecules. Its postpartum utilization for cosmetic and healthcare purposes have long been performed through topical application, subcutaneous injection or oral consumption. We previously reported that porcine placental extract (PPE) powder, manufactured through heat treatment and enzyme digestion as a cosmetic ingredient, contains biologically active substance(s) that activates fibroblast growth factor (FGF) receptors. Since FGF signalings play multiple roles in hair growth cycle regulation, we aimed at examining the effects of PPE on murine hair growth in this study. [Methods] Nine-week-old C3H/HeN male mice, with their dorsal hair follicles in telogen (resting) phase of hair growth cycle, were used. The dorsal club hairs were trimmed short, and the mice were topically given various test samples in 100 µl solution for 28 consecutive days, and the hair growth was observed and photographed. The samples tested were; phosphate buffered saline (negative control), 5% Minoxidil (positive control), 40 mg/ml Unfractionated PPE (UPPE), High-MW PPE (HPPE: MW > 10 kDa), Medium-MW PPE (MPPE: 3~10 kDa) and Low-MW PPE (LPPE: MW < 3 kDa). The hair growth was scored from the photographs. After 28 days, the mice were sacrificed, skin samples were collected and the hair follicles were morphologically observed. [Results] a significant hair-growth-suppressing effects were observed for all the PPE samples examined. UPPE showed the strongest hair-growth-suppressing effect, followed by HPPE, MPPE and LPPE in this order. Hair follicles of telogen (resting) and early anagen (growing) phases were observed in mice that received UPPE and HPPE. In MPPE- and LPPE-treated mice, hair follicles of late anagen and catagen (regressing) phases were also observed, indicating modest retardation of telogen-to-anagen transition. [Conclusions and Discussion] PPEs exert strong suppressive effects on both telogen-to-anagen transition and anagen progression. As UPPE and HPPE exert strong effects, it is likely that high-MW substances contained in PPE are responsible for this activity. This finding may suggest, or does not exclude the possibility, that one or some of the FGF receptor agonist substances are responsible for the hair-growth-suppressing activity of PPE.

P1733/B873

The Inhibition of Cxxc5-dvl Interaction Stimulates Hair Regrowth and Wound-induced Hair Neogenesis through Activation of Wnt/b-catenin Pathway.

Y. RYU; YONSEI UNIVERSITY, SEOUL, KOREA, REPUBLIC OF.

The Wnt/β-catenin pathway has been implicated in hair follicle development and hair regeneration in adults. We discovered that CXXC-type zinc finger protein 5 (CXXC5) is a negative regulator of the Wnt/β-catenin pathway involved in hair re-growth and wound-induced hair follicle neogenesis (WIHN) via an interaction with Dishevelled (Dvl). CXXC5 was up-regulated in miniaturized hair follicles and arrector pili muscles in human balding scalps. The inhibitory effects of CXXC5 on alkaline phosphatase activity and cell proliferation were demonstrated using human hair follicle dermal papilla cells. Moreover, CXXC5-/- mice displayed accelerated hair re-growth and treatment with valproic acid, a glycogen synthase kinase 3β inhibitor that activates the Wnt/β-catenin pathway, further induced hair re-growth in the CXXC5-/- mice. Disrupting the CXXC5-Dvl interaction with a competitor peptide activated the Wnt/β-catenin pathway and accelerated hair re-growth and WIHN. Overall, these findings suggest that the CXXC5-Dvl interaction is a potential target for treatment of hair loss.

Different Protein Expression in Raw 264.7 Cell Treated with Pentoxifylline through Immunoprecipitation High Performance Liquid Chromatography.

M. Eo[1], M. Seo[1], T. Nguyen[1], B. Sodnom-Ish[1], Y. Cho[1], **S. Kim**[1], S. Lee[2]; [1]Department of Oral and Maxillofacial Surgery, Dental Research Institute, School of Dentistry, Seoul National University, Seoul, KOREA, REPUBLIC OF, [2]Department of Oral Pathology, College of Dentistry, Gangneung-Wonju National University, Gangneung, KOREA, REPUBLIC OF.

Pentoxifylline (PTX) is a methylxanthine derivative that have been developed as an immunomodulatory agent and an improvement of microcirculation. To reveal PTX effects as the cellular levels, protein expression profiles were analyzed in the PTX-treated RAW 264.7 cells by using immunoprecipitation high performance liquid chromatography (IP-HPLC). After treating RAW 264.7 cell with PTX at 10 μg/ml for 12, 24, and 48 hours, RAW 264.7 cells were harvested. The protein extracts were used for IP-HPLC analyze of proliferation-, epigenetic modification-, translation-, differentiation-, growth factor-, immunity-, inflammation-, p53-mediated apoptosis-, FAS-mediated apoptosis, cell protection -, antioxidant-, angiogenesis-, and osteogenesis-related protein in the macrophage. PTX was shown to inhibit cellular proliferation, apoptosis, and inflammation in RAW 264.7 cells. Conversely, angiogenesis and antioxidant activity were not significantly affected. Although RAW 264.7 cells are a macrophage cell line, PTX was expected to have an osteogenesis promoting effect, which is expected to provide an advantage in the treatment of osteonecrosis with anti-inflammatory effects IP-HPLC results indicate that PTX plays wound healing roles in RAW 264.7 cells by regulating anti-inflammation-, cell proliferation-, osteogenesis-, immunity-, and apoptosis- related proteins. The anti-inflammatory effect, anti-apoptotic effect and osteogenesis promoting effect are thought to be helpful in the treatment of osteoradionecrosis. *This research was supported by Basic Science Research Program through the National Research Foundation of Korea(NRF) funded by the Ministry of Education (No. 2017R1D1A1B03036054).

P1735/B875

Inhibition of TGF-beta Signaling in a Cellular Model of Human Post-traumatic Heterotopic Ossification.

J. Ferreira de Vasconcellos[1], M. Dingle[2], A. Dimtchev[1], D. Clark[2], A. Piscoya[2], L. J. Nesti[2]; [1]Uniformed Services University of the Health Sciences and Henry M. Jackson Foundation for the Advancement of Military Medicine, Bethesda, MD, [2]Uniformed Services University of the Health Sciences and Walter Reed National Military Medical Center, Bethesda, MD.

Heterotopic ossification (HO) is characterized by the abnormal growth of ectopic bone in non-skeletal soft tissues. Previous studies have demonstrated that TGF-beta (TGFB) levels are elevated in the soft tissues of war-traumatized extremity injuries. Since TGFB mediates most of the initial inflammatory and wound healing response in the traumatized muscle bed, we hypothesized that targeted inhibition of the TGFB pathway may be able to abrogate the unbalanced fibrotic and bone forming response observed in HO. To investigate that we used primary multipotent progenitor cells (MPCs) harvested from debrided traumatized human muscle tissue that are capable of differentiating down multiple pathways, including bone and cartilage. The specimens were taken at the margin of devitalized and healthy appearing tissue and would otherwise have been discarded as surgical waste. The Walter Reed National Military Medical Center IRB waived the need for consent. MPCs treated with TGFB had increased levels of the fibrotic markers *ACTA2*, *COL1A1*, *FN1* and *SERPINE1* (4.1- to 9.5-fold) compared to control, while upon treatment with TGFB inhibitors the expression of the fibrotic markers was reduced 0.3- to 7.9-fold. Treatment of MPCs with TGFB also showed increased expression of the osteogenic regulator *CBFA1* (1.9-fold change) compared to control, while *CBFA1* induction was moderately reversed (0.1- to 0.9-fold decrease) when treated with TGFB inhibitors. At the protein level, treatment with inhibitors that block the TGFB receptor showed a dose-dependent reduction of pSMAD2 and pSMAD3 compared to control. In addition, targeted SMAD3 inhibitors had no significant effects in pSMAD2, while a dose-dependent inhibition of pSMAD3 compared to the control was observed. Total SMAD2 and SMAD3 levels were mostly not significantly affected. Finally, selected TGFB inhibitors abrogated the formation of fibrotic nodules in a model of fibrotic nodule formation using MPCs. These results demonstrate that TGFB alone is sufficient to induce a fibrotic and osteogenic phenotype in post-traumatic MPCs, demonstrating that these cells are a robust in *vitro* model for the study of HO. In addition, our results support the notion that targeted inhibition of the TGFB pathway may be a useful therapeutic strategy for post-traumatic HO patients. **Disclaimer:** the contents of this publication are the sole responsibility of the author(s) and do not necessarily reflect the views, opinions or policies of Uniformed Services University of the Health Sciences (USUHS), the Henry M. Jackson Foundation for the Advancement of Military Medicine, Inc., the Department of Defense (DoD), the Departments of the Army, Navy, or Air Force. Pentoxifylline and Tocopherol Effect on Cortical Bone of Rat Irradiated Jaw: a Micro-Ct and Immunohistochemical Study.

T. Nguyen, B. Sodnom-Ish, Y. Cho, M. Eo, **S. Kim**; Department of Oral and Maxillofacial Surgery, Dental Research Institute, School of Dentistry, Seoul National University, Seoul, KOREA, REPUBLIC OF.

Pentoxifylline (PTX) and tocopherol (TP) combination is believed to have the effect of reducing the chronic fibrosis and induce bone healing in osteoradionecrosis (ORN) of mandible, but evidence of its effectiveness on cortical bone is lacking. This study was designed to determine effect of PTX and TP

combination on mandibular cortical bone remodeling in ORN rat model, using micro-CT and histological analysis. Forty-eight eight-week-old male Sprague-Dawley rats randomly divided into irradiated group (n=40) and non-irradiated (n=8). An imals in irradiated group were divided into 4 sub-groups, including PTX, TP, both PTX and TP and NS (normal saline). Three weeks after irradiation, mandibular posterior tooth extraction was performed and animals were sacrificed seven weeks after irradiation. The mandible was analyzed using micro-CT and histological evaluation. The alveolar bone height (ABH) and cortical bone thickness (CBT) of PTX+TP group were significantly higher than other groups. In the irradiated group, the cortical bone volume (Ct.BV) and total cortical bone surface (Ct.S) of PTX+TP group were significantly higher than those of the PTX, TP and NS groups. The average CBT (Ct.Th) of the PTX+TP group was significantly higher than that of the NS group ($p < 0.05$). In the 3D reconstructed images, there was an inadequacy in the residual volume of cortical and cancellous bone in the irradiated groups. Viable blood vessels within the Haversian canals can be observed in the PTX+TP group, and a small quantity is observable in the PTX group. Our finding demonstrated that the combination of PTX and TP improved quality and quantity of cortical bone in irradiated rat mandible, thus supporting its utility as treatment and prophylaxis agent for ORN. We observed an inadequacy in the destruction of cortical bone and cancellous bone in ORN mandible, suggesting that cortical bone could play an important role in further ORN studies. *This research was supported by Basic Science Research Program through the National Research Foundation of Korea(NRF) funded by the Ministry of Education (No. 2017R1D1A1B04029339).

Dec1-mediated Circadian Rhythm Disruption Aggravates Osteoarthritis Pathogenesis.

G. Lee, K. Park, J. Ryu; Chonnam National University, Gwangju, KOREA, REPUBLIC OF.

Molecular circadian clock pathway including BMAL1, CLOCK, PER1/2, and CRY1/2 are involved in the most physiological and behavioral process such as the blood pressure, metabolic state, sleep/wake cycle with 24-hour oscillations. It is also known that the disruption of circadian rhythms is closely related to human health and aging. As an aging, rhythmical behaviors such as sleep/wake patterns become fragmented, and amplitude of molecular clock gene oscillations are progressively weakened. Although the effect of circadian rhythms on skeletal development and degenerative disease remains unclear, there is some evidence indicating the role of circadian rhythm on the pathogenesis of osteoarthritis (OA), the most frequent degenerative disease in the world. Given that aging is a well-known risk factor of OA, weakened oscillation of molecular clock gene pathway during aging could affect the catabolic effect on chondrocytes, a sole component of joint cartilage tissue. In this study, we investigate the link between OA and DEC1-mediated circadian rhythm disruptions. Differentiated embryo chondrocyte expressed gene 1 (DEC1) is one of the target genes regulated by core clock genes, BMAL1-CLOCK heterodimer, and also known to inhibit the activity of BMAL1-CLOCK heterodimer by binding to the E-box region of target genes promoter. For in vivo experiments, Human OA cartilage and mouse OA animal model were used. The expression of DEC1 was upregulated in cartilage tissue of OA patients. Furthermore, cartilage degradation induced by DMM surgery on mice joint was decreased in DEC1 KO mice. Moreover, adenoviral overexpression of DEC1 in the mice joint by intra-articular injection showed severe cartilage degradation. For in vitro experiments, primary chondrocyte was used. In chondrocytes, it was confirmed that the expression of DEC1 increased by treatment of IL-1β. IL-1β also caused rhythmicity disruption of clock genes including BMAL1, CLOCK, and PER2. Additionally, overexpression of DEC1 upregulated the expression levels of OA related catabolic factors, such as MMP3, MMP13, IL6,

PTGS2 and ADAMTS4, and DEC1 knockdown reduced IL-1β-induced overexpression of catabolic factors. In conclusion, our results suggest that upregulation of DEC1 cause disruption of circadian rhythms and this disruption cause degradation of cartilage by upregulation of OA-related catabolic factors.

P1738/B878

Role of Chondrocyte-derived Serotonin on Arthritic Cartilage Destruction.

S. Lee, W. Song, J. Ryu; Chonnam National University, Gwangju, KOREA, REPUBLIC OF.

Serotonin synthesized by Tph2 in brain acts as a neurotransmitter and it synthesized by Tph1 in the periphery acts as a hormone or intracellular signaling factor. In this study, we investigated the effect of chondrocyte-derived serotonin on cartilage breakdown in osteoarthritis (OA). Tph1 was increased not only in human and mouse OA cartilage but in chondrocytes which induced arthritis-like condition. Also serotonin amount in synovial fluid was increased in OA mouse model. So we hypothesized that serotonin both intracellular and extracellular exacerbates cartilage destruction. Exogenously added serotonin did not affect gene regulation such as inflammatory factors and matrix degrading enzymes. However, serotonin treatment increased the key inflammatory genes such as Cox2, iNOS, and IL-6 as well as MMPs in the presence of IL-1β. Moreover, we found that IL-1β treatment exhibited the increased gene expression of serotonin receptors such as Htr1B and Htr2A. To investigate the molecular regulatory action modes of serotonin on the up-regulation of inflammatory gene expression, specific antagonist against Htr1B or Htr2A was applied into chondrocytes. Inhibition of Htr1B or Htr2A by each si-RNA blocked serotonin-induced expression of Cox2, iNOS, and IL-6 in chondrocytes. Tph1 overexpression in chondrocytes showed up-regulated catabolic and inflammatory factors. Etopic expression of Tph1 in mouse cartilage tissue caused OA cartilage destruction. Interestingly, serotonin can act as an intercellular signaling molecule via its receptors, also intracellularly via regulation of the activity of target protein through covalent coupling of serotonin to them by transglutaminase 2 (TGM2). This coupling, called serotonylation activates small GTPases such as RhoA may induce OA cartilage destruction via increased catabolic and inflammatory factors. To determine whether these effects were due to TGM2-induced serotonylation when increased serotonin in arthritis-like condition, we treated LDN, a TGM2 inhibitor, and Y-27632, a Rho kinase inhibitor and confirmed the reduction of inflammatory factors. Taken together, our findings indicate that serotonin may be newly synthesized in OA cartilage by cytokine-induced Tph1 and following chondrocyte-derived serotonin plays a pivotal role in the regulation of inflammatory osteoarthritis.

Promotion of Osteoblast Differentiation and Matrix Mineralization in Response to Quercetin Hydrate in *Vitro*.

D. Wyche, K. Walewska, **J. Belcher**; Cabrini University, Wayne, PA.

Skeletal homeostasis throughout a lifetime is modulated on the cellular level, chiefly between the actions of bone forming osteoblasts and bone resorbing osteoclasts. The interaction between these two bone cells is a novel area of study in order to identify agents which could potentially have therapeutic applications to benefit populations who are afflicted with bone degenerative disorders or those who have suffered fractures. Our lab focuses on naturally derived or plant-based supplements. Quercetin hydrate (QH) is a non-citrus flavonoid that has been studied for its antioxidant qualities in models of cardiac dysfunction, cancers, and inflammatory diseases. Previous studies from our lab have implicated

QH as an agent which positively promoted osteoblast proliferation and early markers of differentiation. The objective of our current study was to evaluate the effects of QH on pre-osteoblastic cell lines MC3T3-E1 and MG-63 at physiologically relevant concentrations. There were no treatment-induced cytotoxic effects in response to QH treatment. Cultures treated with QH showed significant increase in calcium and phosphate deposition with QH. There was also an increase in matrix mineralization with QH compared to untreated control. This data combined with our previously reported finding suggest QH can be integral in the promotion of osteoblast cell differentiation, matrix organization and maturation in *vitro*. This gives us a potential avenue to further explore QH and possible therapeutic applications of supplementation for the benefit of promoting skeletal health.

P1740/B880

Electron Microscopy Findings in Spinal Arachnoid Mater Calcifications.

Y. Putri[1], **K. Miyake**[2]; [1]School of Medicine, International University of Health and Welfare, Narita, JAPAN, [2]Center for Basic Medical Research, International University of Health and Welfare, Narita, JAPAN.

A number of white depositions were found in a 65-year-old male cadaver during the opening of the spinal canal. The depositions were found under the spinal arachnoid mater from thoracic to lumbar level. Histological examination were proceed to make diagnosis. We think this might represent a case of Arachnoiditis Ossificans (AO) which is a term used to describe a partial ossification of spinal arachnoid mater. The process is said to be related to previous trauma or surgery which might lead to dural and arachnoid mater inflammations which eventually lead to ossification. We would like to present electron microscopy findings and our hypothesis for the formation of bony deposit that is somehow related to cell wound healing.

P1741/B881

Inhibition and Recovery of Human Dental Pulp Cells Biomineralization in Extracellular Matrix.

G. Kaufman[1], A. Kotula[2], W. Jones[1], F. Xhyliu[1]; [1]ADA Foundation/Volpe Research Center, Gaithersburg, MD, [2]National Institute of Standards and Technology, Gaithersburg, MD.

Formation of tertiary dentin via differentiation and mineralization of dental pulp stem cells is essential to support the architecture of the pulp chamber and protect the tissue from bacterial invasion. Triethyleneglycol dimethacrylate (TEGDMA), a toxic monomer that leaches out from the adhesive restorations close to pulp, reaches the tissue to inhibits dentin formation. The inhibitory effect of the monomer on mineral deposition in *vivo* and capability of N-Acetyl Cysteine (NAC) to recover this process can be successfully investigated by developing and characterizing a biomineralization extracellular matrix (ECM) platform. In this study, we employ the ECM platform to demonstrate NAC's ability to resume growth of cells affected by TEGDMA. Cell differentiation and mineral deposition are characterized at different time points (14 and 21 days) using alkaline phosphatase (ALP) detection and alizarin red S (ARS) staining procedures. Mineral spread pattern can be detected on a 2.5D culture of cells seeded on a thin layer of ECM and analyzed by quantitative phase imaging (QPI). At TEGDMA concentrations of 0, 0.5, 1.5 and 2.5 mmol/L and with administered 10 mmol/L NAC, the hydroxyapatite content, percentage area covered, and spatial organization are validated by Raman microscopy, ARS staining and confocal imaging of cultures stained with the fluorescent Osteoimage™ reagent. In induced platforms, after 14 days, the percentage of the differentiating cells and expression of ALP increased more than seven-fold compared to the non-induced counterparts. After 21 days, the mineral covered

approximately 78% of the entire area/frame. At early and late stages, the focal accumulation of the mineral replaced by a spreading pattern revealed a gradient with an optical thickness peak and distance of 3-4 μm and 500 μm, respectively. With increased TEGDMA concentration, the percentage area covered decreased 3-,18- and 85-fold, respectively. The administration of NAC prevented the formation/deposition of the mineral in healthy cells and recovered the mineralization in cells affected by TEGDMA. The percentage area covered by the mineral in cultures exposed to 1.5 mmol/L TEGDMA increased 6-fold when treated with NAC. In samples exposed to 1.5 mmol/L TEGDMA and treated with NAC, the hydroxyapatite peak (detected by Raman spectroscopy) increased more than three times compared to the non-treated ones. Our study authenticates the ECM platform as an efficient tool for studying the impact of dental leachables on cell biomineralization and identifying drugs that efficiently restore tissue functionality.

Wine Your Way to Good Health: Anti-inflammatory Effects of Resveratrol.

G. Greco, J. Slee; DeSales University, Center Valley, PA.

Wine your way to good health: anti-Inflammatory effects of resveratrol Graziella Greco and Joshua B. Slee Department of Natural Science, DeSales University, Center Valley, PA 18034 Abstract Resveratrol, an antioxidant found in red wine and grapes, is thought to possess anti-inflammatory properties in relation to cardiovascular disease, and may have beneficial effects on incisional wound healing and the body's response to implantable devices. Liquid-liquid extraction of resveratrol from red wine was performed, and used to study its anti-inflammatory effects in *vitro*. After culturing Bovine Aortic Endothelial cells (BAOECs) in resveratrol to ensure there was no adverse effect on normal cell growth and morphology, it was concluded that there was no effect due to resveratrol addition. An established way to model inflammation in BAOECs is by using Tumor Necrosis Factor-α (TNF-α), which induces a large accumulation of actin stress fibers. Our data suggest that resveratrol pretreatment reduces the amount of actin stress fiber accumulation, caused by TNF-α, thus exhibiting anti-inflammatory properties. A large amount of inflammation in the cardiovascular system is caused by a wound to the endothelial layer. A wound healing assay was conducted to determine the wound healing properties of resveratrol. Resveratrol was shown to dramatically aid in the wound healing process, compared to an untreated control. Furthermore, the immune response of the body to implantable devices was investigated using aTHP-1 cell adhesion assay to polyurethane, a common biomaterial used in medicine. When a foreign material is introduced into the body, an immune response is stimulated, and monocyte-derived macrophages stick to the biomaterial, hindering its function. THP-1 cells are a good in *vitro* model of the monocyte-derived macrophages found in the immune system. THP-1 cell attachment to the polyurethane was significantly reduced in the presence of resveratrol. These data indicate that resveratrol possesses promising anti-inflammatory qualities that may prove to be useful in the prevention of cardiovascular disease, improving wound healing, and decreasing biomaterial rejection.

P1743/B883

Inflammatory Profile of Chronic Recurrent Multifocal Osteomyelitis of Jaw.

B. Sodnom-Ish[1], T. Nguyen[1], M. Eo[1], Y. Cho[1], Y. Kim[2], **S. Kim**[1], S. Lee[3]; [1]Department of Oral and Maxillofacial Surgery, Dental Research Institute, School of Dentistry, Seoul National University, Seoul, KOREA, REPUBLIC OF, [2]Department of Dental Hygiene, Cheongju University, Cheongju, KOREA, REPUBLIC OF, [3]Department of Oral Pathology, College of Dentistry, Gangneung-Wonju National University, Gangneung, KOREA, REPUBLIC OF.

Chronic recurrent multifocal osteomyelitis (CRMO), also known as chronic non-bacterial osteomyelitis (CNO), is a rare inflammatory disorder that primarily affects children. We analyzed the postoperative exudate through immunoprecipitation high performance liquid chromatography (IP-HPLC) from the mandibular lesion of 12-year-old Korean girl, and evaluated its pathological wound healing process. In order to obtain the postoperative exudate, a decompressive drainage apparatus was applied in the site of CRMO operation. After the first operation, the postoperative exudate was collected in 6 hours, 1, 4, 5 days until the exudate drainage was stopped. An d also after the second operation, the postoperative exudate was collected in 1, 2, 3 days. After the first biopsy of CRMO lesion, inflammatory reaction was enhanced by upregulation of TNFα, IL-1, IL-6, IL-12, IL-28, CD20, CD44, LL-37, CD54, and CD56, while macrophage activating proteins, CD68, lysozyme, and IL-8 were decreased. Particularly, anti-inflammatory factors, TGF-β1 and IL-10 were markedly decreased, and wound healing-related angiogenesis and osteogenesis proteins were consistently down-regulated. After the second decortication, inflammatory reaction was stimulated by increases of IL-6, CD31, IL-10, IL-12, COX2, CD20, and CD40, and concurrent activation of macrophages/monocytes-related factors, IL-8, lysozyme, and CD68, together with upregulation of wound healing proteins, CD31, MMP-2, MMP-10, and RANKL during the postoperative 3 days. The present study showed the reduced expressions of angiogenesis and osteogenesis-related proteins after the first operation, but the angiogenesis and osteogenesis-related proteins were slightly increased after the second operation. Besides that, there was few evidence of adaptive inflammation caused by bacterial infection by consistent down-regulation of TNFα, CD3, IL-28, cathepsin C and G. Therefore, it was presumed that the surgical treatment is necessary to remove the inflammatory lesion of CRMO to reduce the pro-inflammatory cascade, and simultaneously to activate the innate antigen presenting cells (macrophages/monocytes). *This study was supported by grant no 03-2019-0043 from the SNUDH Research Fund

P1744/B884

Investigating the Role of Low-grade Inflammation in Osteoarthritis Progression.

Y. Won[1,2], S. Park[1], Y. Shin[1], J. I. Yang[1,2], I. Jung[1], J. S. Chun[1,2]; [1]National Creative Research Initiatives Center for Osteoarthritis Pathogenesis, Gwangju, KOREA, REPUBLIC OF, [2]School of Life Sciences, Gwangju Institute of Science and Technology, Gwangju, KOREA, REPUBLIC OF.

Osteoarthritis (OA) is a degenerative joint disease that is primarily characterized by cartilage destruction. Growing evidence indicates that both OA and metabolic syndrome (MetS) are low-grade inflammatory condition with elevation in systemic inflammatory mediators. However, the exact role of low-grade inflammation in OA pathogenesis has not been fully investigated. Here, we examined whether chronic low-grade inflammation affects experimental OA in mice. An d, we identified possible key factors responsible for the low-grade inflammation in OA pathogenesis. We established two experimental mouse models in this study. First, C57BL/6 male mice were fed either low-fat diet (10

kcal% from fat) or a high-fat diet (60 kcal% from fat) starting at 8 weeks of age and operated destabilization of the medial meniscus (DMM) at 12 weeks of age. Mice were sacrificed at 6 weeks after DMM operation and subjected to histological and biochemical analysis. Second, DMM-operated 12-week-old male mice were intraperitoneally injected with either phosphate-buffered saline or lipopolysaccharide (5 ng per kg body weight) twice weekly for 1 month. Mice were sacrificed at 8 weeks after DMM surgery and subjected to histological and biochemical analysis. Microarrays were used to analyze the transcriptome of chondrocytes stimulated by interleukin-1β (IL-1 β) treatment or hypoxia-inducible factor (HIF)-2α, or the zinc importer, ZIP8 overexpression. Our data shows chronic low-grade inflammation exhibited increased severity of OA caused by DMM surgery in mice. Our microarray analysis revealed that, from among the examined inflammation-related genes, Toll-like receptor (TLR) signaling components were differentially expressed in chondrocytes stimulated with IL-1β, Ad-HIF-2α or Ad-ZIP8 using microarray analysis. Overall, our findings demonstrate the possible role of TLR signaling components as the mediator of low-grade inflammation and OA which may help to establish promising therapeutics for the treatment of OA.

P1745/B885

Benzydamine Inhibits Osteoclast Differentiation and Bone Resorption Via Down-regulation of Interleukin-1β Expression.

J. Lee, H. Son, H. LEE, M. KWON, G. LEE, N. KIM, N. KIM, H. Lee, J. Park, W. Jeong; EWHA womans university, SEOUL, KOREA, REPUBLIC OF.

Bone diseases such as osteoporosis and periodontitis are induced by excessive osteoclastic activity, which is closely associated with inflammation. Benzydamine (BA) has been used as a cytokine-suppressive or non-steroidal anti-inflammatory drug that inhibits the production of pro-inflammatory cytokines or prostaglandins. However, its role in osteoclast differentiation and function remains unknown. Here, we explored the role of BA in regulating osteoclast differentiation and elucidated the underlying mechanism. BA inhibited osteoclast differentiation and strongly suppressed interleukin-1β (IL-1β) production. BA inhibited osteoclast formation and bone resorption when added to bone marrow-derived macrophages and differentiated osteoclasts, and the inhibitory effect was reversed by IL-1β treatment. The reporter assay and the inhibitor study of IL-1β transcription suggest that BA inhibits nuclear factor-κB and activator protein-1 by regulating IκB kinase, extracellular signal regulated kinase and p38, resulting in the down-regulation of IL-1β expression. BA also promoted osteoblast differentiation. Furthermore, BA protected lipopolysaccharide- and ovariectomy-induced bone loss in mice, suggesting therapeutic potential against inflammation-induced bone diseases and postmenopausal osteoporosis.

P1746/B886

Parkin Negatively Regulates Bone Resorbing Activity of Osteoclast.

H. An , E. Kim, B. Choi, S. Park, S. Oh, J. Kim, K. Jang, E. Chang; Asan Medical Center, Seoul, KOREA, REPUBLIC OF.

Dysfunction of Parkin (Park2) is linked to the progression of parkinsonism which contributes to a progressive systemic skeletal disease characterized by low bone mineral density. However, the role of Parkin in bone erosion has not been elucidated yet. In this study, we observed that Parkin expression was decreased in osteoclast (OC) progenitor cells, monocyte/macrophages, but markedly increased in

mature OC. Parkin overexpression in bone marrow-derived macrophages did not affect the differentiation of these cells. However, knockdown of Parkin using siRNA significantly induced bone resorbing capacity of mature OC, indicating that loss of Parkin promotes OC activity. These results suggest that Parkin negatively regulates osteoclastic bone resorption, implying the possible contribution of Parkin to the maintenance of bone turnover balance.

P1747/B887

Cellular and Secreted ApoE Protein Expression After Inflammation Is Glia Cell-type and *APOE*-Genotype Specific.

M. Lanfranco Gallofre, J. Sepulveda, G. Kopetsky, G. Rebeck; Georgetown University, Washington, DC.

Neuroinflammation is a common feature in neurodegenerative diseases, such as Alzheimer's disease. Inflammation in the brain is characterized by activated glial cells and increased levels of cytokines and chemokines. A protein with immunomodulatory properties is apolipoprotein E (apoE). ApoE is synthesized in the brain and modulates the inflammatory response of microglia and astrocytes. In humans, apoE exists in three isoforms, apoE2, apoE3 and apoE4. The apoE4 isoform increases an individual's risk for Alzheimer's disease; whereas the apoE2 isoform is considered neuroprotective. We hypothesized that E4 glial cells have a more pronounced pro-inflammatory response compared to E3 and E2. We took advantage of human *APOE* targeted replacement mice where the human *APOE2, E3* and *E4* genes have been introduced into *APOE* knockout mice. This allows the study of various apoE specific isoforms without the influence of mouse apoE. We isolated both astrocytes and microglia from these mice. Conditioned media and cells were collected and apoE was analyzed by western blot. Since apoE undergoes post-translational modifications, and these modifications can alter the way the protein migrates on a SDS-PAGE gel, we first determined the migration pattern of cellular and secreted apoE in glial cells. Our data showed that secreted apoE in astrocytes is characterized by two species, whereas secreted apoE in microglia by a single species. Cellular apoE in astrocytes is associated with one of these species, whereas microglial cellular apoE by both. Next we tested the effects of *APOE* genotype on the expression of apoE by glial cells following a pro-inflammatory stimuli. We used LPS and TNFα, two well-known pro-inflammatory molecules. E2, E3 and E4 glial cells were exposed to LPS (5-500ng/mL) or TNFα (3-30ng/mL) for 24 hrs in serum deprived conditioned media. E4 astrocytes released more apoE than E2 or E3 astrocytes, only at the highest dose of LPS (500ng/mL). In contrast, E2 and E3 microglia released more apoE than E4 microglia at moderate and high doses of LPS (50-500ng/mL). No changes in cellular apoE content was observed in either cell type. In contrast to LPS, TNFα reduced the secretion of apoE in E4 astrocytes. The rank order of reactivity was E4>E3=E2. Interestingly, TNFα stimulated the secretion of apoE in E4 microglia, without altering the secretion of apoE in E3 or E2 microglia. Together, our data suggest that activation of the innate immune response by LPS and TNFα results in opposing outcomes for secreted apoE in microglia and astrocytes.

P1748/B888

Prostaglandin $F_{2\alpha}$ Exaggerates LPS-induced Sepsis in Mice.

T. Maehara, F. Higashitarumi, R. Kondo, K. Fujimori; Osaka, Takatsuki, JAPAN.

Sepsis is the systemic inflammatory response to infection. It is known that the levels of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) is increased in the plasma of the patients with sepsis. However, the functions of $PGF_{2\alpha}$ in the regulation of sepsis remains unclear. We investigated the role of $PGF_{2\alpha}$ in the progression of sepsis.

Sepsis was induced by intraperitoneal injection of 5 mg/kg LPS. In the treatment group, mice were intraperitoneally administrated with AL8810 (10 mg/kg) at 30 min before LPS administration. LPS administration promoted $PGF_{2\alpha}$ production in peritoneal lavage fluid (PLF). LPS administration enhanced the gene expression of proinflammatory cytokines such as IL-6, IL-1β, and TNF-α in lung and liver. In contrast, these gene expression was decreased by the administration of AL8810. It is known that neutrophil-derived IL-10 attenuates sepsis. At 6 hr after the LPS administration, the number of neutrophils and anti-inflammatory IL-10 levels in PLF were increased. In addition, inhibition of FP receptors further elevated neutrophil migration and IL-10 levels. Immunostaining analysis showed that IL-10 was detected in Gr-1-positive neutrophils in PLF. Then, administration of anti-IL-10 antibody increased LPS-induced gene expression of IL-6, IL-1β, and TNF-α in lung and liver. Furthermore, anti-IL-10 antibody administration enhanced AL8810-decreased expression of these genes. We concluded that inhibition of FP receptors attenuated the LPS-induced sepsis in mice. Administration of AL8810 promoted LPS-mediated IL-10-induced neutrophil migration and ameliorated the LPS-induced sepsis.

P1749/B889

The Decrease in Expression of Monocarboxylate Transporter-1 in Response to LPS Is a Secondary Event of the Inflammatory Response of Monocytes.

J. D. Ochrietor, L. Peter, V. J. Ochrietor; University of North Florida, Jacksonville, FL.

The molecule Toll-like Receptor-4 (TLR4) recognizes Gram negative bacteria, specifically the lipopolysaccharide component (LPS) and initiates a signal transduction cascade leading to an inflammatory response. Recent studies by this laboratory suggest the cell adhesion glycoprotein Basigin (CD147) interacts with TLR4 via their transmembrane domains. The role of Basigin in mouse retina has been well-studied and includes an association with Monocarboxylate Transporter 1 (MCT1) for metabolic support of photoreceptor neurons. The role of Basigin in innate immune responses is less-well studied, but a recent study by this laboratory indicated that Basigin and MCT1 transcript expression is significantly reduced in response to LPS. The purpose of the present study was to assess the expression of Basigin and MCT1 protein expression in response to LPS. Expression of another metabolic transporter, the glucose transporter GLUT-1, was also assessed. It was hypothesized that Basigin and MCT1 protein expression would decrease in response to LPS and that GLUT-1 expression would increase to indicate a metabolic shift in response to the inflammatory stimulus. To test this, RAW 264.7 mouse monocytes were incubated in the presence of 1 μg/mL LPS in serum-free medium for 24 hours. Control cells received PBS. The cells were subjected to immunocytochemical analyses or were collected for protein isolation and subsequent ELISA analyses. Both methods indicated that the expression of Basigin and MCT1 proteins was significantly decreased in response to LPS treatment, when compared to the control cells. Conversely, the expression of GLUT-1 protein was similar between the control and LPS-treated cells. These findings do not support the hypothesis. Although it was initially proposed that monocytes undergo a shift of resources from general cellular maintenance to induction of an innate immune response through down-regulation of MCT1 expression, the lack of compensation by an increase in GLUT-1 expression does not support this. It is likely that MCT1 expression is influenced by Basigin expression, as it is in the neural retina, and the reduced expression of MCT1 reflects regulation of Basigin by the immune response in monocytes. Future studies will assess the mechanism through which Basigin and MCT1 are regulated by LPS and TLR4 during an inflammatory response.

P1750/B890

Interleukin-22 Induces Duffy Antigen Receptor for Chemokines through Stat5 in Monocytes.

S. Oh, E. Kim, B. choi, S. Park, H. An , J. Kim, k. Jang, E. Chang; Asan Medical Center, University of Ulsan College of Medicine, Seoul, KOREA, REPUBLIC OF.

The atypical chemokine receptor 1 (ACKR1), also known as Duffy antigen receptor for chemokines (DARC) exhibits binding capacity for a wide variety of C-C and C-X-C chemokines that regulate inflammation. However, regulation of DARC expression has been largely unknown. Here, we found that Interleukin-22 (IL-22) regulates immune response by enhancing DARC expression in monocytes. STAT5 signal inhibitor abolished the IL-22-dependent increase in DARC as evidenced by immunoblotting and flow cytometry. The chromatin immunoprecipitation assay revealed that STAT5b directly binds to the DARC promoter. In addition, when we constructed DARC promoter constructs with a luciferase reporter containing wild type or mutated forms of the putative STAT5 binding site, we found that the predicted target sites, TTCCs is required for STAT5-dependent DARC expression. Our findings provide insights into the molecular mechanism by which IL-22 signal modulates STAT5-dependent DARC expression in monocytes.

Macrophage Specificity: Identification of Polyethylene Glycol-resistant Macrophages on Stealth Imaging in Vitro Using Fluorescent Organosilica Nanoparticles.

M. Nakamura, 755-8505; Yamaguchi University Graduate School of Medicine, Ube, JAPAN.

Macrophages have key functions in tissue homeostasis and inflammation. Macrophages are the special cells of differentiation of the mononuclear phagocyte system and show marked heterogeneity in response to environmental stimuli. The heterogeneity of macrophages was characterized by using morphology, surface marker, single cell sequence and so on. We are investigating macrophage heterogeneity to demonstrate macrophage specificity using our nanotechnology. We are developing novel technology of organosilica nanoparticles and performed in vitro imaging to evaluate the diversity and specificity of mouse macrophage uptake. Surface-functionalized organosilica nanoparticles with polyethylene glycol (PEG) were prepared by a one-step process, resulting in a brush-type PEG layer. A simultaneous dual-particle administration approach enabled us to evaluate the stealth function of nanoparticles with respect to single cells using time-lapse fluorescent microscopic imaging and flow cytometry analyses. Single-cell imaging and analysis revealed various patterns and kinetics of bare and PEGylated nanoparticle uptake. The PEGylated nanoparticles revealed a stealth function against most macrophages (PEG-sensitive macrophages); however, a stealth function against certain macrophages (PEG-insensitive macrophages) was not observed. We identified and characterized the PEG-resistant macrophages that could take up PEGylated nanoparticles at the same level as bare nanoparticles. These results indicated heterogeneity of macrophage uptake depending on surface structure of the particles. Our approach showed high possibility to characterize uptake diversity and specificity of macrophages. Reference: [1] M. Nakamura, S. Ozaki, M. Abe, T. Matsumoto and K. Ishimura, *J. Mater. Exosomal Mirna19a from Human Nasal Epithelial Cells Induce Pro-inflammatory Responses of Macrophages.

S. Oh[1], C. Shin[1], N. Tran[1], T. Kim[2], S. Kim[1]; [1]Korea Institute of Science and Technology(KIST), Seoul, KOREA, REPUBLIC OF, [2]Korea University, Seoul, KOREA, REPUBLIC OF.

Macrophages are phagocytes that play a critical role in the immune system. They are involved in both innate and adaptive immunity by either removing pathogens or antigen presentation. It has been shown that macrophages are polarized to subgroups with distinct functions, M1 and M2. M1 polarization is characterized by pro-inflammatory and anti-cancer functions, whereas M2 macrophages promote immune suppression and tumor growth. In this study, we investigate that exosomal miRNAs from human nasal epithelial cells play roles in airway mucosal microenvironment. Specifically, we demonstrated that the human nasal epithelial cells treated with urban dust modulate airway mucosal microenvironment through upregulation and release of miRNAs. The result shows that the human nasal epithelial cells treated with urban dust altered miRNA expression profile and released miRNAs promotes macrophage polarization. The study will further investigate exosomal miRNA mediated-communications between epithelium and macrophages in airway mucosal microenvironment.

Effects of Statins on the Inflammatory Response of Macrophages Activation through the Tlr3 Signaling Pathway.

A. Koike, K. Tsujinaka, K. Fujimori; Osaka University of Pharmaceutical Sciences, Takatsuki, Osaka, JAPAN.

Statins, HMG-CoA reductase inhibitors, are lipid-lowering medications. Recently, statins have pleiotropic effects such as antioxidant and plaque stability, which are cholesterol independent effects. However, statins have also been reported to exert immunosuppressive effects against viral and bacterial infections, Thus, statins cause so various unexpected problems. The aim of this study is to investigate the effects of statins such as simvastatin and pitavastatin, on poly(I:C)-activated macrophages. Macrophages were pre-treated with statins for 24 or 48 hrs, followed by treated with 10 μg/mL of poly(I:C) for 4 hrs. The expressions of the IFN-β, IP-10/CXCL10, RANTES/CCL5, IFIT, and TLR3 genes, which are induced by viral infection, were significantly reduced by treating with simvastatin or pitavastatin. Furthermore, these statins impaired the poly(I:C)-induced IRF-3 phosphorylation and the production of IFN-β. These suppressive effects of statins were effectively cleared by adding mevalonate or geranylgeranyl pyrophosphate, but not farnesyl pyrophosphate and cholesterol. These results suggest that simvastatin and pitavastatin have the inhibitory effect of IFN-β production on poly(I:C)-activated macrophages, and this effect may be due to the suppression of the TLR3 pathway. Furthermore, these suppressive effects of statins appear to be exerted via the Rho pathway.

P1754/B894

Phagocytosis Increases After Disruption of *Cis* Interactions between the Macrophage Checkpoint Receptor SIRPa & CD47.

B. H. Hayes[1], R. K. Tsai[1], D. Pantano[1], J. W. Shin[2,1], P. L. Rodriguez[1], S. Subramanian[1], D. E. Discher[1]; [1]University of Pennsylvania, Philadelphia, PA, [2]University of Illinois at Chicago, Chicago, IL.

Checkpoint receptors on an immune cell generally allow a ligand on a 'self' cell to signal against immune activation, and in the case of macrophages, SIRPα signals against engulfment by binding CD47 expressed on all cells - including macrophages. Here, inhibiting *cis* interactions between SIRPα and CD47 on the same macrophage increases phagocytosis approximately the same as inhibiting *trans* interactions. Antibody blockade of CD47, as pursued in clinical trials against cancer, is applied separately to human-derived macrophages or to red blood cell (RBC) targets for phagocytosis, and both scenarios produce surprisingly similar increases in RBC eating. Knockdown of macrophage CD47 likewise increases engulfment of foreign cells and particles, decreases SIRPα's baseline inhibitory signaling, and linearly increases binding in *trans* of soluble CD47, consistent with mathematics of *cis-trans* competition. Soluble SIRPα binding to human-CD47 displayed on Chinese hamster ovary (CHO) cells is indeed suppressed by SIRPα co-display, with molecular simulations confirming SIRPα can bend over and bind CD47. Safety and efficacy profiles for CD47-SIRPα blockade can thus reflect disruption of *cis and trans* interactions.

P1755/B895

Ratio of Activating to Inhibitory Signaling Dominates Phagocytic Decision-Making.

E. C. Suter, E. M. Schmid, A. M. Joffe, D. A. Fletcher; UC Berkeley, Berkeley, CA.

Cancer immunotherapies involving macrophages broadly aim to modulate their effector function in one of two ways, either by increasing phagocytic activating signals or decreasing inhibitory signals. To increase activating signals, therapeutic antibodies targeting cancer antigens are introduced to drive antibody-dependent phagocytosis through activating Fc receptors (FcRs) on the macrophage. To decrease inhibitory signals, blocking antibodies targeting macrophage inhibitory receptor SIRPα (or its ligand CD47) are introduced to enable the macrophage to bypass this inhibitory checkpoint, thereby removing the brakes on macrophage effector function. In each strategy, the goal is to tip the balance of activating vs. Inhibitory receptors present at the interface between the macrophage and target cell, either by promoting activating FcR engagement or by preventing inhibitory SIRPα engagement. However, little has been shown quantitatively about how macrophages integrate these competing receptor signals to ultimately determine phagocytic behavior. Here we demonstrate that macrophage phagocytic decisions are finely tuned to the ratio of activating ligand (antibody) to inhibitory ligand (CD47) present on the target cell. Using reconstituted cell-like target particles with defined surface proteins, we found that the same activation-inhibition ratio drives similar levels of phagocytosis across a broad range of absolute molecule densities. To test the dependence of this ratiometric decision-making on specific receptors, we examined a panel of synthetic activating and inhibitory receptors and found similar results, indicating this ratiometric paradigm applies broadly to both endogenous and artificial (e.g. CAR) immune receptors. Our results demonstrate that ratio—not an absolute threshold—dominates macrophage phagocytosis decisions. This understanding of how macrophages integrate contradictory signals may be useful when designing combination immunotherapies. Additionally, this study suggests that characterization of tumor surface composition could be critical for determining patient-specific immunotherapy regiments.

P1756/B896

Emergence and Systemic Redistribution of Tumor-resident Dendritic Cell Subsets.

T. B. Fessenden, S. Spranger; MIT, Cambridge, MA.

Dendritic cells (DC) are cellular sentinels that gather and distribute tissue-derived antigens to coordinate adaptive immunity, including anti-tumor responses. Recent studies demonstrated that DC subsets residing in the tumor microenvironment can drive infiltration and activation of cytotoxic T cells. However, the origin of these DC subsets from circulating vs. tissue-resident precursors is poorly defined. More broadly, scant data exists on the temporal dynamics of DC influx into and redistribution out of tumors despite their central role for anti-tumor immunity. These gaps in knowledge have stymied attempts to map the wide variety of DC behaviors in *situ* onto DC of different origins. We dissect the expansion and behaviors of tumor-resident vs migratory DC using lineage tracing and intravital imaging. We first asked whether DC are generated within the tumor microenvironment or are recruited from circulation. Over several days, we tracked lineage-marked tumor-resident or migratory DC within tumors and draining lymph nodes. Distinct populations emerged at both sites that were not mirrored by newly infiltrating DCs, suggesting the tumor microenvironment may profoundly dictate differentiation of DC subtypes in *situ*. We correlated these trends at the population level with behaviors of tumor-resident DC using intravital imaging over consecutive days. Quantitative image analysis of DC revealed cell morphological and cell motility shifts that corresponded with the generation of tumor-resident DC subsets. Finally, we monitored DC trafficking out of tumors into the periphery in real time and over consecutive days by coupling an in *vivo* cytometry platform with photolabeling to mark tumor-resident DC. We quantified and captured tumor-experienced cDC shed into the periphery on consecutive days from the same mouse, demonstrating the feasibility of this approach for future studies. These observations reveal the origins and behaviors of DC residing in tumors and prompt novel avenues to perturb DC subsets, thereby improving immunotherapies for cancer.

P1757/B897

Role of Advanced Glycation End Products in Neutrophil Extracellular Trap Formation.

R. Cooney, L. Ahmadi, M. Petreaca; DePauw University, Greencastle, IN.

Soon after injury or microbial contamination, neutrophils exit the circulation and move to the affected area, where they generate reactive oxygen species (ROS) that damage and kill microorganisms and produce chromatin-based neutrophil extracellular traps (NETs) that trap bacteria and fungi and facilitate neutrophil-mediated microbial killing. While ROS and NETs are critical in preventing infection, they also damage nearby host cells, causing more inflammation and tissue damage. This positive feedback loop ends in a process called inflammation resolution, leading to decreased neutrophil recruitment to the area, reduced production of pro-inflammatory ROS and NETs, and increased neutrophil apoptosis. Previous studies have suggested that chronically elevated glucose levels in type II diabetes increase NET formation, which may contribute to the prolonged inflammation and reduced wound healing seen in patients with this disease. In this study, we are investigating whether the advanced glycation end products (AGEs) produced by prolonged hyperglycemia promote NET formation through the AGE receptor for advanced glycation products, RAGE. To do so, we induced NET formation in HL-60-derived neutrophil-like cells with phorbol myristate acetate (PMA), in the presence and absence of two types of AGEs, AGE-modified bovine serum albumin (AGE-BSA) or Nε-(1-Carboxymethyl)-L-lysine. We then

quantified NET formation by fluorimetry of treated cells stained with Sytox Green, which primarily stains extracellular DNA. Because histone H3 is citrullinated during NET formation, we also used fluorescence microscopy of treated cells stained with anti-citrullinated histone H3 antibody to identify cells undergoing NETosis. Our results demonstrate that both AGE-BSA and Nε-(1-Carboxymethyl)-L-lysine exacerbate NET induction in neutrophil-like HL-60 cells. We then examined the role of RAGE in this AGE-enhanced NET formation by treating HL-60 neutrophils with AGEs in the presence and absence of FPS-ZM1, a RAGE inhibitor. We found that the RAGE inhibitor prevented the AGE-enhanced production of NETs, implicating RAGE in AGE-enhanced NET production. These results suggest the intriguing possibility that AGE-mediated RAGE activation contributes to the excessive NET production seen in hyperglycemic type II diabetic patients.

P1758/B898

Gambogic Acid from *Garcinia Hanburyi* Inhibits the Production of Neutrophil Extracellular Traps in *Vitro*.

J. Reinke, C. Gardner, A. Jackson, S. Kumar, M. Petreaca; DePauw University, Greencastle, IN.

The innate immune system responds rapidly to early signs of an infection or tissue damage by recruiting neutrophils to the affected area, where these inflammatory cells kill microbes through the production of reactive oxygen species (ROS) and neutrophil extracellular traps (NETs). Although these inflammatory responses are necessary to eliminate potential pathogens before they proliferate and establish an infection, ROS and NETs are non-specific mechanisms that can also damage host tissues. In chronic inflammation associated with various diseases, such as rheumatoid arthritis or Crohn's disease, prolonged or non-resolving inflammation can cause severe pain and permanent tissue damage. We are currently investigating the potential of gambogic acid, a compound derived from the Garcinia hanburyi plant used in Ayurvedic and traditional Thai medicines, to reduce inflammation and/or promote its resolution. Previous studies found that gambogic acid promotes apoptosis in multiple cell types, suggesting that this molecule might promote apoptosis in neutrophils and thereby inhibit their inflammatory functions. Because separate studies suggest that apoptosis interferes with NET formation, we investigated whether gambogic acid could reduce neutrophil survival and production of NETs. To determine the impact of gambogic acid on NET formation, we treated neutrophil-like HL-60 cells with gambogic acid in the presence and absence of phorbol myristate acetate (PMA), a known NET inducer, and used fluorimetry to quantify NET formation after staining cells with Sytox Green, which primarily detects extracellular DNA. We found that gambogic acid decreases PMA-induced NETs in these neutrophil-like HL-60 cells. We then used the colorimetric WST-8 cell survival assay and LDH release assay to quantify cell survival and necrosis, respectively. We found that gambogic acid reduces the survival of HL-60-derived neutrophil-like cells, as shown by their decreased metabolic activity and increased membrane permeability after treatment with gambogic acid. Furthermore, the inhibitory effect of gambogic acid on NET formation was reversed if cells were treated with Boc-D-FMK, a pan-caspase inhibitor, providing evidence that gambogic acid inhibits NET formation by promoting apoptosis. We are currently performing additional experiments to confirm that gambogic acid induces neutrophil apoptosis and also using more specific caspase inhibitors to better understand the mechanisms through which gambogic acid may promote apoptosis and reduce NET formation in these cells.

P1759/B899

Disruption of TFAM in T Lymphocytes Leads to Impaired Mtdna Copy Number Regulation, Altered CD8+ T Cell Effector Function and Metabolism.

S. Kapnick, R. Genner, P. McGuire; National Institutes of Health, Bethesda, MD.

Mitochondria contain multiple copies of maternally-inherited DNA (mtDNA) that encodes for 13 proteins all important for energy production via the respiratory chain. Loss of mtDNA copy number or integrity is associated with mitochondrial depletion syndromes - clinically heterogenous disorders caused by mutations in genes important for mitochondrial maintenance. Mitochondrial transcription factor a (TFAM) is an essential protein that binds mtDNA regulating packaging, replication, mitochondrial transcription, and mtDNA copy number and mitochondrial biogenesis. Total disruption of TFAM by gene targeting in mice results in embryonic lethality, while heterozygous mice exhibit reduced mtDNA copy number and respiratory chain deficiency in cardiac tissue. Although TFAM has been shown to also play a role in neurodegeneration, its contribution to mitochondrial maintenance in other tissues with high energetic demands remains poorly understood. To mount effective immune responses, T cells migrate between tissues, clonally expand, and secrete effector molecules; highly energetic processes known to be dependent on changes in metabolism. To better understand the role of mtDNA copy number regulation in T cell function, we disrupted TFAM expression in T cells using a loxP-flanked *Tfam* allele in combination with a Cre-recombinase transgene under the control of the CD4 promoter. TFAM-deficient T cells undergo normal thymic development and exhibit expected total numbers in the periphery. While T cell receptor-mediated activation of naïve CD8+ T cells results in reduced proliferative capacity, stimulated CD8+ T cells display increased expression of activation markers and enhanced cytotoxic function, on a per cell basis. Although mtDNA content is significantly reduced in TFAM-deficient T cells, MitoTracker staining suggests increased mitochondrial mass. Studies are currently underway investigating the bioenergetics and expanded immune responses in TFAM-deficient T cells. By understanding how loss of TFAM alters T cell metabolism, we expect to contribute to our knowledge of the link between mtDNA copy number regulation and immune cell function. This work has the potential to aid in the development of improved strategies for evaluating and treating immune dysfunction in patients with mitochondrial disease associated with mtDNA depletion.

A Splice Acceptor Variant Associated with Multiple Sclerosis Affects Hla-dra Conformation and Cellular Localization.

H. Shams[1], M. R. K. Mofrad[2], J. A. Hollenbach[1], J. Oksenberg[1], A. Didonna[1]; [1]University of California, San Francisco, San Francisco, CA, [2]University of California, Berkeley, Berkeley, CA.

The strongest genome-wide association signal in multiple sclerosis (MS), an autoimmune disease of the central nervous system, maps within the major histocompatibility complex (MHC). This locus encodes a large group of proteins governing both adaptive and innate immune responses. Among them, MHC class II proteins form alpha/beta heterodimers on the membrane of professional antigen-presenting cells (APCs), where they display pathogen-derived exogenous antigens to CD4+ T lymphocytes. In a recent fine-mapping effort on a cohort of 1,427 MS cases and 1,203 controls with African American ancestry, we have identified a splice acceptor variant (rs8084) in the alpha-chain encoding *HLA-DRA* gene, which is in complete linkage disequilibrium with the major MS risk allele *HLA-DRB1*15:01*. This variant mediates the transcription of an alternative version of the alpha-chain lacking 25 amino acids in its extracellular

portion. Although this shorter isoform is still able to form stable heterodimers with the corresponding beta-chain, it is not clear how changes in its conformation may affect its function in the context of antigen presentation and MS susceptibility. In this regard, we have performed detailed molecular dynamics (MD) simulations suggesting the stability of the short DRA is significantly lowered due to the absence of a disulfide bond between two beta-sheets in its alpha2 Ig-like domain. Nonetheless, the dimerization domain remains intact in agreement with the experimental data. Also, the relative orientation of these two domains is changed, leading to a reduction in the radius of gyration of the protein. Such extensive structural rearrangement dramatically affects the maturation process of short DRA, which remains entrapped into the endoplasmic reticulum as confirmed by immunofluorescence experiments in cells expressing the short isoform along with the beta chain. However, short DRA is detected on the cell surface upon co-expression with the standard MHC receptor and co-immunoprecipitation assays clearly indicate this isoform binds the alpha/beta heterodimer. Due to its more compact conformation, protein-protein docking predicts that short DRA can potentially bind the native HLA-DRB1-DRA heterodimer and affect antigen presentation. Further experiments will be required to elucidate whether this isoform can function as a possible neo-antigen for autoreactive CD4+ T cells and assess its putative role in central nervous system (CNS) autoimmunity and MS pathogenesis.

Elucidation the Role of ADAR1 in the Innate Immune Response.

D. Vukic, J. Sedmík, K. Sinigaglia, L. Keegan, M. O´Connell; CEITEC, MU, Brno, CZECH REPUBLIC.

Adenosine deaminases acting on dsRNA (ADARs) are essential for normal embryonic development and are essential in preventing the innate immune being activated by endogenous dsRNA. ADARs deaminate adenosine to inosine by hydrolytic deamination, known as A-to-I editing. Our group was the first to demonstrate that this editing event in endogenous dsRNA prevents the interferon (IFN) signalling cascades from dsRNA sensors in the cytoplasm: RIG-I and MDA5. In accordance, mice that are null for *Adar1* die at embryonal stage E12.5 with heightened levels of type-I IFN and widespread apoptosis. In humans, mutations in *ADAR1* cause the autoimmune disorder Aicardi Goutières syndrome (AGS). Most of the AGS mutations reduce the editing activity of the enzyme, except *ADAR1 D1113H*. This mutation is in the deaminase domain and it is possible that it can lead to perturbation in protein-protein interactions. To address this, we investigated the ADAR1 interactome under different conditions. We have prepared a tetracycline-inducible HE239T stable cell line, expressing both the long and short isoform of ADAR1. These proteins were tagged with Strep-tag or BirA at either N- or C-terminus. To further elucidate biological functions of ADAR1p150, cells were treated with type I IFN. In addition, we have induced immune response in HeLa cell line and performed co-IP of ADAR1 to determine the protein complexes formed at the endogenous level. Taken together, we currently have a comprehensive data set of ADAR1 protein complexes with or without induction of immune response; both with IFN and HMW Poly I:C. Our data are consistent between all sets and in agreement with all published interacting proteins of ADARs. In addition to the different protein complexes found to interact with ADAR1 upon immune response, we have found that tags at the different terminus strongly influences protein stability and interactions. This work was supported from European Regional Development Fund-Project ,,A-C-G-T“ (No. CZ.02.1.01/0.0/0.0/16_026/0008448).

Regulation of Osteoclast Differentiation and Function by Ew6.

M. Kwon, j. lee, Y. jo, H. Lee, G. Lee, S. Hong, N. Kin, N. KIM, H. Kim, J. Park, W. Jeong; Seoul National University, seoul, KOREA, REPUBLIC OF.

Excessive osteoclastic activity causes many bone diseases, such as osteoporosis and rheumatoid arthritis, of which control thus has significant clinical implications. Here we found that EW6 significantly inhibited the receptor activator of nuclear factor-kB ligand (RANKL)-induced osteoclast differentiation and its function. It attenuated the activation of NF-kB leading to the decreased NFATc1, a key transcription factor of osteoclast differentiation, as well as c-fos. EW6 exhibited abnormal actin ring formation via facilitating proteasomal degradation of integrin signaling molecules, such as p130cas, src and G proteins, leads to inhibition of bone resorption activity in differentiated osteoclasts. These results suggest that EW6 inhibits RANKL-induced osteoclastogenesis via regulation of the activation of NF-kB and also the osteoclast maturation by modulating stability of proteins which control morphology of osteoclast and function. In keeping with the results, EW6 inhibited bone loss in an inflammation- and Ovariectomy- induced bone erosion model. Thus, EW6 is promising drug candidate for bone related disorders.

New Techniques in Single Molecule and Super-resolution Microscopy

Development of the Green Photo-switchable Fluorescent Protein with Fixation Resistance, a Variant of Eos Fluorescent Protein.

M. Osuga, T. Nishimura, S. Suetsugu; Nara Institute of Science and Technology, Nara, JAPAN.

Super-resolution microscopy has overcome the diffraction limit of visualization of fluorescent molecules. One of the super-resolution microscopies, photoactivated localization microscopy (PALM), reconstructs images by the position of each fluorescent molecule, that is determined by the Gaussian fitting of the stochastically observed single molecule fluorescence. Such observation can be enabled by the blinking of the fluorescent proteins or molecules. To obtain larger number of protein positions for image reconstruction, larger numbers of images were required, and thus, sample fixation is required for large number of image collection during longer duration. However, most fluorescent proteins for PALM imaging lose their fluorescence and blinking ability after fixation. Here, we made novel green reversibly-photo-switchable fluorescent proteins with fixation resistance, named frSkylans, by combining the amino acid sequences of mEos4b, which is a photo-converting protein from green to red with fixation resistance, and those of Skylans, which are green photo-switchable proteins without fixation resistance, since they all are derivatives of EosFP. frSkylans showed higher fixation resistance than Skylans and retained photo-switching ability in cells. Their fixation resistance enabled larger number of signal acquisition and higher resolution of the reconstructed images by PALM observation, as shown by frSkylan-tagged vimentin or clathrin light chain expressed in fixed U2OS cells, showing that frSkylans can be used as fluorescence tag for PALM observation with green fluorescence.

P1764/B2

Integrated Super-resolution Imaging Toolbox for Diagnosis of Motile Ciliopathies.

Z. Liu; the Hospital for Sick Children, Toronto, ON, CANADA.

Lung clearance of pathogens and particulates relies on motile cilia. Impaired cilia motility can lead to reduction in lung function, lung transplant or death. Over 40 proteins regulating cilia motility are linked to primary ciliary dyskinesia (PCD), a heterogeneous recessive genetic lung disease. Accurate PCD molecular diagnosis is essential for identifying therapeutic targets, initiating therapies that can stabilize lung function and reducing the economic and social impact caused by this disease. To date, PCD diagnosis has mainly relied on non-quantitative methods either with limited sensitivity or requiring a-priori knowledge of the genes involved. Here, we developed a super-resolution microscopy toolbox aimed at addressing current limitations in PCD diagnosis: 1) to increase sensitivity, we built a localization map of PCD proteins by 3D-structured illumination microscopy (3D-SIM) and implemented quantitative image analysis to detect protein mis-localization; 2) to detect nanometer-scale structural defects in PCD patients' cells, we analyzed axonemal structure by stochastic optical reconstruction microscopy (STORM); 3) to detect motility defects caused by yet to be discovered genes, we developed a quantitative super-resolution method to detect motile cilia un-coordination by rotational polarity. Altogether, we show that super-resolution methods are powerful tools for improving molecular diagnosis of motile ciliopathies.

Whole Cell 3D Single Molecule Localization Microscopy Using Single-Objective Selective Plane Illumination Microscopy (soSPIM).

M. Cabillic[1,2,3], H. Forriere[1,3], J. Rossbroich[1,3], C. Butler[1,3], G. Grenci[4,5], V. Viasnoff[4,5], **J. Sibarita**[1,3], R. Galland[1,3]; [1]University of Bordeaux, Interdisciplinary Institute for Neuroscience, Bordeax, FRANCE, [2]Sanofi-Aventis, Paris, FRANCE, [3]CNRS UMR5297, Bordeaux, FRANCE, [4]Mechanobiology Institute, National University of Singapore, Singapore, SINGAPORE, [5]Biomechanics of cell-cell contacts, CNRS UMI 3639, Singapore, SINGAPORE.

Assessing protein organization and dynamics in their native cellular context provides invaluable insights into their activities and functions. The development of super-resolution microscopy approaches, allowing imaging proteins of interest with spatial resolution down to the nanometer scale, has been a great step forward in this direction. Amongst these techniques, Single Molecule Localization Microscopy (SMLM) enables localizing and tracking biomolecules in their cellular environment with the highest spatial resolution. However, this resolution is critically dependent on strong background rejection, limiting the penetration depth of standard SMLM implementation to the first micron above the coverslips using TIRF or HiLo. Conventional 3D imaging methods like confocal and Selective Plane Illumination Microscopy (SPIM) lack the sensitivity to efficiently localize single molecule events. To overcome those limitations, we developed the soSPIM technique, which uses a single high numerical aperture objective in combination with microfabricated devices. This architecture benefits from both a high collection efficiency and an optimal optical sectioning in depth, allowing to perform SMLM tens of microns above the coverslip[1]. Here we will present the capabilities and requirements for soSPIM to probe the 3D nanoscale organization of proteins in depth at the single-molecule level. This involves the use of adaptive optics for aberration-free astigmatism-based 3D localization as well as a computerized method for real-time mechanical drift correction. We will illustrate this work by showing the quantitative 3D nanoscale organization of several membrane proteins of entire T-Cells. **References:** R. Galland, G. Grenci, A. Aravind, V. Viasnoff, V. Studer, JB. Sibarita, “3D high- and super-resolution imaging using single-objective SPIM”, Nature Methods, 2015, **12**(7): p. 641-44

Quantifying IRES-mediated Viral Translation Dynamics with Single Molecule Resolution in Living Cells.

A. Koch, T. Morisaki, L. Aguilera, B. Munsky, T. Stasevich; Colorado State University, Fort Collins, CO.

Viruses use Internal Ribosome Entry Site (IRES) sequences to efficiently hijack host ribosomes away from the canonical 5’ cap and to a viral RNA. Although viral infection mechanisms have been studied extensively for years, the translation dynamics of the non-canonical mechanisms that viruses employ remain unexplored in living cells at the single-molecule level. To visualize host ribosome hijacking with single RNA resolution, a bicistronic construct with an IRES of interest between two reporter probes was developed. Nascent chain tracking (NCT) of this construct was employed to track and monitor single molecules of translating mRNA through time. Within single cells, mRNA were observed to exist in three different populations: Cap-only, IRES-only, and both Cap and IRES translation. Counting the number of translation sites per cell revealed that Cap Only translation occurred more frequently than IRES Only and Cap+IRES translation. However, interestingly, Cap+IRES translation occurred more frequently than expected if Cap and IRES initiation were two independent events, suggesting cross-talk between Cap and IRES translation within single translation sites. To further dissect the differences in translation efficiency,

we measured the ribosomal occupancy of translating mRNA. Intensity measurements of mRNA translating in either a Cap or IRES manner were compared revealing that Cap open reading frames (ORFs) have twice as many occupying ribosomes as IRES ORFs. Run-off assays revealed this difference was not due to elongation, but rather due to initiation, with Cap initiation occurring nearly twice as fast as IRES initiation. Viruses that harbor IRES elements often utilize a cell's stress response to shift the translational landscape to favor viral IRES-mediated over canonical Cap-dependent translation. After addition of a cell stressor to our system, we observed a significant initiation shift toward IRES Only translation. Interestingly, we also observed an increase in the number of Cap+IRES translation events after stress, further indicating a cross-talk between Cap and IRES translation within single translation sites. Altogether, our system allows us to fairly and accurately measure the efficiency of Cap- versus IRES-dependent translation with spatial resolution on the tens of nanometers scale and temporal resolution on the seconds timescale. Given the ubiquity of viral translation, we anticipate our biosensor will find broad application to better understand viral biogenesis in different cellular conditions.

P1767/B5

Applying Genetic Code Expansion and Bioorthogonal Labeling to Quantitative High-resolution Live Cell Imaging.

N. Elia, A. Koening, I. Segal; Ben Gurion University of the Negev, Beer Sheva, ISRAEL.

Genetic code expansion (GCE)-based bioorthogonal labeling is an emerging approach for fluorescence labeling of proteins in live cells. In this approach, proteins are directly labelled with fluorescent dyes at 1:1 ratio. The superb photophysical properties of fluorescent dyes together with the minimal size of the tag (an order of magnitude smaller than GFP) hold great potential for improving the performance of current methods for quantitative imaging and super resolution microscopy. However, in spite of its potential, this approach is not widely used in live cell imaging applications. Here, we set out to expand the use of this approach and test its performance in quantitative single molecule applications. To this aim, we: 1) optimized conditions for intracellular and extracellular labeling of proteins in live mammalian cells; 2) engineered a 14-residues long N-terminal peptide tag for straightforward bioorthogonal labeling of essentially any cellular protein and constructed a library of GCE-tagged organelle markers; and 3) calibrated conditions and performed Single Particle Tracking (SPT) and live-Single Molecule Localization Microscopy (SMLM) of bioorthogonally labeled proteins in mammalian cells. Conclusively, our results show that GCE and bioorthogonal chemistry is a suitable, flexible approach for protein labeling in quantitative high-resolution live cell microscopy that outperforms current live cell labeling approaches. This opens up new opportunities for quantitative analysis of cellular processes in the cellular milieu with improved spatiotemporal accuracy.

P1768/B6

Identifying Patterns of Protein Organisation in 3d Super-resolution Datasets.

A. Curd[1], R. Hughes[1], A. Cleasby[1], M. Baird[2], Y. Takagi[2], J. Ries[3], H. Shroff[2], **M. Peckham**[1]; [1]University of Leeds, Leeds, UNITED KINGDOM, [2]National Institutes of Health, Bethesda, MD, [3]EMBL, Heidelberg, GERMANY.

Super-resolution microscopy techniques can now precisely locate specific molecules within cells and cellular structures, to within ~10 nm. However, proteins within macromolecular complexes are organized at length scales that are still very difficult to access. Single-particle averaging techniques

adopted from electron microscopy show some promise, but are of limited use in many fluorescently-labelled samples. As well as limits on precision for the location of each detected molecule, low labelling density of a sample, and heterogeneity between and internal to macromolecular complexes, pose significant problems. We have developed a novel approach to determine protein organization with these complexes that overcomes these problems, by aggregating the relative positions between localisations to reveal common organizational features. We applied this new analysis technique to super-resolution data acquired for several different molecular organizations. We first used 3D STORM data for a nuclear pore (Nup107) protein, which has known rotational symmetry, and provides a good test for our approach. We successfully extracted accurate organizational information (symmetry and distances) from this data, demonstrating the strength of our technique. Next, we tested 3D STORM data for cardiomyocyte Z-disks. A major component protein of the Z-disc, α-actinin-2 (ACTN2) was labelled using a novel small non-antibody binding protein (Affimer, Tiede et al., 2017;6:e24903), conjugated to Alexa 647. Z-disks are crucial for muscle structure and contractility, and contain a repeating complex, which has a dense, inhomogeneous, ~20-nm tetragonal lattice structure. We successfully uncovered this known repeating pattern of ACTN2 across the Z-disc (~20nm repeat) along the long axis of the muscle fibre. A similar analysis of 3D PALM data using mEos-tagged ACTN2 in Z-discs was also successful despite low labelling and detection efficiency of the labels, and an average localization precision comparable with the lattice length scales. 3D PALM data for Eos-tagged myopalladin and LIM-nebulette, or LASP2) showed novel organizational features, suggesting a new model for the localization of LASP2. Using these, and other examples, we have demonstrated that this tool can be used to find pattern information from samples with unknown structures, and expect this analysis to be applied to study regularity and symmetry in many other complexes.

P1769/B7

High Speed Single Molecule Dynamics in the Endoplasmic Reticulum.

C. J. Obara[1], J. Nixon-Abell[2], F. Riccio[2], C. Blackstone[2], J. Lippincott-Schwartz, 20147[1]; [1]HHMI Janelia Research Campus, Ashburn, VA, [2]NINDS\NIH, Bethesda, MD.

The endoplasmic reticulum (ER) is an expansive, membrane-enclosed organelle that plays crucial roles in numerous cellular processes. Besides its clearly defined roles as the major site of cellular translation, the master regulator of calcium homeostasis, and origin of the secretory pathway; it also maintains elaborate and highly dynamic contacts with essentially all the other subcellular organelles. Despite this clear role as a central regulator of many important processes in cell biology, the way in which the many functions of the ER are spatially regulated has remained enigmatic. Diffraction-limited imaging experiments have failed to identify clear separation between components of ER biology, suggesting that functional microdomains within the membrane or lumen are either too small or too transient to be detected by conventional imaging techniques. Here, we correlate high speed single molecule trajectories of proteins in the endoplasmic reticulum to simultaneously collected imaging data of the context in which the molecules are moving. We show this approach works well with structured illumination microscopy, hyperspectral imaging, and even simple diffraction-limited imaging using a standard commercial widefield scope. By analyzing the trajectories of ER-localized proteins in the context of the ER itself, we show that functional microdomains do frequently exist in the ER, however they appear to be highly regulated in both space and time. For some classes of proteins, the existence of these domains is highly dependent on the underlying membrane structure, while others are transiently recruited to sites of interaction with specific cytoplasmic factors, often contact sites with other

organelles or large protein complexes. Collectively, this data suggests correlating single molecule trajectories into cellular context may provide a valuable tool for connecting biological process regulation across diverse spatial scales.

P1770/B8
Versatile Tools Towards Real-time Single-molecule Biology.
A. Raja, A. Candelli; LUMICKS, Cambridge, MA.

Biological processes performed by proteins interacting with and processing DNA and RNA are key to cell metabolism and life. Detailed insights into these processes provide essential information for understanding the molecular basis of life and the pathological conditions that develop when such processes go awry. The next scientific breakthrough consists in the actual, direct, real-time observations and measurements of the individual mechanisms involved, in order to validate and complete the current biological models. Single-molecule technologies offer an exciting opportunity to meet these challenges and to study protein function and activity in real-time and at the single-molecule level. Here, we present our efforts for further enabling discoveries in the field of biology and biophysics using both the combination of optical tweezers with single-molecule fluorescence microscopy. We show the latest applications in protein conformation, folding, and unfolding; protein droplet fusion during liquid-liquid phase transitions; DNA-protein interactions and genome modifications; effects of mechanical stress on DNA/RNA structure; motility of cytoskeletal molecular motors; cell receptor force activation; as well as various other intracellular dynamic processes.

P1771/B9
Investigation of Lentiviruses and Their Glycoproteins Using Real-time 3D Tracking.
J. C. Exell, S. Hou, K. Welsher; Duke University, Durham, NC.

Lentiviruses live double lives either as therapeutic vehicles or a threat, and both Jekyll and Hyde behaviours are mediated through studded envelope glycoproteins (Env). The generation of lentiviral vectors (LVs) through replacement of cognate Envs with versatile, more promiscuous, classes of Envs with broader cellular targets has become a main gene-editing delivery system. Therefore, our ability to understand Env incorporation into mature viruses will not only give us improved strategies to defend ourselves but also our ability to harness them as beneficial gene therapy tools. While the number, organization, and distribution of Env protrusions on the HIV-1 surface is engrained in literature from structural and modelling experiments, less is known about Env incorporation into lentiviral vectors. Here we focus on one of the most commonly used lentiviral vectors, whereby the G protein of vesicular stomatitis virus (VSV-G) decorates the surface of the viral membrane and try to understand what controls the number of these novel Envs on custom designed lentiviral vectors. Mature lentiviruses live fast and die young, thus, to study their actions requires a microscope that is capable of keeping up. In this work, we track, at unprecedented timescales (10 μsec to minutes), single rapidly diffusing and fluorescent virus-like-particles (VLPs) in solution using a 3D Dynamic Photon Localization Tracking (3D-DyPLoT) microscope. This enables both the size and Env number to be determined for each individual virus. Active feedback tracking by 3D-DyPLoT is achieved using a dynamically scanning laser pattern and converting photon arrival times into 3D positional information. In real-time, the diffusing particles' position is continually updated and held within the center of the continually scanning laser spot using a piezoelectric stage, relaying high spatiotemporal diffusion and intensity information. We find that the

number of VSV-G Envs incorporated into integration-competent lentiviral vectors is low, on average there were 12 ± 2 Envs per VLP, but the vast majority of VLPs were skewed to a very low number, one or two, of incorporated Envs. 3D-DyPLoT can adapt to different diffusive regimes enabling us to track VLPs on their journey to the cell surface and initial membrane-binding events taking advantage of the full potential of this system to characterize Env-receptor interactions. With LVs being more commonly used in clinical applications, regardless of their payload, successful targeting of LVs to nominated cells is largely dependent on the interaction of Envs with endogenous membrane receptors. Ultimately, results here can help to design effective LVs with fit-for-task envelope glycoproteins.

Simultaneous Multi-Color 3D Whole Cell Super-Resolution Imaging and Particle Tracking Using Engineered Point Spread Functions.

A. Agrawal, W. Colomb, S. Gaumer, R. Zimmerman, L. Kimerling; Double Helix LLC, Boulder, CO.

Widefield fluorescence optical microscopes are the workhorse of laboratories in numerous fields including biology, medicine and pharmacology, providing invaluable visual information and informative quantitative data. The function of bio-molecules is often inferred by comparing the behavior of different intercellular functions by labeling them with different molecules. It is therefore valuable to localize and track multiple colors simultaneously in 3D. However, currently available microscopes are often limited in their imaging depth, resolution, and ability to image different fluorophores simultaneously. Current solutions rely on sequential imaging or an additional camera and do not provide the required flexibility to work with the recently available large sensor formats (25 mm diagonal) and the ubiquitous legacy format (11.6 mm diagonal). Furthermore, none of the existing solutions take advantage of the increased depth, speed, and 3D resolution enhancements provided by engineered PSFs[1]-[3]. Here, we present two unique solutions that overcome these limitations and enable simultaneous 3D extended depth multi-color imaging of biological samples. We address the limitations of existing solutions in two ways. Our first solution is based on multi-color phase masks (MC-PM) [4], which uniquely identify two or more probes on the same camera sensor area by encoding the spectral information, and thus 3D position, into a distinct PSF for each color. An example of this is shown in Fig 1 where the MC-PM encodes DH-PSFs at perpendicular orientations for two selected wavelengths. Our second solution is a universal modular subsystem - SPINDLE-2C, which can be installed between most scientific microscopes and cameras. Along with a library of engineered PSFs including the MC-PMs[4], Double-Helix[1], Tetrapod[3], the SPINDLE-2C can be used with dichroic mirrors or polarizing/non-polarizing beam splitters. It is easily adjusted to work with a wide range of camera formats with no loss of resolution across the full field of view. The module features interchangeable mounts enabling users to optimize the PSF for their experiments, while allowing easy switching between single color, dual color, and bypass modes.The unique combination of multimodal image and engineered PSFs has been used to extend the imaging capabilities of microscopes for nanometer-scale single-molecule imaging[1], [2], light sheet[5], 3D particle tracking [3], [4], in the study of cancer[6], immunology, neuroscience[7], and more.

Live Simultaneous Multi-receptor Tracking in Neurons with 5-D Single Molecule Localization Microscopy.

C. Butler[1,2], G. E. Saraceno[1,2], M. A. Kechkar[3], V. Studer[1], L. Groc[1,2], R. Galland[1,2], J. Sibarita[1]; [1]University of Bordeaux, Interdisciplinary Institute for Neuroscience, Bordeaux, FRANCE, [2]CNRS UMR5297, Bordeaux, FRANCE, [3]Ecole Nationale Supérieure de Biotechnologie, Constantine, ALGERIA.

Single particle tracking (SPT) techniques such as sptPALM, uPAINT, and quantum dot tracking have given unprecedented insight into molecular dynamics in living cells. They allow monitoring the behavior and molecular interaction of individual proteins at millisecond temporal resolution and high spatial resolution (<30 nm) by fitting the point spread function (PSF) of individual emitters and tracking their position over time. While these SPT methods have been extended to study the temporal dynamics and co-organization of multiple proteins, conventional experimental setups used to perform multicolor imaging are typically limited to two simultaneous wavelengths. Increasing the number of colors requires additional filters for specific fluorescent tags and is usually performed at the expense of spatial or temporal resolution and/or field of view. This limits the minimum diffusion coefficient that can be measured and reduces the statistics that can be gathered from a single experiment, thereby degrading the ability to differentiate between molecular diffusion regimes like immobilization and confined diffusion. Moreover, simultaneous multi-receptor tracking could also reveal specific interactions between different protein populations, which could previously only be inferred from the behavior of a single population without any knowledge of the presumed partner behavior. By employing a dual-objective imaging configuration compatible with routine live cell imaging, we will present a single molecule tracking technique that allows for simultaneous 3D single particle tracking of multiple distinct species without compromising spatio-temporal resolution. A dispersive element introduced into the second optical path induces a spectrally-dependent displacement, which is used to separate numerous fluorescent species of single emitters based on their emission spectra. A proof of concept of the spectral separation abilities of the system will be shown via simultaneous 3D DNA-PAINT of fixed samples, where the acquisition time is significantly reduced compared to conventional sequential multicolor imaging. Lastly, we will demonstrate how the technique can be applied to track multiple receptors in live neuron cultures, and we will discuss possibilities of how advanced data analysis techniques can fully exploit the 5-dimensional data (x,y,z,t,λ) to extend the capabilities of conventional single particle tracking, such as the investigation of protein-protein interactions.

P1774/B12

Live-cell Imaging and an alysis of the Plasma Membrane Dynamics during Clathrin-mediated Endocytosis by High-speed Atomic Force Microscopy.

A. Yoshida[1], N. Sakai[2], N. Takahashi[1], S. H. Yoshimura[3], Y. Ohba[1]; [1]Department of Cell Physiology, Faculty of Medicine and Graduate School of Medicine, Hokkaido University, Sapporo, JAPAN, [2]R&D Group, OLYMPUS Corporation, Tokyo, JAPAN, [3]Laboratory of Plasma Membrane and Nuclear Signaling, Graduate School of Biostudies, Kyoto University, Kyoto, JAPAN.

Clathrin-mediated endocytosis (CME) is a process through which cells incorporate extracellular materials and membrane proteins into the inside of cells. Such a process is accompanied by a series of morphological changes of the plasma membrane, which is mediated by a successive assembly of many protein components. Although the protein assembly has been elucidated by fluorescence microscopy,

dynamic changes in the plasma membrane morphology during CME have not been fully clarified in living cells. We have previously developed a combined system of a fast-scanning atomic force microscope and a confocal microscope and performed simultaneous imaging of morphological changes of the plasma membrane and protein dynamics in living cells. Through this observation, we have revealed that actin polymerization at a clathrin-coated pit (CCP) provides a major force to drive membrane protrusion and push vesicle downward for irreversible closing of CCPs in an Arp2/3 complex-dependent manner (Yoshida et al., PLoS Biology, 2018). In this study, with the use of the combined system, the dynamic changes of plasma membrane morphology during CME in the presence of extracellular stimuli were studied. When serum-starved Cos-1 or A431 cells that stably express Venus-fused clathrin-light chain a were stimulated by EGF, a division and frequent appearance of CCP were observed. This resulted in the clustering of CCPs in the limited area of the membrane with a diameter of 800-1600 nm. This phenomenon was conserved among cell lines because it was observed in both Cos-1 and A431 cells. The clustering of CCP was suppressed by the treatment with EGF receptor inhibitors. Furthermore, upon the closure of CCPs in EGF-stimulated cells, it was frequently observed that membrane protrusion collectively covered and capped the clustered CCPs. Taken together, these results indicate that there exists a domain on the plasma membrane, where CME frequently emerges, and the formation of such the membrane domain is maintained by EGF receptor activity. In conclusion, contrary to the previous assumption that clathrin assembly is induced by ligand binding to the receptors, cells appear to have a “pre-opened gate” for coming extracellular materials to be incorporated.

P1775/B13

Mutation in the *HTT Gene* Critically Affects the Cell Motility and Alter Cytoskeleton Organization in Cultured Dermal Fibroblast of Patients with Huntington's Disease.

A. S. Taran[1], O. A. Zubkova[2], A. E. Kharitonov[2], M. A. Lagarkova[2], **I. B. Alieva**[1]; [1]A. N. Belozersky Institute, Moscow State University, Moscow, RUSSIAN FEDERATION, [2]Federal Research and Clinical Center of Physical-Chemical Medicine of Federal Medical Biological Agency, Moscow, RUSSIAN FEDERATION.

Huntington's disease (HD) is a severe and currently uncurable hereditary autosomal dominant neurodegenerative disease, effected by the progressive death of the medium spiny neurons of the striatum, leading to death after 8-15 years since the manifestation. The cause of HD development is an expansion of CAG repeats in the *gene* of huntingtin protein (HTT). Despite the fact that this mutation has the greatest impact on neural cells, it is shown that HTT is expressed in all cells and tissues of mammals. The function of HTT in humans is not clear, however, it is revealed that HTT interacts with proteins involved in (1) transcription, (2) signal transduction in the cell and (3) intracellular transport. We investigated morpho-functional disorders occurring at the cellular level and affecting subcellular cytoskeletal structures (microtubules and actin components). The primary fibroblasts obtained from the skin biopsy of HD patients with different length of CAG repeats in the *HTT gene* (42, 44 and 76) were used as the object of the study. Fibroblasts from skin biopsies of healthy donors corresponding to patients by sex and age have been applied as control. Physiological tests showed that fibroblasts of HD patients have different characteristics of spreading and movement compared to fibroblasts from healthy donors. They have a shorter stage of spreading, are capable to polarize before complete cell spreading and start the movement before polarization stage is fully completed. Patient’s fibroblasts do not form a pronounced leading edge and tail at the stage of polarization, their lamella forms numerous thin outgrowths on the leading edge during the process of attachment and spreading on the substrate. During the experimental wound healing fibroblasts of HD patients moved faster than control cells, but

their movement was more chaotic - they often changed direction of movement compared to normal cells. Confocal microscopy and SIM showed that the structure of the microtubule network does not change critically in the cytoplasm of HD fibroblasts. However, the architecture of cytoplasmic actin network changes and the mutual arrangement of γ - and β-actin structures is disturbed. Herewith the total amount of γ - and β -actin proteins does not differ from that in fibroblasts of healthy donors. In patient's cells the process of formation of primary cilia is violated: the number of cilia was lower, and their average length was less than in fibroblasts of healthy donors. Thus, our results had shown for the first time that in Huntington's disease morphological disorders caused by mutations in the *HTT gene* affect the cell cytoskeleton structures, which leads to changes in cell spreading and motility. Supported by RSF (#19-15-00425) and MSU Development Program PNR 5.13.

P1776/B14

***In Vitro* Actin Cytoskeleton Organization during Endothelial Monolayer Integrity Formation and Regulation Revealed by Super-Resolution Microscopy.**

A. S. Shakhov, **I. B. Alieva**; A. N. Belozersky Institute, Moscow State University, Moscow, RUSSIAN FEDERATION.

Endothelial cells have a flattened shape and, tightly adjacent to each other, form a layer of cells lining the inner surface of blood vessels. The endothelium plays a barrier role and regulates vascular tone and vascular wall permeability. However, the endothelial monolayer is sensitive to the effects of various physical and chemical stimuli, both in physiological and pathological states. The barrier function efficiency is dependent on the interaction of cell cytoskeleton structures and adhesive (cell-cell and cell-substrate contacts) components. All three types of cytoskeletal structures (microtubules, actin and intermediate filaments) operate coordinately through various linkers and mediators, contributing to the strengthening or weakening of the endothelial barrier. Initially, barrier function and dysfunction researches were focused on the actin system of the endothelial cells. Actin structures are an essential component for cell contraction. In endothelial cells, both in *vivo* and in *vitro*, two actin isoforms are present: non-muscle β- and γ-cytoplasmic actin. In this study, double immunofluorescent labeling and super-resolution microscopy (Structural Illumination Microscopy, SIM), as well as correlation analysis, were used to study the relative position of cytoskeleton components consisting of different actin isoforms during endothelial monolayer integrity formation and regulation. The results of the study demonstrate significant differences in actin structures intracellular localization - β-actin is found mainly in stress fibers and ring bundles, and the extensive actin network of the cell cytoplasm consists of γ-actin. In the area of lamellipodia, near to complete colocalization of cytoplasmic β- and γ-actin structures is often observed, but simultaneously, in the same endotheliocyte, colocalization is not observed in the zone of stable cell edges and in cell central regions surrounding the cell nucleus. Relative localization of β- and γ-actin components changes during the formation of endothelial cell monolayer. Similar changes are observed during endothelial barrier dysfunction development resulting of experimental microtubule- depolymerizing treatments. The reported study was supported by Russian Foundation for Basic Research (project number 18-29-09082) and Moscow State University Development Program (PNR 5.13).

P1777/B15

High Speed, High Throughput Super-resolution Imaging.

A. E. S. Barentine[1], Y. Lin[1], J. Bewersdorf[1], **D. Baddeley**[2,1]; [1]Yale University, New Haven, CT, [2]University of Auckland, Auckland, NEW ZEALAND.

Single-molecule switching (SMS) nanoscopy techniques like STORM/(F)PALM circumvent the diffraction limit by sacrificing temporal resolution. SMS typically requires several minutes to reconstruct a single super-resolution image, severely limiting its throughput. High-speed SMS has been achieved using high laser power and sCMOS cameras, however, conventional analysis pipelines cannot handle the resulting 70 TB/day data volume. We have overcome this by developing a platform for high-throughput SMS, enabling us to perform automated super-resolution imaging of ~10,000 3D fields of view a day. Our integrated system comprises a biplanar-astigmatism microscope specifically designed to produce high volumes of 3D and two-color SMS data as well as a computer cluster for real-time analysis. It can record SMS images of whole nuclei (25 x 25 x 4 um) in 8 s, and can image autonomously for at least 30 hrs. The computer cluster runs PYthon Microscopy Environment (PYME) software, which we have developed to include a microscopy-specific compression algorithm and distributed storage framework to receive the full 800 MB/s bandwidth of sCMOS cameras in real-time. We additionally use the computer cluster to run our now fully GPU-accelerated sCMOS-specific localization algorithms to localize 39,000 emitters/s, which is real-time at our 800 Hz imaging rate for up to 49 emitters/frame. The distributed analysis backend in PYME additionally supports batch-processing post-localization analysis recipes over thousands of super-resolution images or point-clouds. Our platform converts SMS imaging from a qualitative or small-scale quantitative tool into a valid imaging technique for large-scale quantitative hypothesis testing. After preliminary high-throughput demonstrations characterizing nuclear phenotypes, we are now leveraging our advances to study the organization of the interphase nucleus, specifically studying the size and positioning of lamin-associated domains with respect to the nuclear envelope.

Single Particle Motions of Axonal Proteins Captured by a Confocal Laser Scanning Microscopy.

K. Mouri[1], Y. Okada[2]; [1]RIKEN BDR, Osaka, JAPAN, [2]The university of Tokyo, Tokyo, JAPAN.

Fluorescence correlation spectroscopy is an established single-molecule based method for a variety of measurements in the field of protein science, such as estimating the concentration and diffusion coefficient of proteins, which enables to calculate a dissociation constant (Kd) of proteins, and so on. There are several difficulties in applying these methods, and its application in cell biology is still limited and a challenging work. To overcome these problems, we developed a new FCS methods based on the confocal laser scanning microscopy (CLSM) equipped with high speed scanner combined with an image processing technology. CLSM is also used in image correlation spectroscopy (ICS), but this is usually applied for molecules on plasma membrane. Even if soluble proteins in cells are measured, the accuracy of estimation is limited caused by fluctuation of cells or organelle. Our methods succeeded in accurate and multi-point calculation of auto- and cross-correlation functions in living cells. In addition, the cross correlation between pixels enabled us to extract one directional flow of proteins which have only been achieved by FCS equipped with multi-detector systems. Some neuronal axons extend over several meters long. In axons, motor proteins, such as kinesin and dynein, enable to transport synaptic vesicles and other soluble proteins. We modified our methods to optimize a balance between scan speeds and

S/N ratio to visualize single particles. At last, we could capture trajectories of single particles diffusing in axon. We applied these methods to several axonal proteins, and discussed quantitative results of them.

Optimized Expansion Microscopy of Chromatin.

R. X. Norman, E. Recchia, S. Liu, R. Garcia-Varela, M. E. Burkard, A. Suzuki; University of Wisconsin-Madison, Madison, WI.

Imaging biological structures at high resolution is critical for understanding their functions. Due to the diffraction limit in light microscopy, the maximum achievable resolutions in the lateral and axial dimensions are approximately 250 nm and 500 nm respectively, which are lower than the size of protein complexes in the cell. Expansion microscopy (ExM) is a super-resolution method based on physical expansion of a biological sample such as a monolayer of cells or a tissue slice embedded in a hydrogel. After expansion, the specimen can be observed by a wide field florescent microscope as well as super-resolution microscope to further improve the spatial resolution making it an economic tool for super resolution imaging. However, optimization is required to apply to chromatin-bound structures, such as the kinetochore. Although ExM shows potential to be used for the analysis of sub-cellular protein complexes, detailed characterization of chromatin expansion in three dimensions is lacking. To this end, we optimized two types of ExM, using either Methylenebisacrylamide (MBAA) or Dimethylacrylamide (DMAA) monomers. Three of major problems faced while imaging an ExM sample are photobleaching, sample drift, and anisotropic expansion. We achieved stable, high-fluorescence signal using an optimized mounting media. We developed a sample mounting chamber to constrain the sample with minimal drift in X,Y and Z dimensions and allow long-term imaging. Before applying the method to chromatin, we measured the isotropy of expansion. The MBAA gel expands 4 fold in all three dimensions. The DMAA gel expands to 10 fold in the lateral dimensions but only to 5 fold in the axial dimension. To assess whether expansion of chromatin is similar to the gel, we applied expansion to mitotic and interphase chromatin in HeLa cells. Both chromatin size and volume isotopically expand 3- and 6-fold for MBAA and DMAA, indicating that chromatin expansion is restricted (compared to gel expansion). To further improve uniformity in chromatin expansion, we investigated and optimized the use of proteinase K and micrococcal nuclease. We have further applied optimized ExM methods in MCF10a-organoid 3D cultures and found that the chromatin expands to 4 and 8 fold with MBAA and DMAA, respectively. We would like to share our optimized MBAA and DMAA ExM methods and discuss the potential to apply analysis of chromatin or chromatin-bound structures in the cell.

P1780/B18

Single-molecule Subcellular an alysis of Rna Distribution in Three Dimensions Using Open Source Tools.

P. V. Ryder, D. A. Lerit; Emory University, Atlanta, GA.

Imaging is a foundational component of cell biological research, as it allows investigators to interrogate relationships between cellular components and reveals unique aspects of cellular function. Quantification of imaging data discriminates between different biological states, reduces observer bias, and facilitates research rigor and reproducibility. Our laboratory investigates how localized RNA regulates the centrosome, a crucial organelle that coordinates cell division and cellular organization. To do this, we combine single-molecule RNA fluorescence in *situ* hybridization (smFISH) with

immunofluorescence imaging in the early *Drosophila* embryo. In these embryos, the centrosome is a small target within much larger cells, which makes precise and accurate analysis of RNA distribution challenging. While commercial software exists for spatial analysis of immunofluorescence images, licensing is often cost prohibitive and single-molecule RNA analysis is not supported. Several investigators have shared freely available software for spatial analysis of subcellular localization and/or quantification of smFISH data, but no open-source solutions exist. Here we present the methodology for an open-source pipeline written in Python to quantify the spatial distribution of smFISH data relative to subcellular structures of interest. We applied this pipeline to smFISH data for several putative centrosomal RNAs (cmRNAs) and detected subtle enrichments at centrosomes relative to a control RNA. Further, we developed and applied a batch processing mode of this pipeline, which enabled analysis of more than 50 images for each RNA type across nine stages of early *Drosophila* development, including both interphase and mitotic embryos. This batch analysis demonstrated that cmRNAs are dynamically regulated during the cell cycle and across developmental stages. We also found that multiple cmRNAs are packaged into RNA granules containing at least four transcripts that are enriched at the centrosome. Our pipeline can easily be generalized to any structure that can be segmented, including images of cells, tissues, and objects where spatial distribution is relevant to analysis. We conclude that open-source image analysis pipelines provide opportunities for trainees to gain useful programming skills and enable new biological discoveries without costly software licensing.

P1781/B19

Expanding the Limits of 3D Fluorescence Microscopy.

E. Kamiya[1,2], S. Lockett[2], V. Magidson[2]; [1]Lafayette College, Easton, PA, [2]National Cancer Institute, Frederick, MD.

Since the pioneering work of the Ed Boyden lab (Chen et al., 2015), a new family of sample preparation techniques termed expansion microscopy (ExM) has been rapidly developing. These techniques harness hydrogel-tissue chemistry—previously used for optical clearing—to physically enlarge samples, allowing super-resolution imaging with conventional microscopes. In ExM, samples are embedded in a swellable polyelectrolyte gel, and then undergo digestion or denaturation treatments which drastically reduce the strength of the biological material. Since the gel is densely crosslinked within the sample, when the gel swells, parts of the original sample are pulled away from each other in a uniform manner. This swelling is maximal in pure water due to the repulsion between the negatively charged groups in the gel. The typical linear expansion rate is ~4x, but up to 10x expansion in a single step has been reported. As with most complicated protocols, ExM is not a “one size fits all” approach. Due to the large variability of properties such as size, shape, and mechanical toughness in biological specimens, the protocol must be tailored for each type of sample. Consequently, multiple labs have developed and validated different protocols, even for the same sample types. Because each biological structure requires different considerations for preservation, the expansion microscopy protocol must be optimized and validated for every new set of biological structures. The goal of our laboratory is to facilitate the adoption of new techniques, such as ExM, by researchers at the National Cancer Institute in Frederick, MD who need to image a variety of samples, from viral particles, to cell organelles, to animal models, to tumors. Here, we report the impact of gel composition and gelation conditions, such as temperature and exposure to oxygen, on the performance of expansion microscopy, and present examples of our optimization toward simple and robust protocols.

Optical Pooled Screens.

A. Singh, 02142, D. Feldman, 02142, J. Schmid-Burgk, R. Carlson, F. Zhang, P. Blainey; Broad Institute, Cambridge, MA.

Pooled genetic screens have been critical for the systematic identification of genes underlying cellular processes, but have thus far been limited to phenotypes defined by cellular enrichment or comparatively low-throughput single-cell molecular profiling. We have developed a method to make pooled libraries compatible with the rich set of spatially and temporally resolved phenotypes accessible to high-content microscopy by using targeted in situ sequencing to demultiplex genetic perturbations. We applied this technology to screen 952 genes for involvement in NF-κB signaling by imaging p65 nuclear translocation and relaxation, recovering most canonical pathway members and identifying novel candidate regulators of IL-1β/TNFα-stimulated immune responses. We are currently piloting applications with a range of optical assays and cell models and expect that pooled optical screens will have broad utility in identifying genetic components, analyzing genetic circuits, and interrogating disease variants.

P1783/B21

Clonal an alysis, Genetic Screening and Expression Profiling at a Single-cell Level.

A. Chenchik[1], M. Makhanov[1], R. Darst[1], D. Deng[1], D. Tedesco[1], P. Diehl[1], L. Kobzik[2]; [1]Cellecta, Inc., Mountain View, CA, [2]Harvard School of Public Health, Boston, MA.

Novel methods for profiling clonal composition and phenotypes of primary and metastatic lesions at the single-cell level are required for understanding tumorigenesis mechanisms and development of anti-cancer drugs with unique mechanisms of action. In order to facilitate these studies, we developed a panel of lentiviral barcoded libraries to label and monitor the cancer cells in time-course experiments in *in vitro and* mouse xenograft models. The barcodes are transcribed from lentiviral constructs and could be detected by NGS in a single-cell RNA expression profiling assay to identify the sub-population of descendant cells derived from a single barcoded progenitor cell. Furthermore, cell barcodes were incorporated in conjunction with genetic effector libraries, such as sgRNA libraries, to identify clonal phenotypic changes induced by specific genetic disruptions in progeny cells derived from the single progenitor cell. However, while barcoding cells provides an effective way to group cells based on clonal origin in heterogeneous cell populations, expression profiling at a single-cell level remains challenging. Data will be presented showing how genetic screening and targeted RNA expression profiling of human cells combined with cell barcoding could significantly improve phenotyping of distinct cell populations.

P1784/B22

Simple and Robust Tool for Discovery of Desired Gene Products Using a Genome Wide Full Length Cdna Transfection Array.

Y. B. Shrestha, L. Min, M. Liu, X. Liu, Y. Wang; Origene Technologies Inc, Rockville, MD.

Gene expression array technology has revolutionized the scientific community by making available expression profile of thousands of genes in a single experiment between normal and tumor tissues,

treated and untreated cell cultures, and across the developmental stages of an organism or tissue. However, it also has major limitation in that the expression profile of genes do not inform us about their function, causal or effect, or stimulatory or inhibitory with respect to disease or physiology, but only the abundance or lack thereof in the experimental sample. To overcome this challenge, to rapidly uncover the functions of genes and to identify gene products with desired properties, we have developed a revolutionary platform whereby Genome wide Full length cDNA (GFC) clones are transfected into cells and screened for a desired function. The desired function may include probing for a clone's effect on any of the following but not limited to such as modulation of transcription factors, signaling pathways, metabolic pathways, gene regulation, and glucose homeostasis. The GFC transcription array platform compared to others like the gene silencing method provides an alternate screening advantage with gain of function of genes rather than the inverse, and makes possible study of lethal genes that cannot be silenced. To establish this proof of concept we screened for transcription factor, NFAT (nuclear factor of activated T cells) or its activators among many other clones by measuring its specific ability to bind to its consensus sequence or response element (RE) to activate transcription of target genes. We co-transfected hundreds of full length human cDNA clones each in a separate well of a 96-well plate with the NFAT-RE luciferase reporter plasmid into the HEK293 cells. Two days post transfection the plate was analyzed for luciferase reporter activity. We found that all the NFAT transcription factor variants including NFATC1, NFATC2, NFATC3, and NFATC4 that we tested markedly stimulated luciferase activity by 9-30 folds compared to control (Luciferase reporter alone) and that this observation was reproduced in duplicate set of plate as well. Therefore, these findings establish the proof of concept of our GFC-transcription array platform. In conclusion, GFC transfection array platform presents as an excellent tool for discovering gene products with desired properties from a pool of unknown genes.

P1785/B23

Spatiotemporal Dissection of Single-Cell Proteome Plasticity in Human Cells.

C. Gnann[1,2], A. J. Cesnik[1,2,3], D. Mahdessian[1], W. Ouyang[1], M. D. Leonetti[2], E. Lundberg[1,2,3]; [1]KTH Royal Institute of Technology, Stockholm, SWEDEN, [2]Chan Zuckerberg Biohub, San Francisco, CA, [3]Stanford University, Palo Alto, CA.

The Human Protein Atlas (HPA) project revealed that 17% of the human proteome displays significant expression variability between single cells within a seemingly homogeneous cell population. Understanding the cause and functional consequences of cell-to-cell variation remains an outstanding question in cell biology. Here, we present the first spatiotemporal dissection of cell cycle-independent proteome heterogeneity in HEK293T cells, with single cell resolution. We applied a high throughput CRISPR/Cas9-mediated approach for endogenous fluorescent protein tagging to generate a library of cell lines for the systematic study of phenotypic plasticity. Using a convolutional neural network for cell segmentation, we show that a wide variety of proteins, including metabolic enzymes, transcriptional regulators and proteasome subunits, exhibit cell-to-cell variation in their abundance or their spatial localization. We combine this spatial proteomics approach with mass-spectrometry and time-lapse confocal microscopy for in-depth characterization of the dynamics of protein expression variability. We identify proteins with time-dependent oscillatory expression, as well as proteins whose expression is influenced by the cell's microenvironment. Taken together, our results establish a framework for understanding the causes and functions of cellular heterogeneity in mammalian cells and tissues in health and disease.

P1786/B24

Distinguishing the Practical Applications of BioID and TurboID.

D. G. May, K. Scott, K. Roux; Sanford Research, Sioux Falls, SD.

Proximity-dependent biotin identification (BioID) has become a widely-used method for identifying protein-protein interactions (PPIs) within live cells and in several animal models. To accelerate the 15h-18h labeling period required for robust biotinylation, directed evolution of the BioID ligase was used to create TurboID and miniTurbo biotin ligases that can elicit robust biotinylation after a 10 min incubation with excess biotin. The potential applications for TurboID should allow for monitoring changes in PPIs that occur within minutes or a few hours following drug treatment or some other experimental variable. However, there is reported concern about biotinylation in the absence of biotin in some applications and possible toxicity in animal models. To determine the practical applications of TurboID and ascertain its practical strengths and weaknesses compared to BioID (and vice versa), we analyzed cell lines stably expressing BioID, TurboID, or miniTurbo constructs using several methods including immunoblot, immunofluorescence, and BioID pulldown proteomics. Our studies revealed considerable TurboID and miniTurbo fusion-protein instability, persistent biotinylation in the presence of basal levels of biotin, and a wider labeling radius compared to BioID in most standard applications. However, TurboID use in the lumen of the endoplasmic reticulum allowed for some improved degree of inducibility and overall improved biotinylation as compared to BioID. These studies should help inform investigators seeking to use BioID based methods as to the most appropriate ligase for their experimental needs.

P1787/B25

Proteome-wide an alysis of Cytoplasmic Meso-scale Organization.

F. Keber, **M. Wühr**, C. Brangwynne; Princeton University, Princeton, NJ.

Key organization principles for the eukaryotic cytoplasm are the formation of stable protein complexes, membrane-bound organelles, and membrane-less condensates that utilize liquid-liquid phase separation (LLPS). Despite the importance of LLPS in cytoplasmic organization for many biological processes, it is still unclear what fraction of proteins organize themselves through this mechanism. Here, we assay the organization of proteins into meso-scale assemblies on a proteome-wide scale and reveal the underlying organization principles with molecular resolution. We filtered undiluted cytoplasm from frog eggs through porous membranes under different pressures. We quantified the relative permeation of each protein with multiplexed proteomics. Protein complexes are retained by small pores regardless of applied pressure. In contrast, liquid assemblies are retained by small pores at low pressure but squeeze through the same pores under high pressure. We find that well-known LLPS proteins showed the predicted differential behavior and can be clearly separated from stable protein complexes. We identified hundreds of proteins with similar differential characteristics suggesting that LLPS plays a wide and still mostly undiscovered role in the self-organization of the cytoplasm. This new methods to assay the meso-scale organization of cytoplasm suggests that many condensate organelles still remain to be discovered.

P1788/B26

AirID: a Novel Proximity Biotinylation Enzyme for an alysis of Protein-protein Interaction.

Sawasaki[1]; [1]PROS, Ehime University, Matsuyama-shi, Ehime-ken, JAPAN, [2]Graduate School of Integrated Pharmaceutical and Nutritional Sciences, University of Shizuoka, Shizuoka-shi, Shizuoka-ken, JAPAN, [3]Division of Cell Signaling, Fujii Memorial Institute of Medical Sciences, Tokushima University, Tokushima-Shi, Tokushima-ken, JAPAN.

Proximity biotinylation based on *Escherichia coli* BirA enzyme is thought as a key technology for identification of proteins interacted with a target protein in cell or organism. Firstly, BioID (proximity-dependent biotin identification) was reported, and its main improvement was a single mutation of R118G in BirA. BioID can be used just by expressing BioID fusion protein and adding biotin. Because a BioID-fusion protein biotinylates proximal proteins, it can comprehensively identify interacting proteins by precipitation with streptavidin beads and mass spectrometry. BioID can easily analyze interactome in mild condition. However, to biotinylate interacting proteins, BioID takes long time (>16 hours) and requires high concentration of biotin. Secondly BioID was improved by R118S and several mutations using yeast-surface display, and then TurboID was made. TurboID has extremely high activity and can biotinylate proteins in just 10 min. However, TurboID causes non-specific biotinylation and cell toxicity. Although BioID and TurboID are excellent enzymes, further improvements of BirA enzyme are important to enhance the convenience of the proximity biotinylation in cells. Here we have developed a novel BirA enzyme designed by an algorithm of ancestral enzyme reconstruction using the meta genome data classified by original method. Using this algorithm, five BirA sequences were created, and then these proteins were synthesized by the wheat cell-free system. RG or RS mutation of three proteins indicated the activity of proximity biotinylation like BioID or TurboID. We found a designed protein, named AirID (**A**ncestral B**ir**A for proximity-dependent biotin **id**entification), which showed high activity and specificity of proximity biotinylation. AirID-p53 or AirID-IκBα showed in *vitro* and in cell biotinylation of MDM2 or RelA, respectively. AirID-CRBN showed pomalidomide-dependent biotinylation of IKZF1 and SALL4 in *vitro*. Also, AirID-IκBα biotinylated endogenous RelA protein known as interactor of IκBα, and AirID-CRBN did endogenous CUL4 and RBX1 in $CRL4^{CRBN}$ complex. Mass spectrometry analysis also showed biotinylation of previously known interacting proteins. These results indicated that AirID is a novel and useful enzyme for analysis of protein-protein interaction.

Membrane Protein Inventory of Human Pheochromocytoma and Paraganglioma Using a Multipronged "Pitchfork" Strategy.

O. Vit[1], K. Pacak[2], **J. Petrak**[1]; [1]BIOCEV, First Faculty of Medicine, Charles University, Vestec, CZECH REPUBLIC, [2]National Institutes of Child Health and Human Development (NICHD), Bethesda, MD.

Pheochromocytoma and paraganglioma (PHEO/PGL) are rare neuroendocrine tumors. Prognosis of patients with malignant PHEO/PGL is poor, and specific molecular targets for new therapies are therefore painfully needed. Integral membrane proteins (IMPs) expressed by tumors represent optimal potential targets, due to their specific functions and localization. However, the amphipathic nature of IMPs, lack of trypsin cleavage sites in the hydrophobic segments and relatively low expression levels hinder proteomic analysis of IMPs. In order to maximize the membrane proteome coverage, we recently developed a multi-pronged “Pitchfork strategy” (1). The strategy employs four methods, each selectively targeting different features of IMPs: N-glycosylated peptides are isolated by two N-glycopeptide capture

methods (SPEG, glyco-FASP), hydrophobic transmembrane segments are targeted by the hPTC method using CNBr cleavage and hydrophilic non-glycosylated peptides are accessed by a standard detergent-trypsin method. We applied the four-pronged “Pitchfork strategy” to the membrane proteome profiling of human pheochromocytoma and paraganglioma (PHEO & PGL) samples. The individual ,,Pitchfork” methods are complementary and provide access to all cellular compartments. On average, we identified 900-1300 IMPs in each tumor sample or healthy adrenal medulla. It represents nearly 2600 unique human IMPs identified in all PHEO & PGL or control samples analyzed to date (n=22). Among the identified proteins, we observe several IMPs found only in the tumor tissue and absent in healthy adrenal medulla. Such candidate proteins are currently studied in detail as potential drug targets or disease markers. The Pitchfork strategy enables significantly deeper access into the realm of membrane proteome compared to conventional proteomic methods as documented by high number of identified IMPs and also by finding of numerous “missing proteins”, i.e. proteins with no previous evidence of existence on protein level. 1) Vit O, et al. A three-pronged "Pitchfork" strategy enables an extensive description of the human membrane proteome and the identification of missing proteins. J Proteomics. 2019 Jul 30;204:103411. doi:10.1016/j.jprot.2019.103411.

Comparative an alysis of Postmortem Change in Bovine Skeletal Muscle Using Metabolomic Approach.

S. Ueda[1], Y. Yoshida[2], Y. Shirai[1], M. Yamanoue[1]; [1]Kobe University Grad Sch Agricultural Science, Kobe, JAPAN, [2]Japan Meat Science & Technology Institute, Tokyo, JAPAN.

This study aims to identify the metabolites in skeletal muscle from livestock using a metabolomic approach. Using gas chromatography-mass spectrometry (GC/MS), many metabolites were reproducibly detected in skeletal muscle, and distinct differences between Japanese black cattle and the crossbreed cattle were detected. Comparison of metabolites between skeletal muscle tissue (longissimus thoracis and semimembranosus) detected many metabolites in semimembranosus. Moreover, many amino acid and nucleic acid increased with aging after slaughter. Furthermore, an increase in free fatty acids was observed with aging. As a result of the multivariate analysis of these data, it was possible to determine the aging status of cattle by GC/MS analysis. These results suggest that metabolomics by GC/MS analysis can be used to evaluate beef quality.

Icy2.0: the Newly Redesigned Software for Bioimage an alysis.

J. Olivo-Marin, T. Icy2.0 Team; Institut Pasteur, Paris, FRANCE.

We present Icy2.0 (http://icy.bioimageanalysis.org), which is a major evolution of Icy, our previous free and open software for bioimage analysis. This release has three important features: 1) the ability to handle very large images (> 4Gb); 2) the possibility to process long sequences through an optimized streaming procedure with adaptive caching; and 3) a totally redesigned web site for improved interactions within the Icy community. Icy2.0 has retained and consolidated the major features that made its success in the bioimaging community, namely to make it available to the bioimaging community an image analysis software suite that encompasses the large variety of biological applications (microscopy, particle tracking, HCS/HTS, digital pathology, animal behavior,⋯) and users

(biologist, bioimage analyst, physicist, developer) and to give access to advanced image analysis methods and solutions. Since its launching, it has been the constant philosophy of the Icy tem to promote sharing of source code and know-how and to facilitate the use of quantitative approaches and open new scientific perspectives in terms of exhaustiveness, reproducibility and robustness of the analysis of bioimaging data sets. For those reasons, Icy2.0 has a fully redesigned web-site, that includes new communication channels between the end-users and the developers, new tutorial material and improved maintenance cycles. Icy2.0 now provides more than 400 dedicated plugins covering a large variety of state-of-the-art image analysis methods ranging from active contours models to Machine Learning through statistical spatial analysis, which empowers users with the most recent and adapted quantitative image analysis and visualization tools. Protocols, which are a graphical front-end that enable software development without any programming knowledge, have also been improved and now include the possibility to develop sophisticated image processing pipelines in a more readable and interactive manner. Icy2.0 has a large community of developers and users (4000+ regular users, 700+ students trained, 1500+ visits per month) that are using it for distributing their algorithms and plugins. For its long term sustainability and development, the Icy2.0 project benefits from the institutional support of the French national Infrastructure FranceBioImaging and of Institut Pasteur. Ongoing work aims at improving the interoperability and convergence of Icy2.0 with other open and free image analysis packages as well as facilitating the integration and use of AI packages. The Icy2.0 team is composed of Stéphane Dallongeville, Jean-Yves Tinevez, Daniel Fernandez Obando, Fabrice de Chaumont, Vannary Meas-Yedid, Thibault Lagache, Elodie Brient-Litzler, Robin Chalumeau and Piernicola Spinicelli.

Application of Probe Electrospray Ionization to the an alysis of Blood and Neoplastic Diseases Combined with Machine Learning.

S. Takeda[1], K. Yoshimura[1], H. Tanihata[2], K. Ogata[3]; [1]University of Yamanashi Fac Med, Chuo, JAPAN, [2]Shimadzu, Kyoto, JAPAN, [3]Shimaduzy, Kyoto, JAPAN.

Mass spectrometry (MS) is a powerful analytical tool enabling us to identify the molecules by *m/z*.In recent decade, it is one of the indispensable methods for biomedical sciences due to flourish of omics. For example, proteomic analysis uses MS to annotate the molecules in organelles, cells and tissues. However, there are several limitations inherent to this technique, such as destruction of cells and tissues, necessity of laborious pretreatments and ion suppression effect depending on the ionization methods. Probe electrospray ionization (PESI) is a derivative of ESI and overcomes some of these disadvantages. It does not require the multistep pretreatments of samples, and directly analyzes the living things with least intervention. PESI employs a very fine acupuncture needle serving both for a sample picker as well as for an ion emitter. Only several hundreds femto liter (fL) of sample allow us to obtain mass spectra sufficient for further analysis. Taking the advantage of very fine needle, we can apply it to the living animals to monitor the metabolic processes of internal organ such as liver. Moreover, this is applicable to discriminate the neoplastic region from the surrounding tumor-free regions. Speaking of MS analysis, another important issue to be reconsidered is the manner of data handling and processing. In conventional way of reductionism view, some significant or outstanding spectral peaks are somewhat arbitrarily selected for subsequent analyses. In our method, we make the most of whole spectral data without selecting specific peaks for annotation by any prejudice. Technically, mass spectra ranging from 10 to 2,000 are fed into the database to construct a reference for

judgment. For example, we collected around 200 tissue specimens from liver cancer patients and almost the same number of tumor-free region. After obtaining the mass spectra from these specimens, we built a database that contains combination of data specific to liver cancer and tumor-free liver tissue. Going through this database, classifier such as support vector machine (SVM) will give us the answer without annotating the molecules that underscore the molecular mechanisms of diseases. To date we achieved over 90% of concordance rate when compared with pathology. Other applications to the basic biological sciences will be presented on site.

An Enzymatic Assay to Measure Adherence to Pre-Exposure Prophylaxis and Antiretroviral Therapy.

A. O. Olanrewaju[1], B. Sullivan[1], J. Y. Zhang[1], A. T. Bender[1], D. Sevenler[2], T. J. Lo[1], M. Fernandez-Suarez[3], P. K. Drain[1], J. D. Posner[1]; [1]University of Washington, Seattle, WA, [2]Harvard Medical School, Boston, MA, [3]Independent Consultant, Boulder, CO.

Background. Antiretroviral therapy (ART) can extend the length and quality of life of people living with HIV and prevent HIV infection when given as pre-exposure prophylaxis (PrEP). However, sufficient medication adherence (≥ 4 doses/week) is required to prevent treatment failure and emergence of drug-resistant infections. Ongoing behavioral research aims to improve ART and PrEP adherence and drives the development of a growing number of strategies to measure ART and PrEP adherence. Drug-level measurement provides objective information about adherence patterns and is predictive of PrEP and ART healthcare outcomes. Tenofovir disoproxil fumarate (TDF) is used in 58% of ART and 100% of PrEP regimens. After ingestion, TDF is metabolized into tenofovir (TFV) and phosphorylated into tenofovir diphosphate (TFV-DP) - the active form of the drug. TFV-DP has a long half-life (17 days) making it an effective target for measuring adherence. The gold standard for TFV-DP measurement is mass spectrometry (MS), which is too capital-intensive, heavily-instrumented, and expensive for routine use in HIV endemic areas. Here we present a rapid enzymatic assay to measure TFV-DP. **Assay Principle.** TFV-DP competitively inhibits reverse transcriptase (RT) enzyme that synthesizes HIV cDNA. At *low* TFV-DP concentrations, RT is unlikely to incorporate TFV-DP into the cDNA chain and forms *long* cDNA strands that bind to many intercalating dye molecules and provide a *high* fluorescence signal, and vice-versa. **Experimental.** Master mixes consisted of RT, TFV-DP, a 200 nt DNA template, and dNTP in aqueous buffer and were incubated at 37°C for 30 min. PicoGreen intercalating dye was added and fluorescence was measured in a microplate reader. Data was analyzed using a 4-parameter logistic regression to calculate the 50% inhibition concentration (IC50). To simulate clinical samples, TFV-DP was spiked into whole blood diluted 1:15 by volume. **Results.** RT inhibition assays in buffer had the characteristic sigmoidal shape of enzyme inhibition assays with quantitative regions that could be moved lower or higher than the TFV-DP clinical range by adjusting dNTP concentration. We diluted blood in water to lyse red blood cells and minimize non-specific inhibition from the blood matrix. The assay distinguished TFV-DP spiked in whole blood at low adherence (1.7 doses/week) from medium (3.4 doses/week) ($p=0.038$) and high adherence (6.7 doses/week) ($p = 0.010$). **Conclusion.** We developed a rapid enzymatic assay to measure TFV-DP at clinically-relevant concentrations in whole blood. Ongoing work is focused on validating the assay with clinical samples, benchmarking against MS measurements, and integrating the assay into a near-patient format.
